

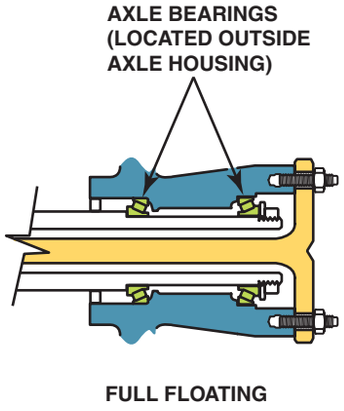

FIGURE 98–25 A typical full-floating rear axle assembly.

The wheel mounts onto the hub, and lug bolts or nuts retain it. In this design, the axle shafts "float" in the axle housing and drive the wheels without supporting their weight. Because the axle shafts do not retain the wheel, the axle shafts can usually be removed from the vehicle while it is standing on the wheels. Many three-quarter-ton pickups, all heavy-duty truck tractors, and trailers use full-floating axles. ● **SEE FIGURE 98–25.**

THREE-QUARTER-FLOATING AXLE The bearings in a three-quarter-floating axle are mounted and retained in the brake drum or rotor hub, which mounts onto the axle housing. The outer extension of the hub fits onto the end of the axle, which is usually splined and tapered, and a nut and cotter pin secure the hub to the axle. The axle shaft splines to the side gears inside the differential. The wheels are mounted on the hub and retained by lug bolts or nuts. As in the full-floating axle, the axle housing and bearings in the hub support the weight in a three-quarter-floating axle. Because of the construction of a three-quarter-floating axle, the wheel must be removed before removing the axle shaft from the vehicle.

SEMI-FLOATING AXLE The wheel bearings in a semi-floating axle either press onto the axle shaft or are installed in the outer end of the axle housing. A retainer plate at the outer end of the axle shaft or a C-clip inside the differential at the other end keeps the axle shaft in the housing. The brake drum or rotor fits onto the end of the axle, and lug bolts or nuts fasten the wheel to the drum or rotor and to the axle. These axles are called "semi-floating" because only the inboard ends of the axle shaft "float" in the housing. The outboard end of the shaft retains the wheel and transmits the weight of the wheel to the housing. Most solid-axle rear-wheel-drive cars and light trucks use a semi-floating type of axle. ● **SEE FIGURE 98–26.**

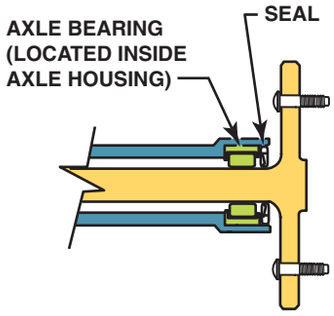

FIGURE 98–26 A semi-floating rear axle housing is the most commonly used in light rear-wheel-drive vehicles.

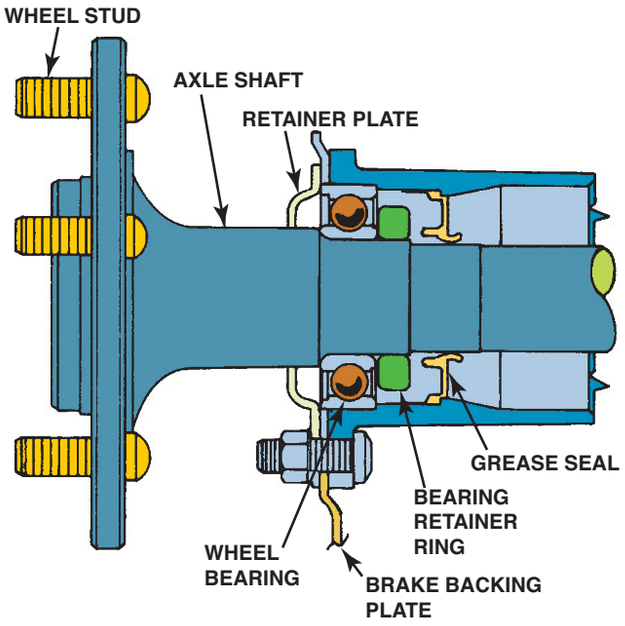

FIGURE 98–27 A retainer plate-type rear axle bearing. Access to the fasteners is through a hole in the axle flange.

REAR AXLE BEARING AND SEAL REPLACEMENT

The rear bearings used on rear-wheel-drive vehicles are constructed and serviced differently from other types of wheel bearings. Rear axle bearings are either sealed or lubricated by the rear-end lubricant. The rear axle must be removed from the vehicle to replace the rear axle bearing. There are two basic types of axle retaining methods:

- **Retainer plate (flange) type**
- **C-Lock (C-clip) type**

RETAINER PLATE-TYPE REAR AXLES

The retainer plate-type rear axle uses four fasteners that retain the axle in the axle housing. To remove the axle shaft and the rear axle bearing and seal, the retainer bolts or nuts must be removed.

The hole or holes in the wheel flange permit a socket wrench access to the fasteners. After the fasteners have been removed, the axle shaft must be removed from the rear axle housing. With the retainer plate-type rear axle, the bearing and the retaining ring are press fit onto the axle and the bearing cup (outer race) is also tightly fitted into the axle housing tube. The retaining ring should be removed by using a cold chisel to notch the ring in several places so it can be removed before pressing off the bearing. ● **SEE FIGURE 98–27.** ● **SEE FIGURE 98–28** for one way to remove the axle shaft using a rear axle puller.

C-LOCK-TYPE AXLES

Vehicles that use C-locks (clips) use a straight roller bearing supporting a semi-floating axle shaft inside the axle housing. The straight rollers do not have an inner race. The rollers ride on the axle itself. If a bearing fails, both the axle and the bearing usually need to be replaced. The outer bearing race holding the rollers is pressed into the rear axle housing. The axle bearing is usually lubricated by the rear-end lubricant and a grease seal is located on the outside of the bearing.

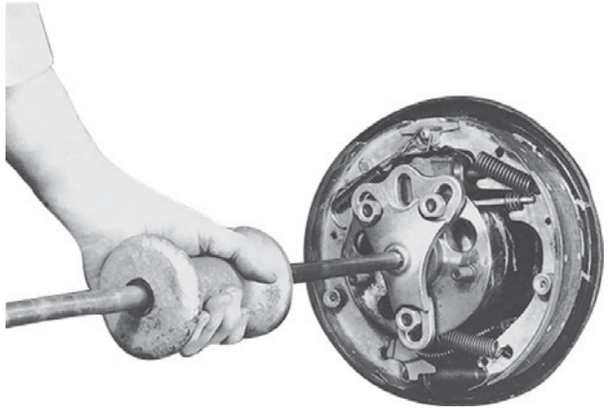

FIGURE 98–28 A slide hammer-type axle puller can also be used.

TECH TIP

The Brake Drum Slide Hammer Trick

To remove the axle from a vehicle equipped with a retainer plate-type rear axle, simply use the brake drum as a slide hammer to remove the axle from the axle housing. ● **SEE FIGURE 98–29.** If the brake drum does not provide enough force, a slide hammer can also be used to remove the axle shaft.

NOTE: Some replacement bearings are available that are designed to ride on a fresh, unworn section of the old axle. These bearings allow the use of the original axle, saving the cost of a replacement axle.

The C-lock-type rear axle retaining method requires that the differential cover plate be removed. After removal of the cover, the

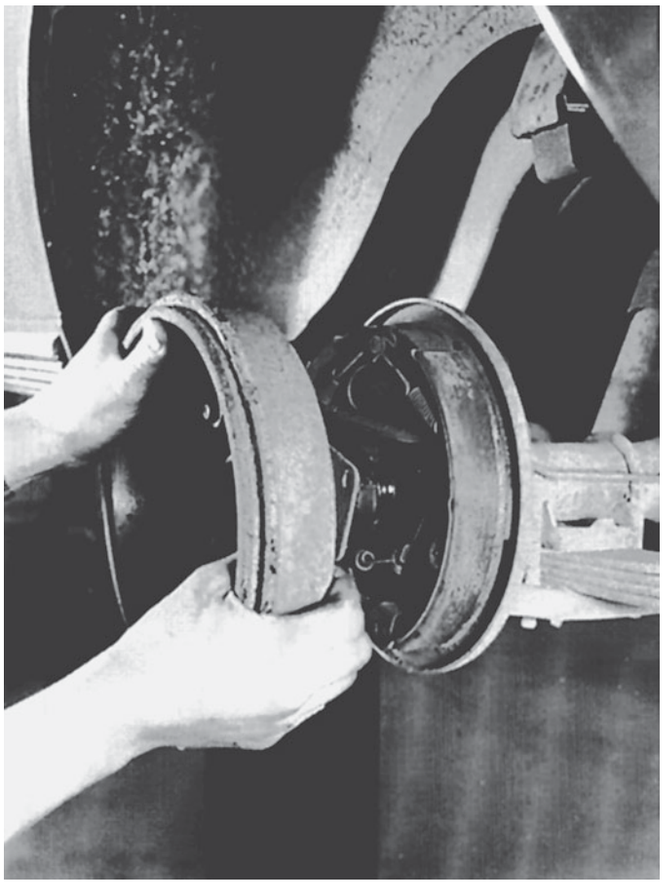

FIGURE 98–29 To remove the axle from this vehicle equipped with a retainer-plate rear axle, the brake drum was placed back onto the axle studs backward so that the drum itself can be used as a slide hammer to pull the axle out of the axle housing. A couple of pulls and the rear axle is pulled out of the axle housing.

differential pinion shaft has to be removed before the C-lock that retains the axle can be removed. ● **SEE FIGURES 98–30 AND 98–31.**

NOTE: When removing the differential cover, rear axle lubricant will flow from between the housing and the cover. Be sure to dispose of the old rear axle lubricant in the environmentally approved way, and refill with the proper type and viscosity (thickness) of rear-end lubricant. Check the vehicle specifications for the recommended grade.

Once the C-lock has been removed, the axle simply is pulled out of the axle tube. Axle bearings with inner races are pressed onto the axle shaft and must be pressed off using a hydraulic press. A bearing retaining collar should be chiseled or drilled into to expand the collar, allowing it to be removed. ● **SEE FIGURE 98–32.**

Always follow the manufacturer's recommended bearing removal and replacement procedures. Always replace the rear axle seal whenever replacing a rear axle bearing. ● **SEE FIGURE 98–33** for an example of seal removal.

DIFFERENTIAL VENTS

All differential use a vent to allow for pressure to equalize inside the differential due to heating and cooling of the part and the rear axle fluid.

Always check the differential vent to make sure it is clear. A clogged vent can cause excessive pressure to build up inside the differential and cause the rear axle seals to leak. If rear-end lubricant gets on the brake linings, the brakes will not have the proper friction and the linings themselves are ruined and must be replaced.

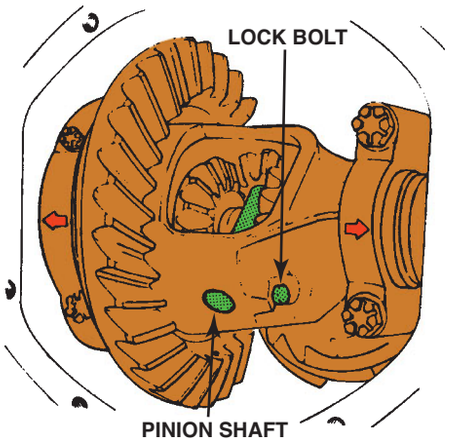

FIGURE 98–30 To remove the C-lock (clip), the lock bolt has to be moved before the pinion shaft.

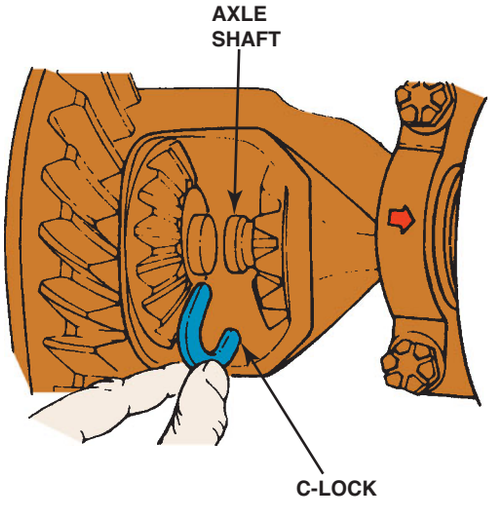

FIGURE 98–31 The axle must be pushed inward slightly to allow the C-lock to be removed. After the C-lock has been removed, the axle can be easily pulled out of the axle housing.

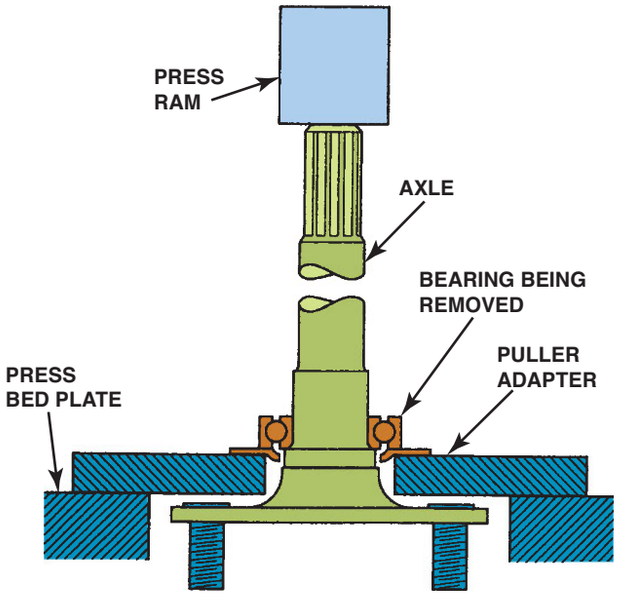

FIGURE 98–32 Using a hydraulic press to press an axle bearing from the axle. When pressing a new bearing back onto the axle, pressure should only be on the inner bearing race to prevent damaging the bearing.

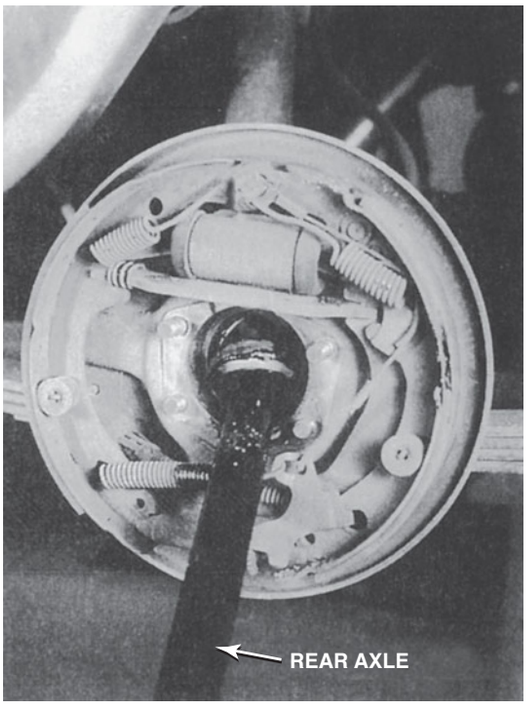

FIGURE 98–33 Removing an axle seal using the axle shaft as the tool.

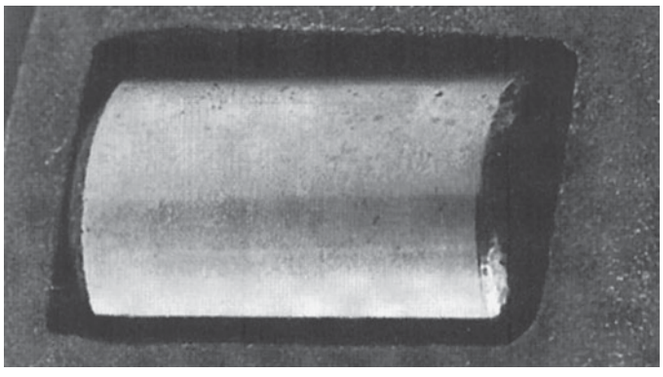

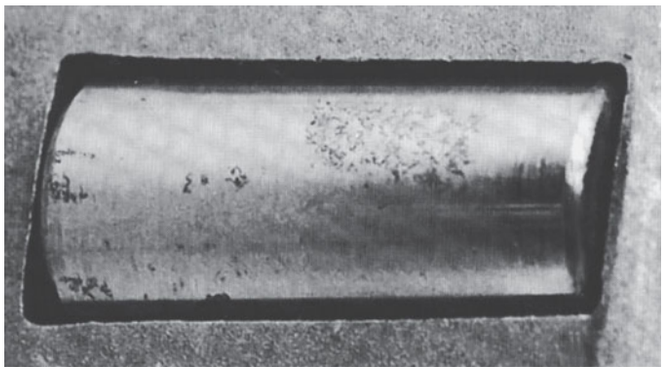

FIGURE 98–34 This is a normally worn bearing. If it does not have too much play, it can be reused. (*Courtesy SKF USA Inc.*)

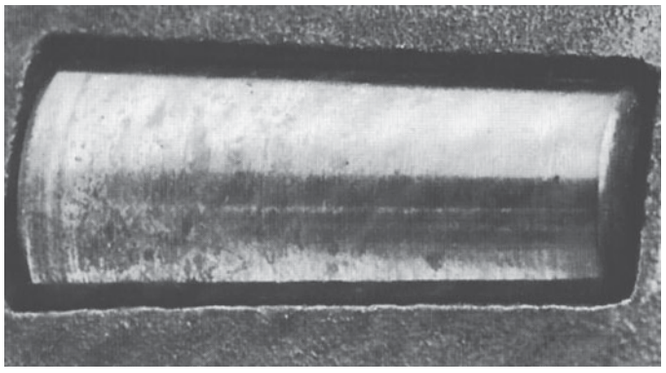
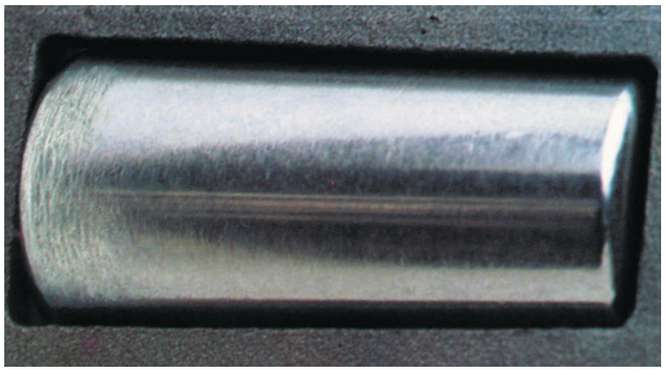
BEARING FAILURE ANALYSIS



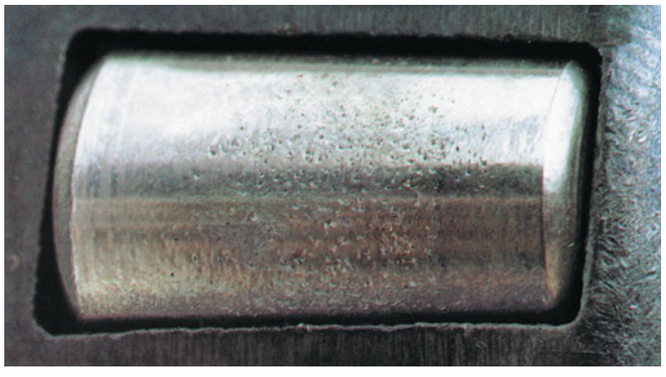
Whenever a bearing is replaced, the old bearing must be inspected and the cause of the failure eliminated. ● **SEE FIGURES 98–34 THROUGH 98–40** for examples of normal and abnormal bearing wear.

A wheel bearing may also fail for reasons that include the following.

METAL FATIGUE Long vehicle usage, even under normal driving conditions, causes metal to fatigue. Cracks often appear, and eventually these cracks expand downward into the metal from the surface. The metal between the cracks can break out into small chips, slabs, or scales of metal. This process of breaking up is called **spalling.** ● **SEE FIGURE 98–41.**



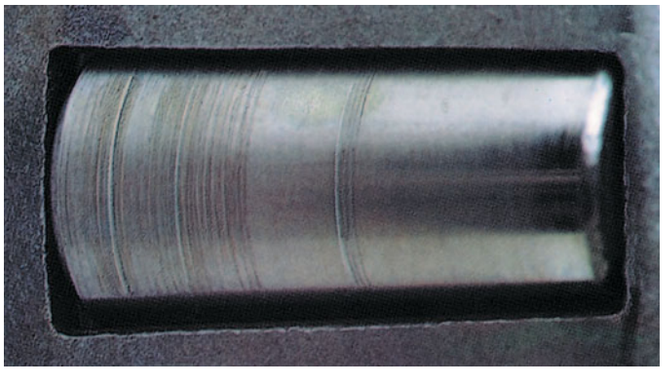
(a)



(b)

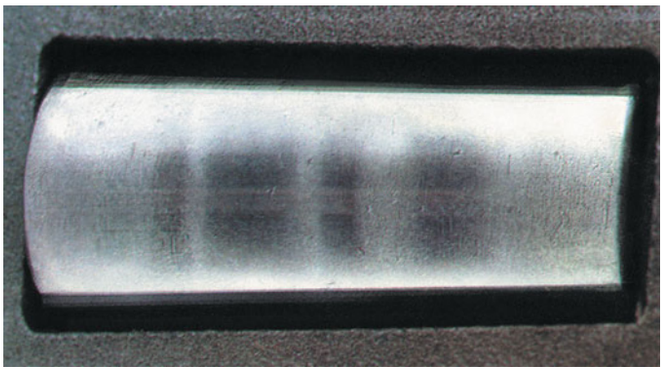
FIGURE 98–35 (a) When corrosion etches into the surface of a roller or race, the bearing should be discarded. (b) If light corrosion stains can be removed with an oil-soaked cloth, the bearing can be reused. (*Courtesy SKF USA Inc.*)

(a)

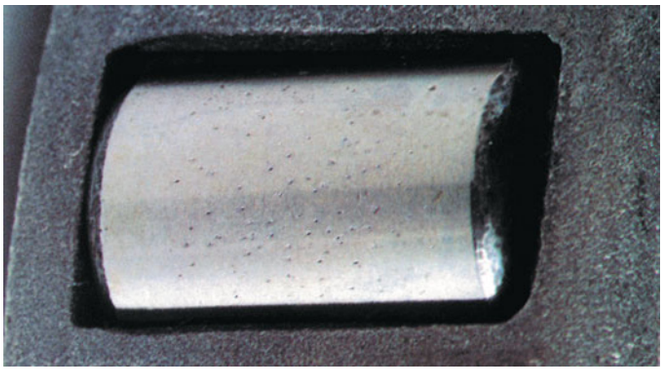


(b)

FIGURE 98–36 (a) When just the end of a roller is scored, it is because of excessive preload. Discard the bearing. (b) This is a more advanced case of pitting. Under load, it will rapidly lead to spalling. (*Courtesy SKF USA Inc.*)



(a)



(b)

FIGURE 98–37 (a) Always check for faint grooves in the race. This bearing should not be reused. (b) Grooves like this are often matched by grooves in the race (above). Discard the bearing. (*Courtesy SKF USA Inc.*)

(a)

(b)

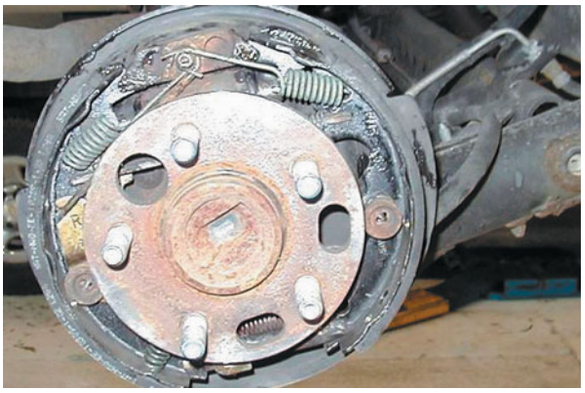
FIGURE 98–41 (a) Pitting eventually leads to spalling, a condition where the metal falls away in large chunks. (b) In this spalled roller, the metal has actually begun to flake away from the surface. (*Courtesy SKF USA Inc.*)

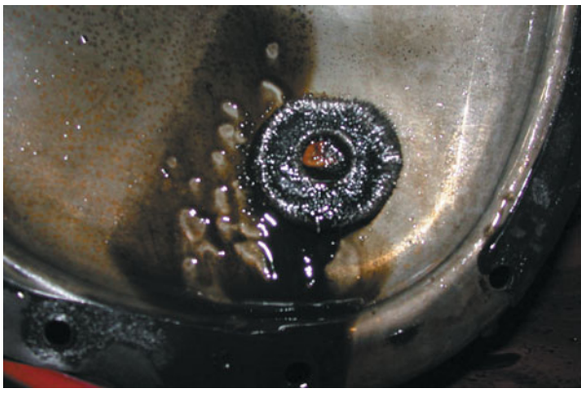
FIGURE 98–42 These dents resulted from the rollers "hammering" against the race, a condition called brinelling. (*Courtesy SKF USA Inc.*)

ELECTRICAL ARCING Bearings can be damaged caused by poor ground wires or improper welding on the vehicle.



SHOCK LOADING Dents can be formed in the race of a bearing, which eventually leads to bearing failure. ● **SEE FIGURE 98–42.**

TECH TIP

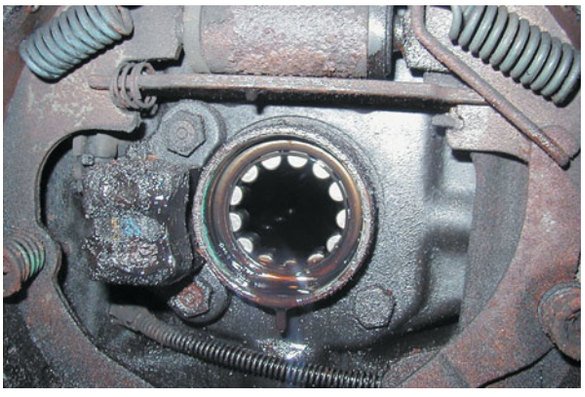


"Bearing Overload"

It is not uncommon for vehicles to be overloaded. This is particularly common with pickup trucks and vans. Whenever there is a heavy load, the axle bearings must support the entire weight of the vehicle, including its cargo. If a bump is hit while driving with a heavy load, the balls of a ball bearing or the rollers of a roller bearing can make an indent in the race of the bearing. This dent or imprint is called **brinelling,** named after Johann A. Brinell, a Swedish engineer who developed a process of testing for surface hardness by pressing a hard ball with a standard force into a sample material to be tested.

Once this imprint is made, the bearing will make noise whenever the roller or ball rolls over the indent. Continued use causes wear to occur on all of the balls or rollers and eventual failure. While this may take months to fail, the *cause* of the bearing failure is often overloading of the vehicle. Avoid shock loads and overloading for safety and for longer vehicle life.

1 After safely hoisting the vehicle, remove the rear wheels and brake drums.

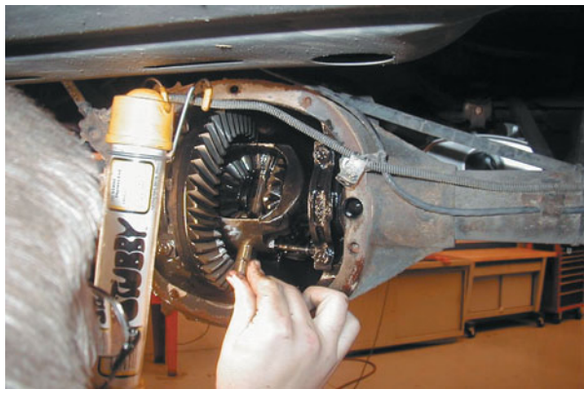


2 Remove the rear differential cover and inspect the magnet for metal particles that would indicate serious wear or damage.

3 Remove the retaining bolt and allow the pinion shaft to be removed.

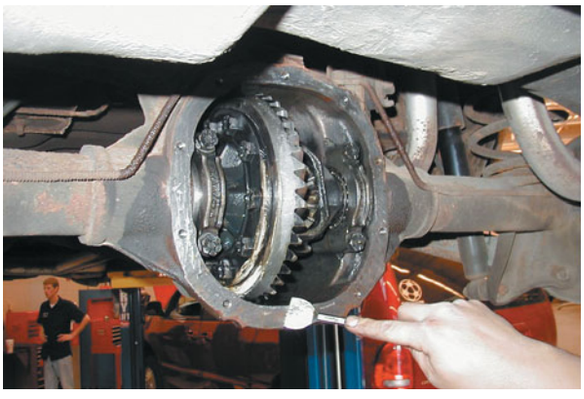
4 Push the axle inward toward the center of the vehicle to free the axle clip.

5 After removing the clip, the axle can then be removed. Note that the backing plate is wet, indicating that the axle seal has been leaking.



6 A seal removal tool being used to remove the axle seal.

CONTINUED ▶



REAR AXLE BEARING (CONTINUED)

7 If a retainer-type axle is being serviced, the bearing and seal need to be pressed off of the axle.

8 After installing a new bearing and seal, insert the axle and install the clip, then the pinion shaft.

9 Clean the differential housing before installing the cover gasket and cover. Refill the differential with the specified fluid.

REVIEW QUESTIONS

1. List three common types of automotive antifriction bearings.
2. Explain the adjustment procedure for a typical tapered roller wheel bearing.
3. List four symptoms of a defective wheel bearing.
4. Describe how the rear axle is removed from a C-lock-type axle.

CHAPTER QUIZ

1. Which type of automotive bearing can withstand radial and thrust loads, yet must be adjusted for proper clearance?
   a. Roller bearing
   b. Tapered roller bearing
   c. Ball bearings
   d. Needle roller bearing
2. Most sealed bearings used on the front wheels of front-wheel-drive vehicles are usually which type?
   a. Roller bearing
   b. Single tapered roller bearing
   c. Double-row ball bearing
   d. Needle roller bearing

3. On a bearing that has been shock loaded, the race (cup) of the bearing can be dented. This type of bearing failure is called _____.
   a. Spalling **c.** Brinelling
   b. Arcing **d.** Fluting
4. The bearing grease most often specified is rated NLGI _____.
   a. #00 **c.** #1
   b. #0 **d.** #2
5. A non-drive-wheel bearing adjustment procedure includes a final spindle nut tightening torque of _____.
   a. Finger tight
   b. 5 lb-in.
   c. 12 to 30 lb-ft
   d. 12 to 15 lb-ft plus 1/16 in. turn
6. After a non-drive-wheel bearing has been properly adjusted, the wheel should have how much end play?
   a. Zero **c.** 0.10 to 0.30 in.
   b. 0.001 to 0.005 in. **d.** 1/16 to 3/32 in.
7. The differential cover must be removed before removing the rear axle on which type of axle?
   a. Retainer plate **c.** Press fit
   b. C-lock **d.** Welded tube
8. What part(s) should be replaced when servicing a wheel bearing on a non-drive wheel?
   a. The bearing cup
   b. The grease seal
   c. The cotter key
   d. Both the grease seal and the cotter key
9. Technician A says that a defective wheel or axle bearing often makes a growling or rumbling noise. Technician B says that a defective wheel or axle bearing often makes a noise similar to a tire with an aggressive mud or snow design. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. Two technicians are discussing differentials. Technician A says all differentials are vented. Technician B says that a clogged vent can cause the rear axle seal to leak. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

chapter 99 DRUM BRAKES

OBJECTIVES: After studying Chapter 99, the reader will be able to: • Prepare for the Brakes (A5) ASE certification test content area "B" (Drum Brake Diagnosis and Repair). • Identify drum brake component parts. • Describe the operation of non-servo brakes. • Explain the operation of dual-servo brakes. • Discuss drum brake adjusters.

KEY TERMS: Anchor eyes 1091 • Beehive holddown 1094 • Bonded linings 1092 • Brake fade 1089 • Brake shoe holddowns 1093 • Brake shoe return springs 1093 • Brake shoes 1091 • Core charge 1091 • Dual-servo brake 1095 • Duo-Servo 1095 • Edge codes 1092 • Gas fade 1089 • Labyrinth seal 1089 • Leading shoe 1094 • Leading-trailing brakes 1095 • Ledges 1089 • Lining fade 1089 • Lining table 1091 • Mechanical fade 1089 • Nibs 1091 • Non-servo brakes 1094 • Over-travel spring 1097 • Pawl 1097 • Piston stops 1090 • Platform 1091 • Primary shoe 1096 • Riveted linings 1092 • Secondary shoe 1096 • Self-energizing action 1094 • Shoe anchors 1090 • Shoe contact areas 1089 • Shoe rim 1091 • Shoe support pads 1089 • Shoe web 1091 • Trailing shoe 1095 • Water fade 1089

DRUM BRAKE ADVANTAGES

Drum brakes were the first type of brakes used on motor vehicles. Even today, over 100 years after the first "horseless carriages," drum brakes are still used on the rear of many vehicles, as shown in ● **FIGURE 99–1.** The drum brake has been more widely used than any other automotive brake design. ● **SEE FIGURE 99–2.**

Although the disc brake has proven its superiority in extreme braking conditions, and has replaced the drum brake on the front axle of vehicles, the drum brake continues to have a number of advantages that contribute to its widespread use on the rear axle of most automobiles.

SELF-ENERGIZING AND SERVO ACTION The primary advantage of drum brakes is that they can apply more stopping power for a given amount of force applied to the brake pedal than can disc brakes. This is possible because the drum brake design offers a self-energizing action that helps force the brake linings tightly against the drum. In addition, some drum brake designs use an effect called servo action that enables one brake shoe to help apply the other for

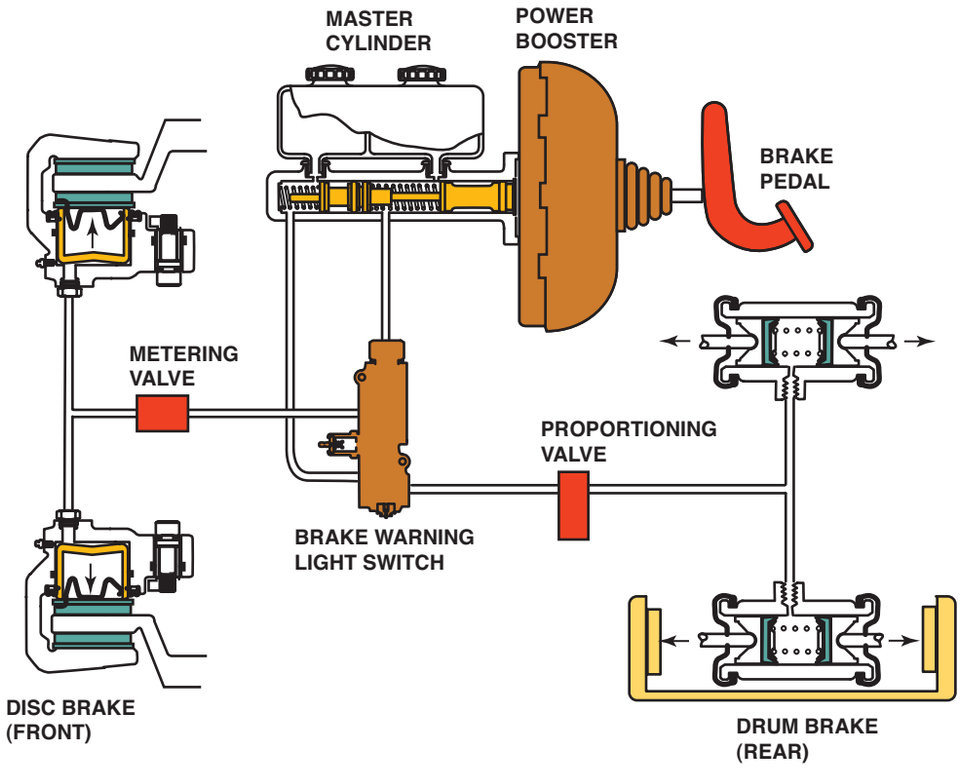


FIGURE 99–1 Typical brake system components showing disc brakes on the front and drum brakes on the rear.

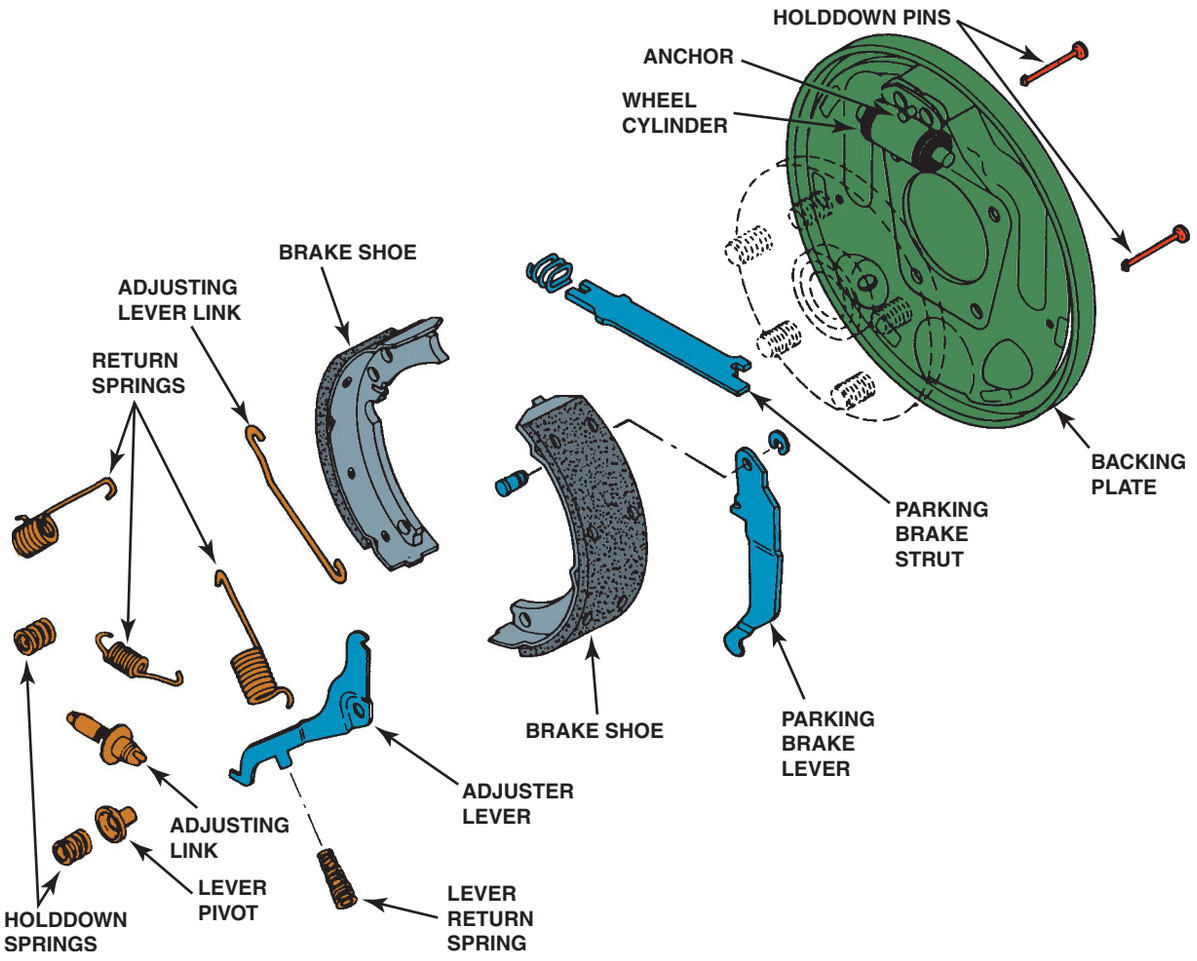

FIGURE 99–2 An exploded view of a typical drum brake assembly.

increased stopping power. Both self-energizing and servo action are explained in detail later in the chapter.

PARKING BRAKE One advantage of drum brakes is that they make excellent parking brakes. A simple linkage fitted to the brake assembly allows relatively low effort from the driver to hold a heavy vehicle in place when parked. Disc brakes, which do not benefit from self-energizing or servo action, require a complex set of extra parts to provide enough force to work well as parking brakes.

DRUM BRAKE DISADVANTAGES

BRAKE FADE Drum brakes are not very efficient at dissipating heat. The brake drum covers the linings, and most of the heat produced during braking must pass through the drum, from the inside out into the air.

The greatest drawback of drum brakes is that they are susceptible to fade. **Brake fade** is the loss of stopping power that occurs when excessive heat reduces the friction between the brake shoe linings and the drum. The four types of brake fade include:

1. **Mechanical Fade. Mechanical fade** occurs when the brake drum gets so hot it expands away from the brake linings. The brake shoes then move outward to maintain contact with the drum, causing the brake pedal to drop toward the floor as additional brake fluid moves into the hydraulic system.
2. **Lining Fade. Lining fade** occurs when the friction coefficient of the brake lining material drops off sharply because intense heat makes it "slippery." Unlike mechanical fade, brake pedal travel does not increase when lining fade occurs. Instead, the pedal becomes hard and there is a noticeable loss of braking power.
3. **Gas Fade. Gas fade** occurs under extended hard braking from high speeds, a thin layer of hot gases and dust particles can build up between the brake shoe linings and drum. The gas layer acts as a lubricant and reduces friction. As with the lining fade, the brake pedal becomes hard, and greater application force is required to maintain a constant level of stopping power.
4. **Water Fade. Water fade** occurs when moisture is trapped between the shoes and drum, where it acts as a lubricant. This lowers braking efficiency until friction creates enough heat to evaporate the water.

BRAKE ADJUSTMENT Another disadvantage of the drum brake design is its need for an adjusting mechanism. As the brake shoe lining material wears, the clearance between the linings and drum increases, resulting in longer brake pedal travel. To maintain a high brake pedal, a mechanism must be included in the brake assembly for adjustment of the clearance between the brake shoe and drum. Most vehicles have automatic adjusters that maintain the proper drum to linings clearance.

BRAKE PULL Brake pull occurs when the friction assemblies on opposite sides of the vehicle have different amounts of stopping power. These differences can be caused by many conditions, component failures, brake fade and mis-adjustment of the clearance between the brake linings and drum.

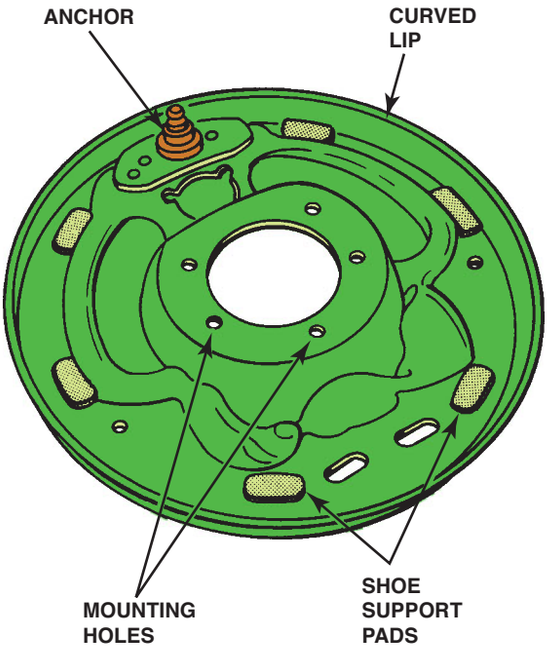

FIGURE 99–3 The backing plate is the foundation of every drum brake. There are normally six pads where the brake shoes contact the backing plate.

TECH TIP

Quick-and-Easy Drum Brake Adjustment Check

Tap the brake drum lightly with a hammer or wrench. If the brake shoes are not contacting the drum, the drum will ring like a bell. If the shoes are contacting the drum, the sound will be muffled.

DRUM BRAKE PARTS

BACKING PLATE The foundation of every drum brake is the backing plate that mounts to the suspension or axle housing on the rear brakes. The **shoe support pads** are stamped into the backing plate and contact the edges of the brake shoes to keep the linings properly aligned with the center of the friction surface inside the brake drum. These pads are also called **ledges** or **shoe contact areas.** The support pads are slightly coated with special high-temperature silicone brake grease to minimize wear, prevent rust, and eliminate squeaking that can occur when the shoes move slightly on the pads during a stop. ● **SEE FIGURE 99–3.**

The backing plate serves as the mounting surface for all the other friction assembly parts. The backing plate also functions as a dust and water shield to keep contaminants out of the brake assembly. The edge of the backing plate curves outward to form a lip that strengthens the backing plate and fits inside the brake drum to help prevent water entry. The lip fits into a machined groove in the open edge of the brake drum to provide an even better water barrier or seal. This type of seal is called a **labyrinth seal.** ● **SEE FIGURE 99–4.**

In addition to mounting holes for the various brake parts, the backing plate may also have openings that are used to inspect the wear of the brake linings, or adjust the lining-to-drum clearance. These openings are sometimes sealed with metal plugs that must

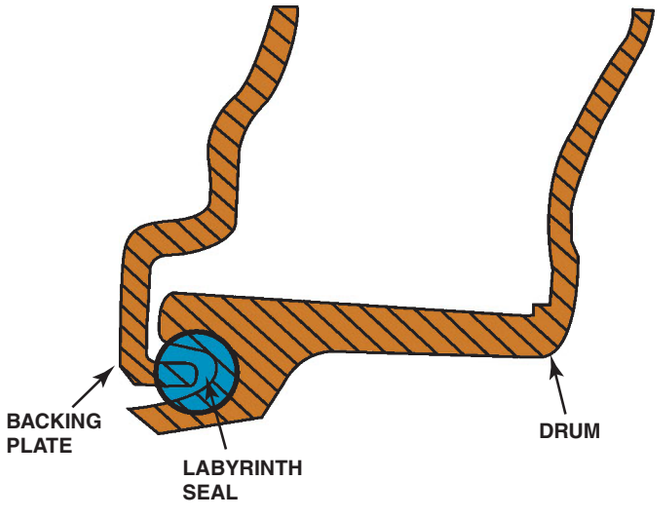

FIGURE 99–4 A labyrinth seal is created between the lip of the backing plate and the groove in the brake drum.

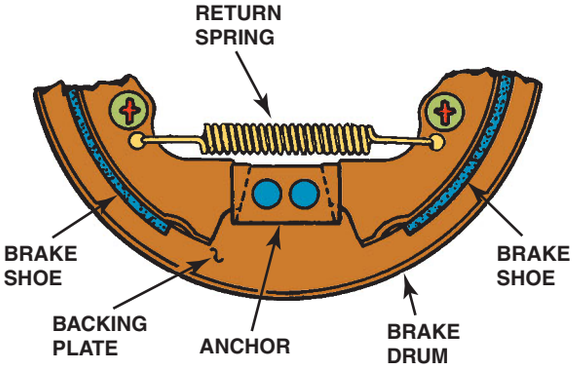

FIGURE 99–5 A keystone anchor allows the brake shoes to self-center in the drum.

be punched out the first time inspection or adjustment is needed. Rubber plugs are available to seal the holes and prevent water entry once the metal plugs have been removed.

SHOE ANCHORS

Shoe anchors prevent the brake shoes from rotating with the drum when the brakes are applied. The majority of drum brakes have a single anchor, but some drum brake designs use two or more.

Many anchors are a simple round post that is permanently mounted on the backing plate. The brake shoes have semicircular cutouts where they contact the anchor, and the anchor positively locates the shoe on the backing plate. Another type of anchor is the self-centering or keystone anchor. ● **SEE FIGURE 99–5.** It is called a keystone anchor because of the angled shape similar to a keystone used on the top center of a stone arch.

PISTON STOPS

Some backing plates incorporate **piston stops** that prevent the wheel cylinder pistons from coming out of their bores when the friction assembly is disassembled for servicing. The stops may be part of a reinforcing plate positioned under the anchor or they can be stamped directly into the shape of the backing plate itself. ● **SEE FIGURE 99–6.**

When piston stops are used, the wheel cylinder must be removed from the backing plate before it can be taken apart for servicing.

WHEEL CYLINDERS

Hydraulic pressure is transferred from the master cylinder to each wheel cylinder through brake fluid. The force exerted on the brake fluid by the driver forces the piston inside the wheel cylinder to move outward. ● **SEE FIGURE 99–7.** Through pushrods or links, this movement acts on the brake shoes, forcing them outward against the brake drum. ● **SEE FIGURE 99–8.**

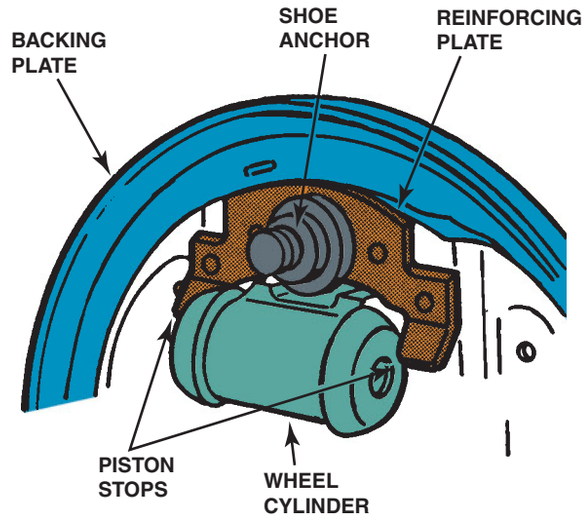

FIGURE 99–6 Piston stops prevent the wheel cylinder from coming apart.

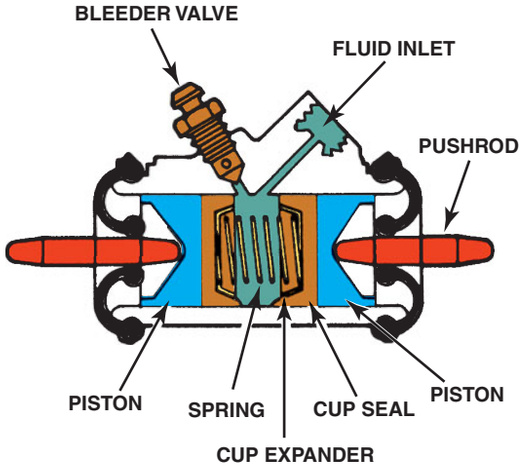

FIGURE 99–7 Cross-section of a wheel cylinder that shows all of its internal parts. The brake line attaches to the fluid inlet. The cup extender prevents the cup seal lip from collapsing when the brakes are released.

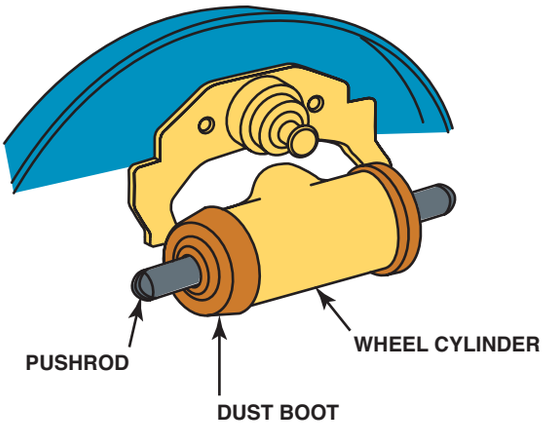

FIGURE 99–8 The pushrods are held in place by the rubber dust boots. As the wheel cylinder pistons move outward, the pushrods transfer the movement to the brake shoes.

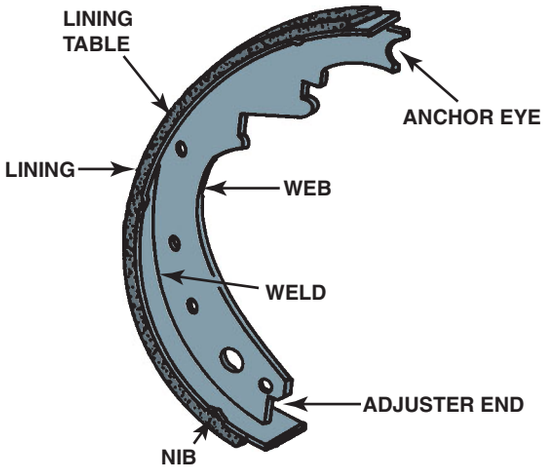

FIGURE 99–9 Steelbrake shoes are made from two stampings welded together—the web and the lining table.

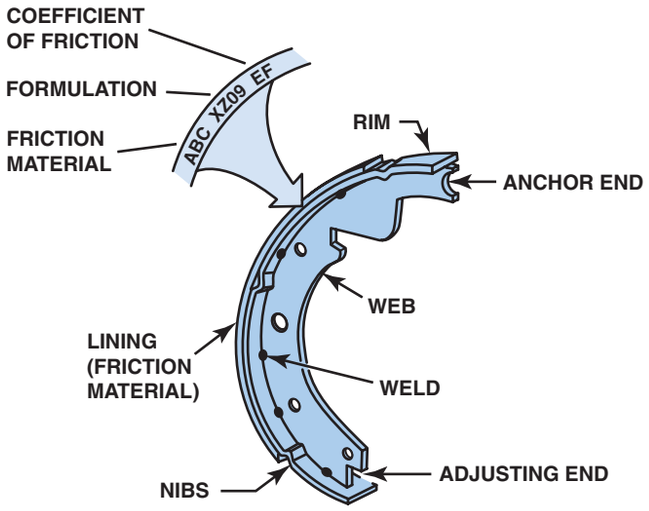

FIGURE 99–11 Typical drum brake shoe and the names of the parts.

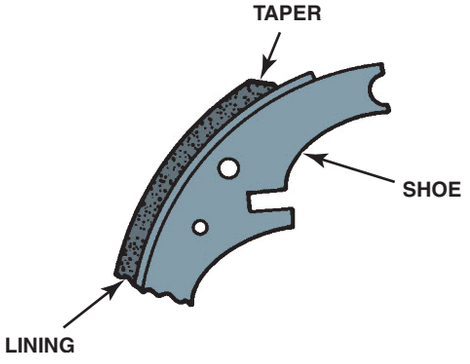

FIGURE 99–10 Tapered ends on the linings help to reduce brake noise.

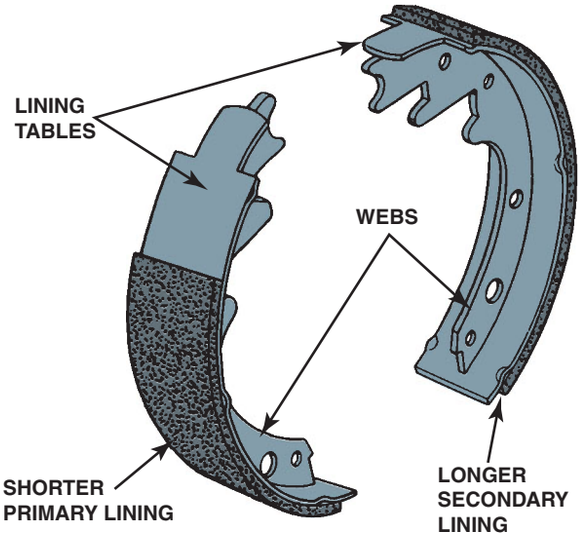

FIGURE 99–12 The primary (forward facing) brake shoe often has a shorter lining than the secondary shoe (rearward facing). The color of the primary and secondary lining can also be different due to differences in friction and wear requirements.

DRUM BRAKE SHOES

The linings of drum brakes are attached to curved metal assemblies called **brake shoes.** Most shoes are made of two pieces of sheet steel welded together in a T-shaped cross section. ● **SEE FIGURE 99–9.**

The outer edge is lined with a friction material that contacts the brake drum to generate the actual stopping power. The ends of the linings on most brake shoes are tapered to prevent vibration and brake noise as shown in ● **FIGURE 99–10.**

The curved metal piece on the outer portion of the shoe is called the **lining table,** the **shoe rim** or **platform.** The lining table supports the block of friction material that makes up the brake lining. On some shoes, the edge of the lining table contains small V- or U-shaped notches called **nibs.** The nibs rest against the shoe support pads on the backing plate when the shoe is installed.

The metal piece of the shoe positioned under the lining table and welded to it is called the **shoe web.** All of the application force that actuates the shoe is transferred through the web to the lining table. The web usually contains a number of holes in various shapes and sizes for the shoe return springs, hold-down hardware, parking brake linkage, and self-adjusting mechanism.

One end of the web usually has a notch where the wheel cylinder touches the shoe, while the other end commonly has a flat or curved surface where the shoe meets an anchor or adjusting link. The upper ends of the webs on dual-servo brake shoes have semicircular cutouts called **anchor eyes.** ● **SEE FIGURE 99–11.**

Brake shoes are parts that can be relined and reused many times if the web and lining table are not damaged. Brake shoes for any given application are usually available in both “new” and “relined” versions from suppliers. Relined brake shoes are usually sold on an exchange basis. At the time of purchase, a **core charge** is added to the cost of the relined parts. This charge is refunded when the old shoes are returned in rebuildable condition.

PRIMARY AND SECONDARY BRAKE SHOES

The primary shoe (forward facing shoe) is self-energized by drum rotation to create a servo action that forces the secondary shoe more firmly against the drum. Because of this, the two shoes have physical differences and cannot be interchanged.

To help deal with the added friction, heat, and wear it undergoes, the lining of the secondary shoe extends nearly the full length of the shoe lining table. ● **SEE FIGURE 99–12.** The secondary shoe lining material also has a high coefficient of friction to provide good stopping power. The primary shoe undergoes far less stress than the secondary shoe, and its lining is often shorter—sometimes less

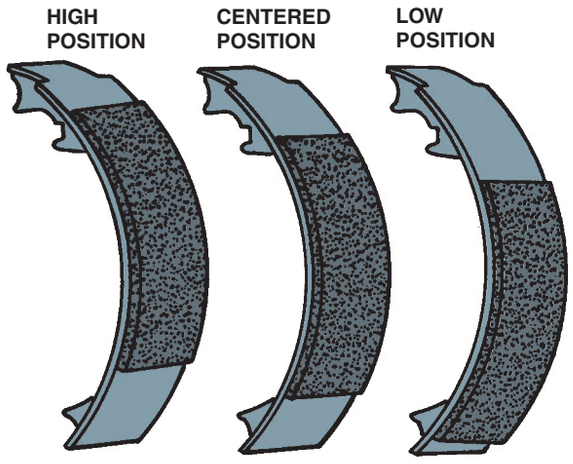

FIGURE 99–13 Primary shoe lining may vary depending on the application.

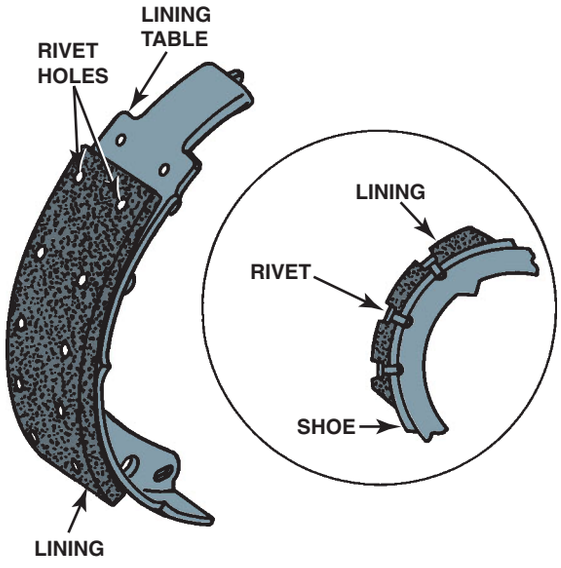

FIGURE 99–14 Riveted brake linings are quiet and reliable at high temperatures.

than half the length of the lining table. In addition, the lining material usually has a lower coefficient of friction. This prevents the shoe from engaging the drum too quickly or harshly, which could cause the brakes to grab or lock.

On most dual-servo brake primary shoes, the lining is positioned near the center of the lining table. However, in some cases, the lining may be positioned above or below the lining table centerline. Higher or lower lining positions provide better braking action, or prevent noise, in some vehicles. ● **SEE FIGURE 99–13.**

LINING ASSEMBLY METHODS

There are two main methods used to mount brake linings to the brake shoe.

RIVETING. The brake lining is attached to the lining table with copper or aluminum rivets. ● **SEE FIGURE 99–14.** Riveting has the following advantages:

- The major advantage of riveting is that it allows a small amount of flex between the brake lining and lining table. This play enables the assembly to absorb vibration, and the result is that **riveted linings** operate more quietly than bonded linings.
- Rivets are also very reliable and will not loosen at high temperatures.

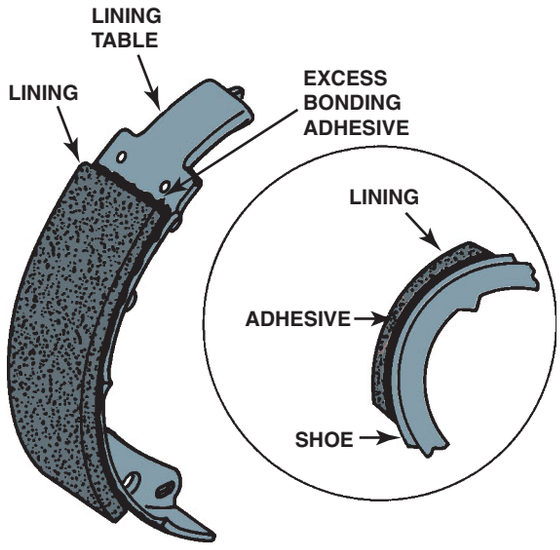

FIGURE 99–15 Many brake linings are bonded.

Riveting has the following disadvantages:

- Rivet holes however do create stress points in the lining where cracks are likely to occur.
- Riveted lining has a reduced service life because the linings must be replaced before the rivet head contacts the brake drum.
- The rivet can cause deep grooves to be cut into the drum often requiring replacement if the worn brakes are not detected early enough to prevent damage.

BONDING. **Bonded linings** use high-temperature adhesive to glue the brake block directly to the shoe lining table or pad backing plate as shown in ● **FIGURE 99–15.** Heat and pressure are then applied to cure the assembly. Bonding is a common form of shoe and pad assembly, and is most often used to mount organic friction materials.

Bonding has several advantages including:

- Without rivets, bonded linings can wear closer to the lining table and provide a longer service life. If the linings wear too far, bonding adhesive is not as destructive to drums or rotors as rivets.
- Bonded linings also have fewer problems with cracking because they have no rivet holes to weaken the brake block.

Bonded linings have the following disadvantages:

- If a bonded lining gets too hot, the bonding adhesive will fail and allow the brake block to separate from the lining table or backing plate.
- Bonded linings are also more prone to be noisy because they do not allow any vibration absorbing flex between the brake block and lining table or backing plate.

EDGE CODES

Starting in 1964, brake linings have been using a standardized way to identify the brake lining materials. The edge codes follow the Society of Automotive Engineers (SAE) Standard J866a. The **edge codes** contain three groups of letters and numbers:

- The first group is a series of letters that identify the manufacturer of the lining.
- The second group is a series of numbers, letters, or both that identify the lining compound or formula. This code is usually known to the manufacturer of the lining material and helps identify the lining after manufacture.
- The third group is two letters that identify the coefficient of friction.

FIGURE 99–16 Typical drum brake lining edge codes, showing the coefficient of friction codes for cold and hot circled.

Code C	0.00 to 0.15
Code D	0.15 to 0.25
Code E	0.25 to 0.35
Code F	0.35 to 0.45
Code G	0.45 to 0.55
Code H	0.55 and above
Code Z	ungraded

CHART 99–1

Edge code letters represent a range of coefficient of friction of the linings.

TECH TIP

Purchase Quality Brake Linings for Best Performance

While many brands of replacement brake lining provide acceptable stopping power and long life, purchasing factory brake lining from a dealer is usually the best opportunity to get lining material that meets all vehicle requirements. Aftermarket linings are not required by federal law to meet performance or wear standards that are required of original factory brake linings.

The coefficient of friction is a number that indicates the amount of friction between two surfaces. A coefficient of friction will always be less than 1; the higher the number, the greater the amount of friction between two surfaces. (For example, a material with 0.55 coefficient of friction has more friction than a material with a coefficient of friction of 0.39.)

These coefficient of friction codes include letters that represent a range of coefficient of friction. ● **SEE CHART 99–1.**

There are always two letters used side by side and the first letter indicates its coefficient of friction when brakes are cold (250°F/121°C), and the second letter indicates the coefficient of friction of the brake lining when the brakes are hot (600°F/316°C).

For example, FF indicates that the brake lining material has a coefficient of friction between 0.35 and 0.45 when both cold and hot. ● **SEE FIGURE 99–16.**

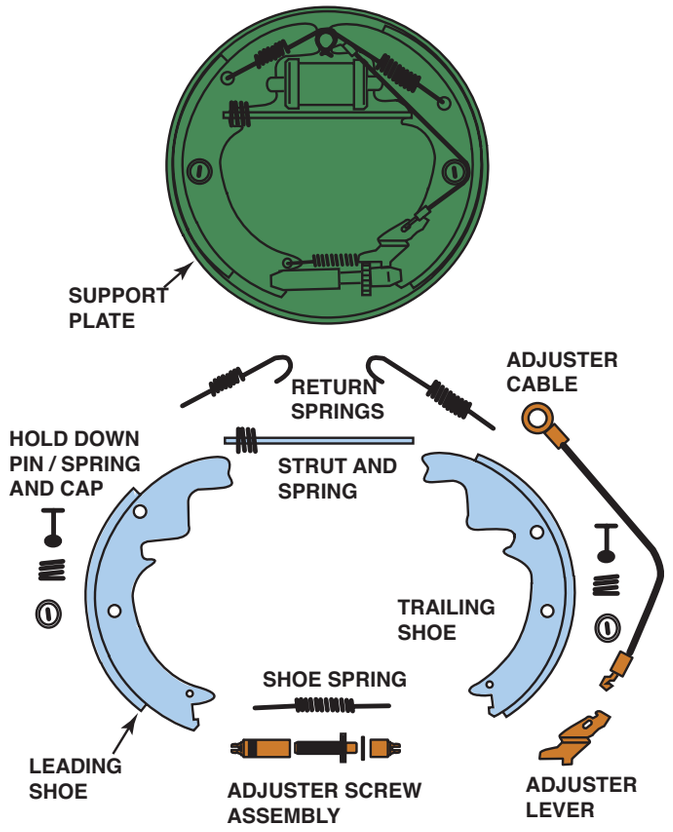

FIGURE 99–17 A typical drum brake assembly showing the support plate (backing plate), brake shoes, and springs.

These letters do not mean the relative quality of the lining material. Lining wear, fade resistance, tensile strength, heat recovery rate, wet friction, noise, and coefficient of friction must be considered when purchasing high-quality linings. Unfortunately, there are no standards that a purchaser can check regarding all of these other considerations. For best brake performance, always purchase the best-quality name-brand linings that you can afford.

DRUM BRAKE PARTS

RETURN SPRINGS

The **brake shoe return springs** retract the shoes to their unapplied positions when the brake pedal is released. This helps prevent brake drag, and aids the return of brake fluid to the master cylinder reservoir. Most brakes use closed-coil return springs to retract the brake shoes. ● **SEE FIGURE 99–17.**

The coils on these springs are very tightly wound and contact one another when the spring is relaxed. Some vehicles have a single, large, horseshoe-shaped return spring. ● **SEE FIGURE 99–18.**

The type, location, and number of return springs vary from one brake design to the next. All springs are installed in one of two ways. Some connect directly from shoe to shoe, while others connect from one shoe to the anchor post.

BRAKE SHOE HOLDDOWNS

While the return springs retract the brake shoes to their unapplied positions, the **brake shoe holddowns** keep the shoes securely against the support pads on the backing plate. The holddowns prevent noise, vibration, and wear, but still allow the shoes to move out and back as the brakes are applied and released. The holddowns also provide enough freedom of movement to allow adjustments of the shoes outward as

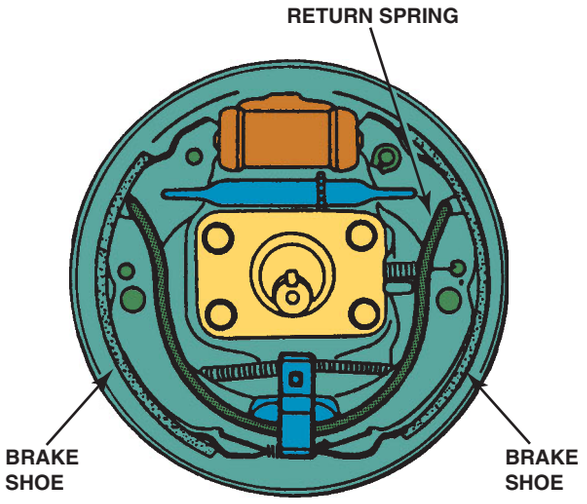

FIGURE 99–18 A single spring-steel spring is used on some drum brakes.

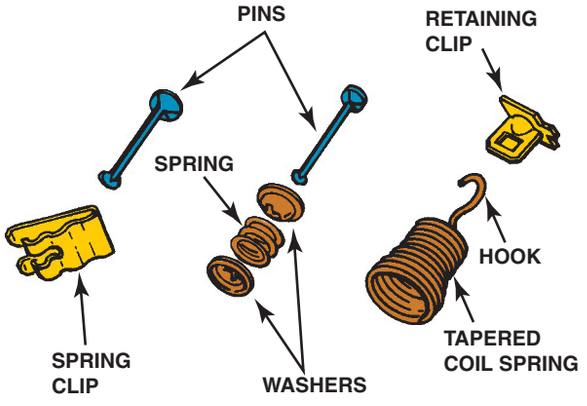

FIGURE 99–19 Various types and styles of hold-down springs. The hold down pins are commonly called *nails.*

the linings wear. Shoe holddowns take many forms, as shown in ● **FIGURE 99–19.**

The most common design is a steel pin installed through a hole in the backing plate and a corresponding hole in the brake shoe web. A spring fits over the end of the pin against the shoe web, and a special washer compresses the spring and locks onto the flattened end of the pin.

Another type of holddown is a taper-wound coil spring with a hook formed on its end. Because of its shape, this part is sometimes called a **beehive holddown.** The hook end of the spring is installed through a hole in the brake shoe web and attached into a retaining clip that fits into a corresponding hole in the backing plate.

PARKING BRAKE LINKAGE Most rear drum brake friction assemblies include a parking brake linkage. The linkage commonly consists of a cable, lever, and strut system that spread the brake shoes apart to apply the brake mechanically. The parking brake strut plays a large part in many of the automatic brake adjusters. ● **SEE FIGURE 99–20.**

BRAKE DRUMS The brake drum is not connected to the backing plate, but turns with the wheel. The drum mounts on the hub or axle, and covers the rest of the brake assembly. Brake drums are made of cast iron or cast aluminum with a cast-iron liner. Many of these drum types may have ribs or fins on their outer edge to help dissipate heat. ● **SEE FIGURE 99–21.**

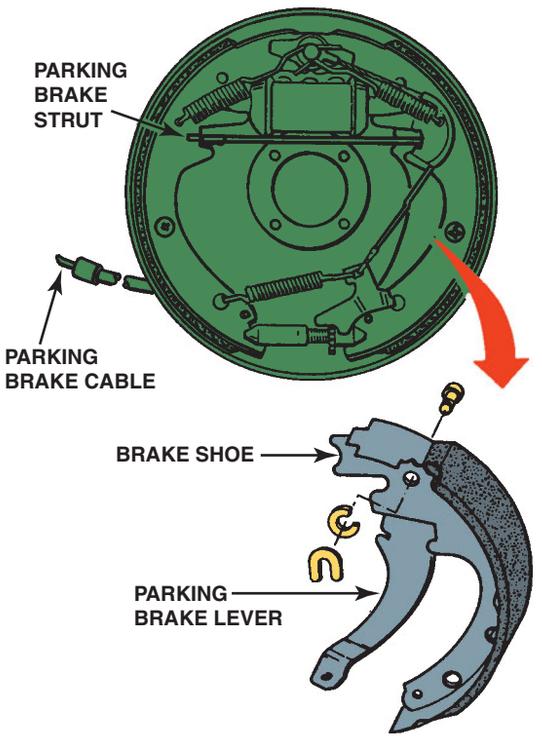

FIGURE 99–20 A mechanical brake linkage is part of most drum brake assemblies.

FIGURE 99–21 An aluminum brake drum with a cast iron friction surface. The cooling fins around the outside help dissipate the heat from the friction surface to the outside air.

NON-SERVO BRAKE DESIGN

PURPOSE AND FUNCTION A **non-servo brake** feature is that each brake shoe is applied individually. The action of one shoe has no effect on the action of the other. Many non-servo drum brakes use **self-energizing action** to improve their braking performance.

PARTS AND OPERATION Self-energizing action occurs when the forward or **leading shoe** contacts the drum and the drum attempts to rotate the shoe along with it. However, the shoe cannot rotate because its far end (relative to drum rotation) is fixed in place by an anchor. As a result, drum rotation *energizes* the shoe by forcing it outward and wedging it tightly against the brake drum.

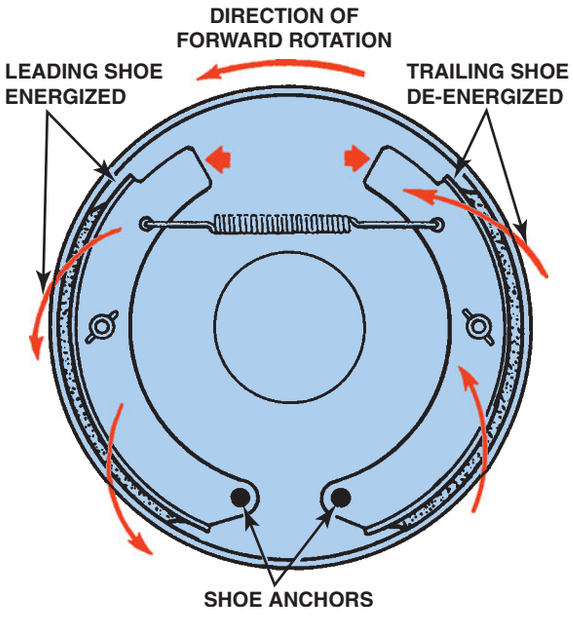

FIGURE 99–22 Self-energizing action can increase or decrease the stopping power of a brake shoe.

The drum also attempts to rotate the reverse or **trailing shoe** as it contacts the drum. However, in this case, the far end of the shoe (relative to drum rotation) is not solidly anchored. As a result, drum rotation *de-energizes* the shoe by forcing it inward away from the brake drum.

When this type of brake is applied with the vehicle backing up, the roles of the forward and reverse shoes are switched. The reverse shoe becomes the leading shoe, which is self-energized by drum rotation, while the forward shoe becomes the trailing shoe, which is de-energized. *A leading shoe is always energized by drum rotation. A trailing shoe is always de-energized by drum rotation.* The simple drum brake assembly shown in ● **FIGURE 99–22** shows how the self-energizing process works.

To identify the leading shoe on a non-servo brake with only one wheel cylinder, the first shoe from the wheel cylinder in the direction of drum rotation is the leading shoe. If the piston of a wheel cylinder moves in the same direction as drum rotation when the brakes are applied, the shoe it actuates is a leading shoe. If the piston moves opposite the direction of drum rotation, the shoe actuated is the trailing shoe.

Leading shoes generally wear at a faster rate than trailing shoes because they are applied with greater force. Where a brake uses one leading and one trailing shoe, the leading shoe will sometimes have a thicker lining or one with a larger surface area than that of the trailing shoe. The thicker or larger lining balances the wear between the two shoes so that they will both need replacement at about the same time.

LEADING-TRAILING BRAKE DESIGN

The non-servo **leading-trailing brake** has one leading shoe and one trailing shoe. ● **SEE FIGURE 99–23.** Typically, a single, two-piston wheel cylinder is mounted at the top of the backing plate and the two brake shoes are anchored at the bottom of the backing plate.

The brake design has one energized and one de-energized shoe regardless of whether it is applied while the vehicle is traveling forward or in reverse. This allows the leading-trailing brake to work equally well in either direction. The leading shoe usually wears more than the trailing shoe.

Leading-trailing brakes are popular on the rear wheels of many small and front-wheel-drive vehicles because, although they are not as powerful as a servo brake, they are less prone to lockup. They have the further benefit of making a good parking brake in both directions.

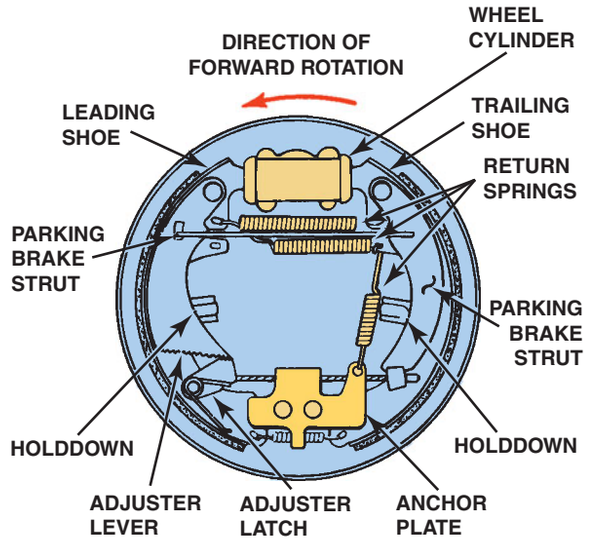

FIGURE 99–23 A leading-trailing non-servo brake.

DUAL-SERVO BRAKE DESIGN

PURPOSE AND FUNCTION

The **dual-servo brake** is the most common drum brake design. The name "servo" comes from the fact that one shoe "serves" the other to increase application force. All servo brakes used on automobiles are of the dual-servo design that works with equal force in both directions.

The primary advantage of the dual-servo brake is that it is more powerful than any of the non-servo designs. Another advantage of the dual-servo brake is that it makes a good parking brake. Dual-servo action not only makes the brake very powerful, it allows the brake to hold equally well in both directions.

Dual-servo brakes are more susceptible to pull than other brake designs, and their greater application force can lead to faster fade under extreme braking conditions.

NOTE: Dual-servo brakes are also called Duo-Servo, which is a brand name of the Bendix Corporation.

DUAL-SERVO BRAKE CONSTRUCTION

The basic dual-servo brake uses one anchor and a single two-piston wheel cylinder. ● **SEE FIGURE 99–24.** The anchor is usually mounted at the top of the backing plate with the wheel cylinder directly beneath it. The tops of the brake shoes are held against the anchor by individual return springs. The bottoms of the shoes are spaced apart by an adjusting link held in position by a third return spring that connects the two shoes.

ADJUSTING LINK (STARWHEEL ADJUSTER). The adjusting link consists of a starwheel that is part of an adjusting screw, a pivot nut that one end of the adjusting screw threads into, and a socket that rotates freely on the opposite end of the adjusting screw. ● **SEE FIGURE 99–25.** The outer ends of the pivot nut and socket are notched to fit over the brake shoe webs. Some adjusting links have a steel thrust washer and/or spring washer installed between the socket and the starwheel. These washers allow easier rotation of the starwheel and help reduce brake squeal.

FIGURE 99–24 A typical dual-servo drum brake.

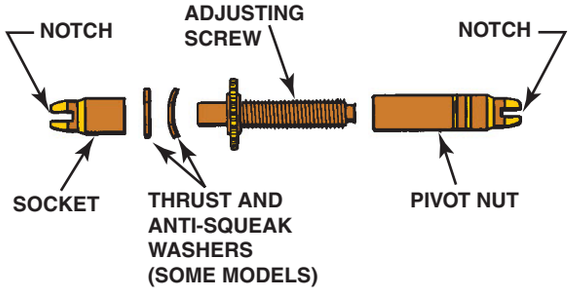

FIGURE 99–25 A typical dual-servo brake adjusting link assembly commonly called a *starwheel adjuster.*

NOTE: Adjusting links generally have specific left- or right-hand threads, and must be installed on the correct side of the vehicle.

PRIMARY AND SECONDARY BRAKE SHOES. Although dual-servo brakes make use of self-energizing action to help provide servo action, the two brake shoes are not called leading and trailing parts as in non-servo brakes. Instead, they are identified as the **primary shoe** and the **secondary shoe.** To identify the primary shoe on a dual-servo brake with a single two-piston wheel cylinder, point to the wheel cylinder, and then move your finger in the direction of drum rotation. The first shoe reached is the primary shoe (always facing to the front of the vehicle) and the other shoe is the secondary shoe (always facing toward the rear of the vehicle).

The secondary brake shoe provides approximately 70% of the total braking power in a dual-servo brake. For this reason, the lining is usually somewhat larger than that of the primary shoe. In addition, some manufacturers use different types of friction materials on the primary and secondary shoes to help equalize wear.

DUAL-SERVO BRAKE OPERATION

When a dual-servo brake is applied, the wheel cylinder attempts to force the tops of both brake shoes outward against the drum. ● **SEE FIGURE 99–26.** As the primary shoe makes contact it rotates with the drum because its far end (relative to the direction of drum rotation) is not directly anchored to the backing plate. As the primary shoe rotates, it forces the adjusting link and the secondary shoe to also rotate until the secondary shoe seats firmly against the anchor.

Although the wheel cylinder attempts to push the top of the secondary shoe outward, the rotational force developed by friction between the brake shoes and drum is much greater than the force developed by hydraulic pressure in the wheel cylinder. As a result, the secondary shoe is held against the anchor. In effect, only one-half of the wheel cylinder is used to apply the brakes.

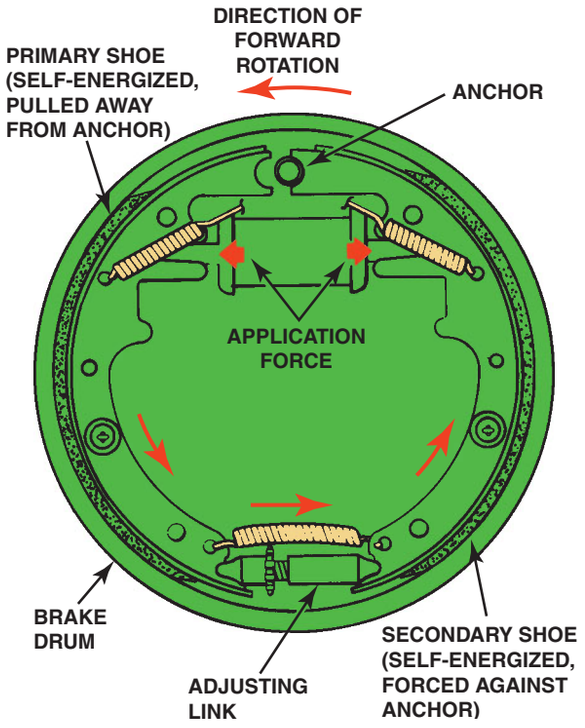

FIGURE 99–26 Dual-servo brake operation. The primary shoe on the left exerts a force on the secondary shoe on the right.

TECH TIP

Rear Wheel Lockup? Check the Adjustment

Servo action enables a drum brake to provide increased stopping power, but it can also cause the brakes to grab and lock if they get too far out of adjustment. As clearance between the shoes and drum increases, the primary brake shoe is allowed a greater range of movement. The farther the shoe moves, the more speed it picks up from the rotating brake drum. At the moment the slack is taken up between the brake shoes, adjusting link, and anchor, the speed of the primary shoe is converted into application force by servo action. If the primary shoe is moving too quickly, it will apply the secondary shoe very hard and fast, causing the brakes to grab and possibly lock the wheels.

SERVO ACTION

Once all clearance is taken up between the brake shoes, adjusting link, and anchor, both brake shoes become self-energized like the leading shoes in a non-servo brake. The anchor pin prevents the secondary shoe from rotating, and the adjusting link (held in position by the secondary shoe) serves as the anchor for the primary shoe. Servo action then occurs as a part of the braking force generated by the primary shoe is transferred through the adjusting link to help apply the secondary shoe. The secondary shoe is "wedged" between the anchor pin and brake drum and therefore provides more stopping force than the primary shoe which is applied only by hydraulic force. ● **SEE FIGURE 99–27.**

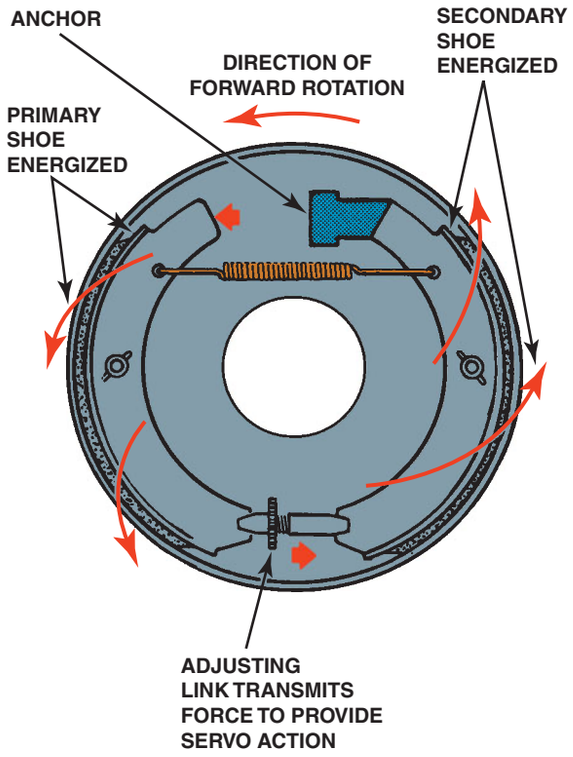

FIGURE 99–27 Dual servo action greatly increases the application force on the secondary shoe.

When a dual-servo brake is applied with the vehicle moving in reverse, the primary and secondary shoes switch roles. The primary shoe is forced against the anchor while the secondary shoe moves outward and rotates with the drum to apply the primary shoe with a greater force.

AUTOMATIC BRAKE ADJUSTERS

SERVO BRAKE STARWHEEL AUTOMATIC ADJUSTERS

Servo brakes use three styles of starwheel adjusters:

- **Cable.** ● **SEE FIGURE 99–28.**
- **Lever.** ● **SEE FIGURE 99–29.**
- **Link.** ● **SEE FIGURE 99–30.**

All three adjusters mount on the secondary brake shoe and adjust only when the brakes are applied while the vehicle is moving in reverse.

As the brakes are applied on a vehicle with a cable or link automatic adjuster, the wheel cylinder and drum rotation combine to move the secondary shoe away from the anchor. Movement of the shoe causes the cable or linkage to pull up on the adjuster **pawl.** ● **SEE FIGURE 99–31.** If the brake lining has worn far enough, the pawl engages the next tooth on the starwheel. When the brakes are released, the pawl return spring pulls the pawl down, rotating the starwheel and moving the brake shoes apart to reduce the lining-to-drum clearance.

Some servo brakes with cable-actuated starwheel automatic adjusters have an **over-travel spring** assembly on the end of the cable. ● **SEE FIGURE 99–32.** In this design, the adjuster pawl is mounted *under* the starwheel, and adjustment is made as the brakes are applied rather than released. The over-travel spring dampens the movements of the adjuster mechanism, and prevents

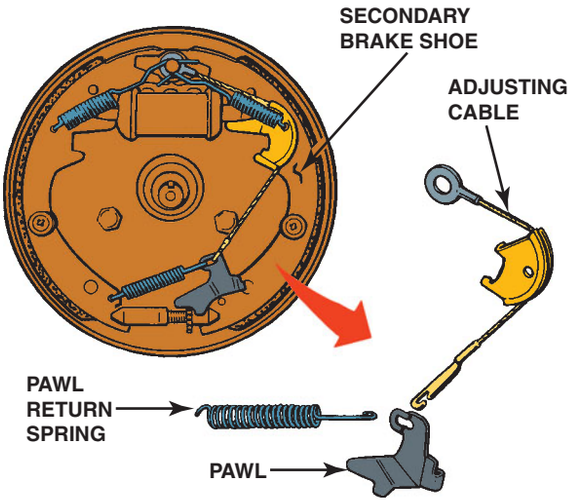

FIGURE 99–28 A cable-actuated starwheel adjuster. This type of adjuster makes the adjustment when the vehicle is being driven in reverse and the brakes are released.

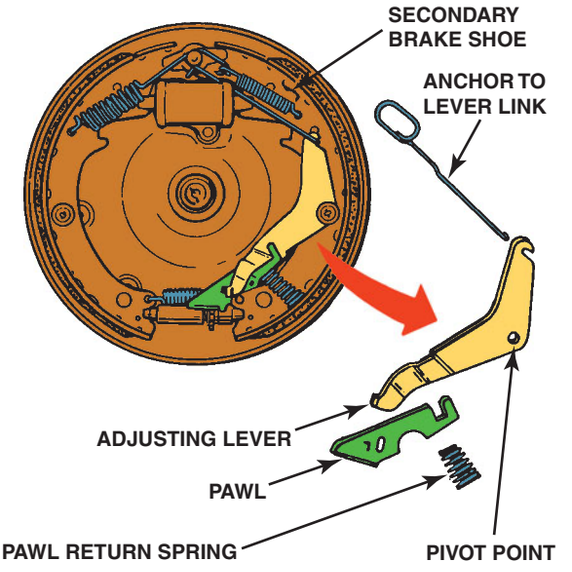

FIGURE 99–29 A lever-actuated starwheel automatic adjuster. This type of adjuster makes the adjustment when the vehicle is being driven in reverse and the brakes are applied.

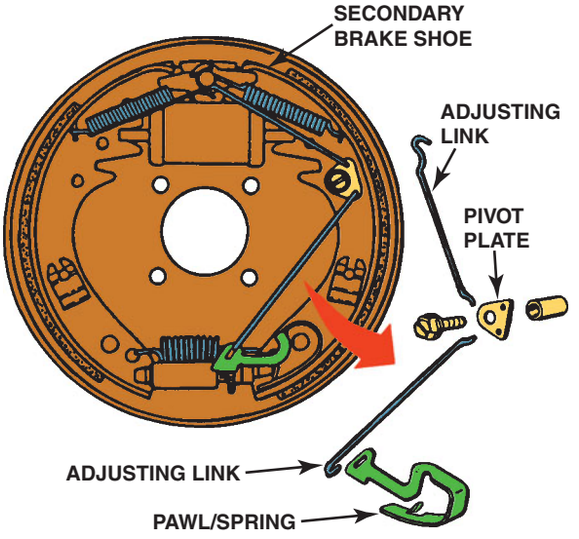

FIGURE 99–30 A link-actuated starwheel adjuster. This type of adjuster makes the adjustment when the brakes are released.

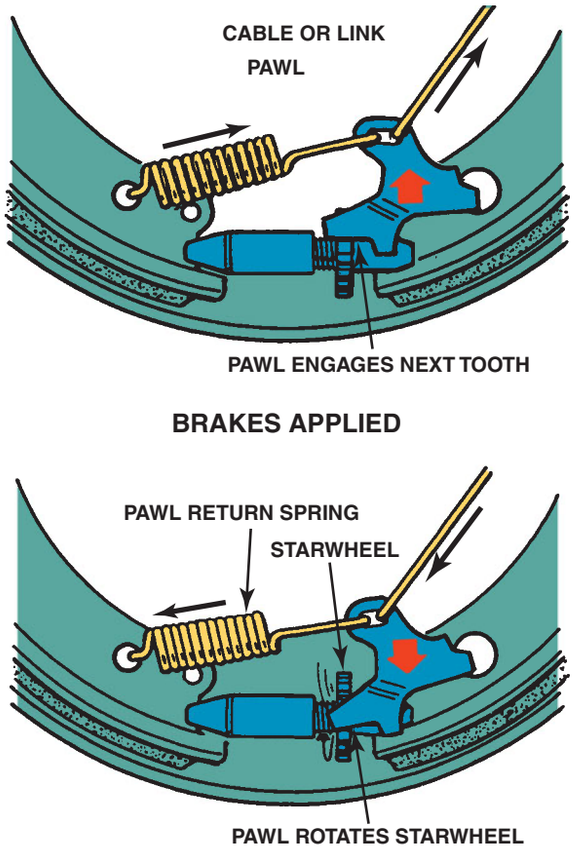

FIGURE 99–31 The operation of a typical self-adjuster. Notice that the adjuster actually moves the starwheel.

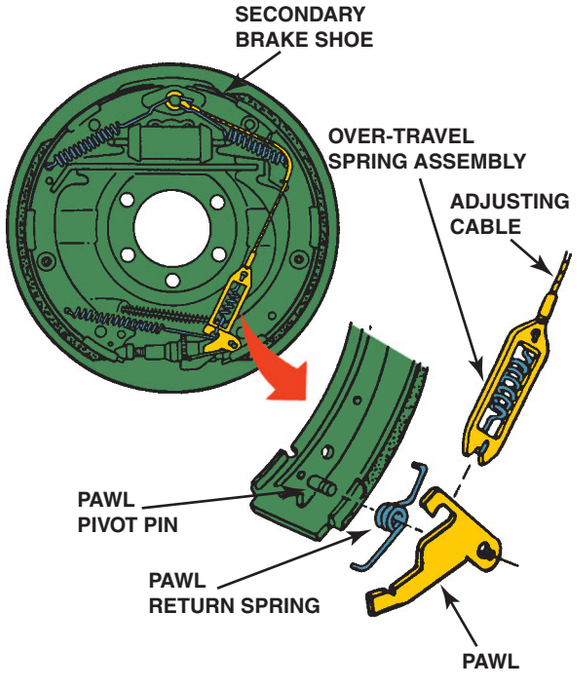

FIGURE 99–32 A cable-actuated starwheel adjuster with an over-travel spring.

overadjustment if the brakes are applied very hard and fast. It also prevents damage to the adjusting mechanism if the starwheel seizes or is otherwise unable to rotate.

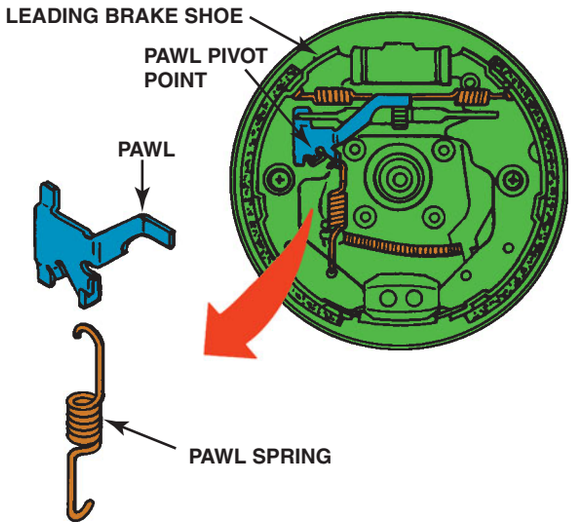

FIGURE 99–33 A non-servo brake with a lever-actuated starwheel automatic adjuster on a leading shoe. This type of adjuster makes an adjustment as the brakes are applied.

The lever starwheel adjuster makes the adjustment as the brakes are applied rather than released. The operation includes the following actions:

- As the secondary shoe moves away from the anchor, the solid link between the anchor and the top of the adjuster lever forces the lever to rotate around the pivot point where it attaches to the brake shoe.
- This moves the bottom half of the lever downward, which causes the pawl to rotate the starwheel and make the adjustment.
- The separate pawl piece is free to pivot on the lever to prevent damage if the starwheel will not rotate.
- When the brakes are released, the return springs lift the lever. If the brakes have worn enough, the end of the lever engages the next tooth on the starwheel and additional adjustment will be made the next time the brakes are applied.

NON-SERVO STARWHEEL AUTOMATIC ADJUSTERS

OPERATION. The starwheel automatic adjusters used on non-servo brakes may be mounted on either the leading or trailing shoe. These types of adjusters work whenever the brakes are applied—in either the forward or reverse direction. A leading-shoe design is shown in ● **FIGURE 99–33.**

When the brakes are not applied, the adjuster pawl is held in position by the parking brake strut. When the brakes are applied and the primary shoe moves out toward the brake drum (away from the parking brake strut), the pawl spring pivots the pawl downward where it mounts on the brake shoe and rotates the starwheel to adjust the brake. When the brakes are released, the return springs retract the shoes and the pawl is levered back into its resting position by the parking brake strut. If the linings have worn far enough, the lever engages the next tooth on the starwheel and further adjustment will occur the next time the brakes are applied.

The trailing-shoe non-servo starwheel adjuster shown in ● **FIGURE 99–34** works somewhat like the leading-shoe design, but it makes the adjustment as the brakes are released rather than applied. The upper shoe return spring in this design returns the brake shoes and operates the automatic adjuster, as follows:

- When the brakes are not applied, spring tension holds the trailing shoe and the adjuster pawl tightly against the parking brake strut.

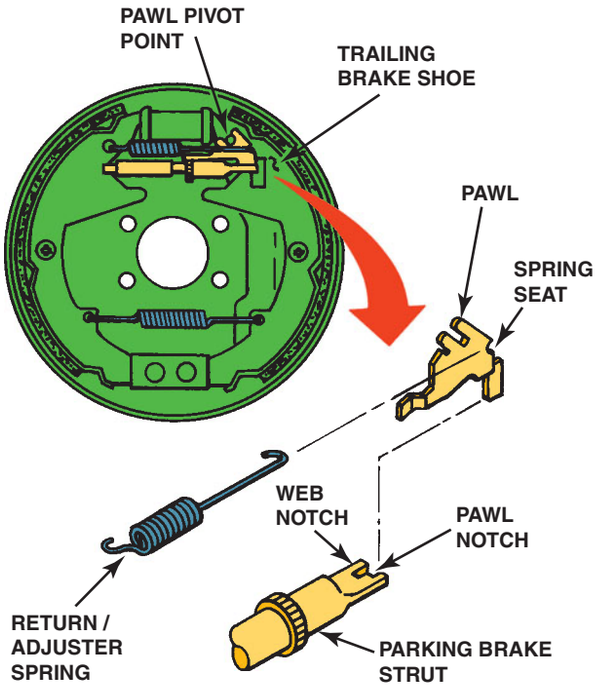

FIGURE 99–34 A non-servo brake with a lever-actuated star-wheel automatic adjuster on the trailing shoe. This type of adjuster makes the adjustment as the brakes are released.

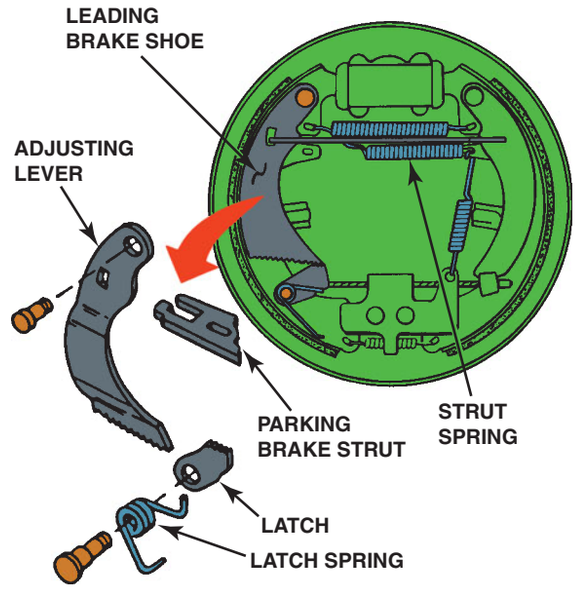

FIGURE 99–35 A lever-latch ratchet automatic adjuster.

- When the brakes are applied, the trailing shoe moves out toward the drum and away from the parking brake strut. This allows the adjuster pawl, which is restrained by the return spring, to pivot where it attaches to the brake shoe, causing the adjuster arm to move upward.
- If the brakes have worn far enough, the arm will engage the next tooth of the starwheel.
- When the brakes are released, the return spring pulls the brake shoes back together and the parking brake strut levers the adjuster pawl downward to rotate the starwheel and adjust the brakes.

RATCHET-TYPE AUTOMATIC ADJUSTERS

Most ratchet automatic adjusters use movement of the brake shoes to adjust the lining-to-drum clearance. The adjustment of a ratchet adjuster is carried out by two parts that have small interlocking teeth. As the adjustment is made, the two toothed elements ratchet across one another. Once adjustment is complete, the teeth lock together to hold the brake shoes in their new positions.

LEVER-LATCH RATCHET AUTOMATIC ADJUSTER. The lever-latch automatic adjuster installs on the leading shoe of a non-servo brake and operates whenever the brakes are applied. ● **SEE FIGURE 99–35.** This design consists of a large lever and a smaller latch with interlocking teeth. A spring on the latch piece keeps it in contact with the lever to maintain the adjustment. One end of the parking brake strut hooks into an opening in the lever and the other end is held against the trailing brake shoe by a strong spring. As the brakes are applied and the shoes move outward toward the drum, the parking brake strut pulls on the adjuster lever and forces it to pivot inward from where it attaches to the top of the leading shoe. If the brakes are sufficiently worn, the bottom of the lever will ratchet one or more teeth on the latch. When the brakes are released, the parking brake strut, which bottoms against the lever, will hold the shoes farther apart to reduce the lining-to-drum clearance.

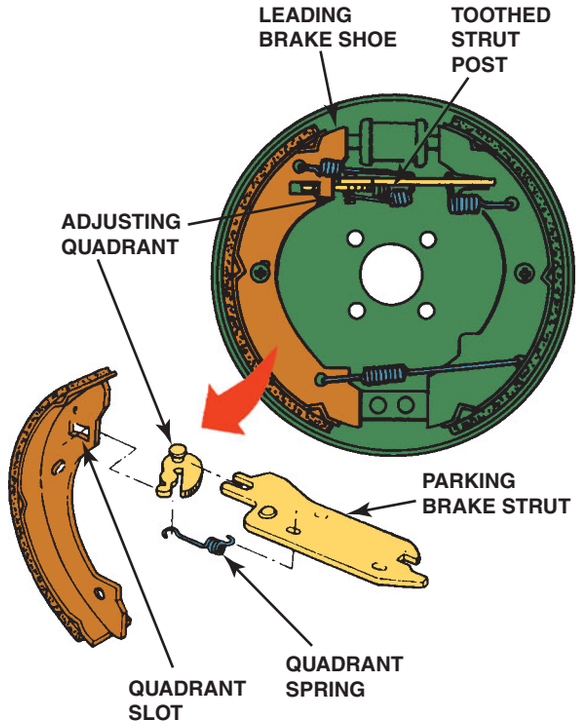

FIGURE 99–36 A strut-quadrant ratchet automatic adjuster.

STRUT-QUADRANT RATCHET AUTOMATIC ADJUSTER. The strut-quadrant automatic adjuster is used on some non-servo brakes. ● **SEE FIGURE 99–36.** The strut-quadrant adjuster consists of three basic parts:

1. The parking brake strut
2. Adjusting quadrant
3. A quadrant spring

The strut has a toothed post solidly mounted on its underside. The adjuster quadrant pivots on a pin that slips into a notch in the end of the strut, and the backside of the quadrant has a toothed, cam-shaped surface that interlocks with the toothed post on the strut. The quadrant also has an arm that extends through an opening in the web of the leading brake shoe. The outer side of this arm serves as the brake shoe stop when the brakes are released. The quadrant

TECH TIP

Cool the Brakes before Backing

Self-adjusters can overadjust the rear drum brakes if the brake drums are hot and have increased in diameter due to the heat. For example, if a pickup truck towing a boat had to brake while backing down a long, steep grade to the boat ramp, the rear brake drums could become larger in diameter due to the heat created during braking. The brakes could overadjust if the driver repeatedly depresses and releases the brake pedal while backing the trailer down the boat ramp. Then, after the boat has been removed from the trailer and the rear brakes have cooled, the drums will shrink and keep the rear brakes from releasing, preventing the truck from moving up the ramp.

NOTE: Some drum brakes are equipped with a bimetallic heat sensor that prevents the self-adjusters from working if the brakes are hot.

spring holds the quadrant in contact with the post to maintain the adjustment.

STEP 1 When the brakes are applied, the leading shoe moves out toward the brake drum.

STEP 2 If there is sufficient wear of the brake lining, the edge of the slot in the shoe web contacts the inner side of the adjuster quadrant arm and pulls it outward.

STEP 3 When this happens, the toothed section of the quadrant is lifted away from the post on the parking brake strut.

STEP 4 The quadrant spring then rotates the quadrant until its pivot pin is bottomed in the slot in the parking brake strut.

STEP 5 When the brakes are released, the quadrant returns inward with the leading shoe.

STEP 6 The toothed section of the quadrant then engages the teeth on the strut post, causing the quadrant arm to remain in its new extended position that holds the shoes farther apart and reduces the lining-to-drum clearance.

REVIEW QUESTIONS

1. Describe the difference between a dual-servo and a leading–trailing drum brake system.
2. List all the parts of a typical drum brake.
3. Explain how a self-adjusting brake mechanism works.
4. What do the last two letters of the lining or pad edge code identify?

CHAPTER QUIZ

1. Two technicians are discussing drum brake shoes. Technician A says that forward and rearward facing shoes are the same and can be installed in either position on any drum brake system. Technician B says that the darker color lining should always be placed toward the front of the vehicle. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. Two technicians are discussing brake lining edge codes. Technician A says that the code can identify the manufacturer. Technician B says that all friction material from the same manufacturer will have the same edge codes. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
3. Technician A says that starwheel adjusters use different threads (left- and right-handed) for the left and right sides of the vehicle. Technician B says that a pawl moves the teeth of the starwheel adjuster. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. Technician A says that drum brakes can fail to slow the vehicle if driven through deep water. Technician B says that when drum brakes get hot, the brake pedal will drop because the drum expands away from the shoes. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
5. Technician A says that the anchor pin (shoe anchor) is used to hold one end of the primary and secondary shoe return springs. Technician B says that shoe anchor prevents the brake shoes from rotating with the drum when the brakes are applied. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
6. Drum brake shoes _____.
   a. Can have riveted linings
   b. Can have bonded linings
   c. Can have one shoe that is longer than the other on the same wheel brake
   d. All of the above are possible
7. Which lining does most of the braking on a dual-servo brake?
   a. Front (forward facing)
   b. Rear (rearward facing)
   c. Both contribute equally
   d. Depends on the speed of the vehicle
8. Which lining does most of the braking on a leading-trailing brake?
   a. Leading (forward facing)
   b. Trailing (rearward facing)
   c. Both contribute equally
   d. Depends on the speed of the vehicle

9. Two technicians are discussing drum brake self-adjusters. Technician A says that some brakes self-adjust when the brakes are released when the vehicle is driven in reverse. Technician B says that some brakes self-adjust when the brakes are applied rather than when released. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

10. A typical drum brake backing plate has how many shoe support pads (also called ledges)?
   a. 3
   b. 4
   c. 6
   d. 8

chapter 100 DRUM BRAKE DIAGNOSIS AND SERVICE

OBJECTIVES: **After studying Chapter 100, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "B" (Drum Brake Diagnosis and Repair). • Discuss symptom diagnosis of drum brakes • Describe how to inspect drum brake components such as wheel cylinders, brake shoes and springs. • Explain why wheel cylinders should be replaced or serviced. • Discuss the procedure recommended for brake drum removal. • Discuss the inspection and lubrication points of the backing plate. • Explain the importance of the proper drum brake hardware. • Disassemble and reassemble a drum brake assembly.

KEY TERMS: Bearingized 1105 • Brake hardware kits 1107 • Speed nuts 1102 • Tinnerman nuts 1102

DRUM BRAKE FAULTS

Drum brakes are very reliable and usually work well for many years and miles. However, like anything mechanical, drum brakes wear and faults can occur. Faults that can occur include:

- Brake lining wear and braking force is reduced.
- Brake springs get weaker due to being exposed to hot brake temperatures and the outside elements such as water and salt in northern areas.
- Brake drum wear as a result of the friction material on the brake shoes rubbing on the friction surface.
- Parking brake mechanisms can wear, rust or corrode. That often allows the brake shoe to fail to retract leading to premature brake shoe and drum wear.
- Faults such as contaminated brake shoes that can cause the drum brakes to grab or lockup.

DRUM BRAKE DIAGNOSIS

Diagnosing brake concerns includes the following steps:

STEP 1 Verify the customer complaint (concern). For example, common drum brake concerns include:
- Low brake pedal
- Parking brake does not hold the vehicle on a hill
- Noise while braking
- Noise when the vehicle is moving, but the brakes are not applied

STEP 2 Perform a visual inspection of the brakes and related parts, such as the wheels, tires, and suspension system.

STEP 3 Determine the root cause. For example, this could include determining that the parking brake linkage is corroded causing the brake shoes to wear. Replacing just the brake shoes will not correct the root cause.

STEP 4 Restore the brake system to like-new operation, which is the purpose of any repair.

STEP 5 Test-drive the vehicle to verify that the service has corrected the customer's complaint.

Drum brake service usually involves the following steps:

STEP 1 Remove the brake drums.

STEP 2 Inspect the brake drums for damage and measure the inside diameter and compare to specifications.

STEP 3 Inspect brake linings and hardware for wear or damage.

STEP 4 Inspect the wheel cylinder and brake lines for leakage.

STEP 5 Check the backing plate for excessive rust or wear.

BRAKE DRUM REMOVAL

The drum has to be removed before inspection or repair of a drum brake can begin. There are two basic types of drums, and the removal procedure depends on which type is being serviced. With either type it is usually recommended that the drums be marked with an "L" for left or an "R" for right so that they can be replaced in the same location.

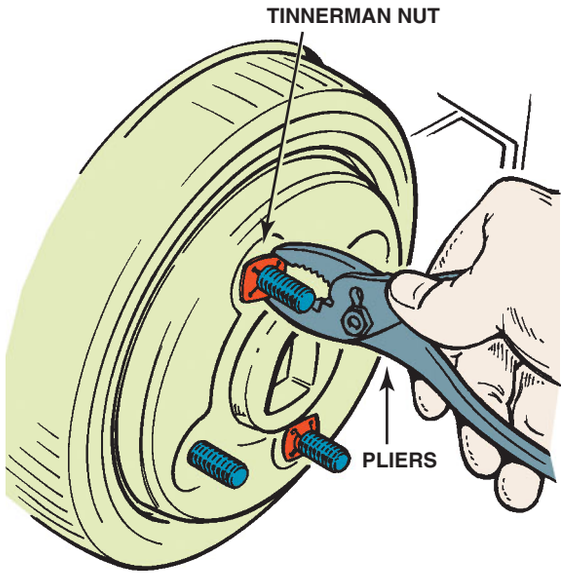

FIGURE 100–1 Tinnerman nuts are used at the assembly plant to prevent the brake drum from falling off until the wheels are installed.

FIGURE 100–2 Turning the bolts that are threaded into the brake drum forces the drum off of the hub.

HUB OR FIXED DRUMS

A fixed or hub-mounted drum is often used on the rear of front-wheel-drive vehicles. The drum has a hub for inner and outer bearings and is retained by a spindle nut. To remove the brake drum, remove the dust cap and cotter key that is used to retain the spindle nut. Remove the spindle nut and washer and then the brake drum can be carefully pulled off the spindle.

HUBLESS OR FLOATING DRUMS

Floating or hubless drums are usually used on the rear of a rear-wheel-drive vehicle. The drums are secured to the axle flange by the wheel and lug nuts. New vehicles have **tinnerman nuts** (clips), also called **speed nuts,** on the stud when the vehicle is being assembled. These thin sheet-metal nuts keep the brake drum from falling off during shipping and handling prior to installation of the rear wheels. ● **SEE FIGURE 100–1.**

The tinnerman nuts can be discarded because they are not needed after the vehicle leaves the assembly plant. After removing the wheels, the drum *should* move freely on the hub and slip off over the brake shoes. Some drum brakes have two threaded holes in the drum that allow bolts to be installed. ● **SEE FIGURE 100–2.**

By tightening the bolts, the drum is forced off of the hub. Two situations that can prevent the drum from being removed include the following:

1. **The Drum Is Rusted to the Hub.** The fit between the drum and the hub is very close because it is this center pilot hole in the drum that centers the drum on the axle. Rust and corrosion often causes the drum to seize to the hub. Use penetrating oil on the hub surface to help free the drum. Striking the area inside the wheel studs will usually break the drum loose from the hub. Sometimes a torch has to be used to expand the pilot hole.

   NOTE: Use of an air hammer with a flat-headed driver against the hub also works well to break the drum loose from the hub.

   CAUTION: Overheating or not allowing the drum to cool slowly can cause the brake drum to distort. Using a puller can also damage a drum.

2. **The Brake Shoes Are Worn into the Drum.** Even if the center hole is loose, many brake drums cannot be removed because the inner edge of the brake drum catches on the lining. Pulling outward on the drum often bends the backing plate or breaks some of the mounting hardware. To prevent damage, remove the adjuster plug from the backing plate or drum and back off the adjuster. ● **SEE FIGURE 100–3.**

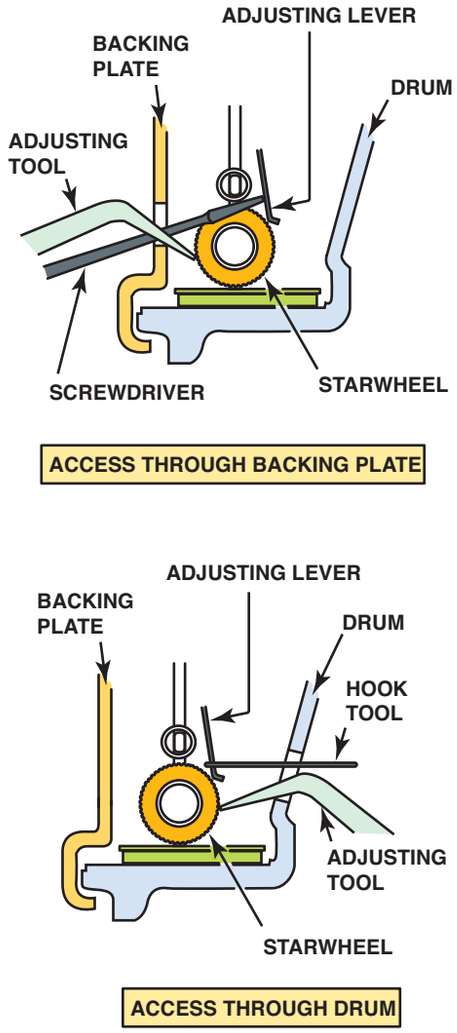

FIGURE 100–3 If the brake shoes have worn into the drum, the adjuster can be backed in after removing the access plug. After removing the plug, use a wire or a screwdriver to move the adjusting lever away from the starwheel, then turn the starwheel with a brake adjusting tool, often called a "brake spoon."

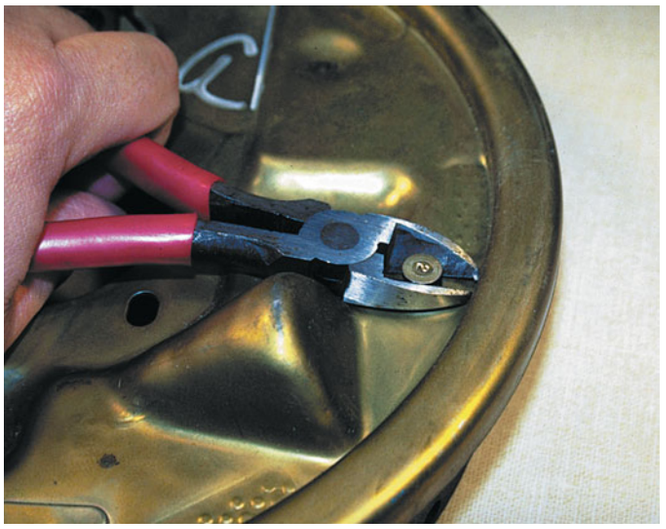

FIGURE 100–4 Using side-cut pliers to cut the heads off of the hold-down pins (nails) from the backing plate to release the drum from the shoes.

TECH TIP

Cutting the Nails Trick

Many times a brake drum cannot be removed because the linings have worn a groove into the drum. Attempting to adjust the brakes inward is often a frustrating and time-consuming operation. The easy solution is to use a pair of diagonal side-cut pliers and cut the heads off the hold-down pins (nails) at the backing plate. This releases the brake shoes from the backing plate and allows enough movement of the shoes to permit removal of the brake drum without bending the backing plate.

The hold-down pins (nails) must obviously be replaced, but they are included in most drum brake hardware kits. Since most brake experts recommend replacing all drum brake hardware anyway, this solution does not cost any more than normal, may save the backing plate from damage, and saves the service technician lots of time. ● **SEE FIGURE 100–4.**

NOTE: Be sure to reinstall the adjuster opening plugs. These plugs help keep water and debris out of the brakes.

After removing the brake drums, they should be cleaned, inspected, measured, and possibly machined before being returned to service.

DRUM BRAKE DISASSEMBLY

After removal of the brake drum, the brake shoes and other brake hardware should be wetted down with a solvent or enclosed in an approved evacuation system to prevent possible asbestos release into the air. Precautions should be taken to prevent any asbestos that may be present in the brake system from becoming airborne. Removal of the brake drum should occur inside a sealed vacuum enclosure equipped with a HEPA filter or washed with water or solvent. ● **SEE FIGURE 100–5.**

Usually, the first step in the disassembly of a drum brake system is removal of the return (retracting) springs. ● **SEE FIGURE 100–6.**

FIGURE 100–5 A liquid soaking solvent, such as brake cleaner, should be used to wet the linings. The purpose of wetting the lining material to prevent the possibility of asbestos from the lining becoming airborne. Asbestos is only hazardous when asbestos dust is airborne and is breathed in during brake system service.

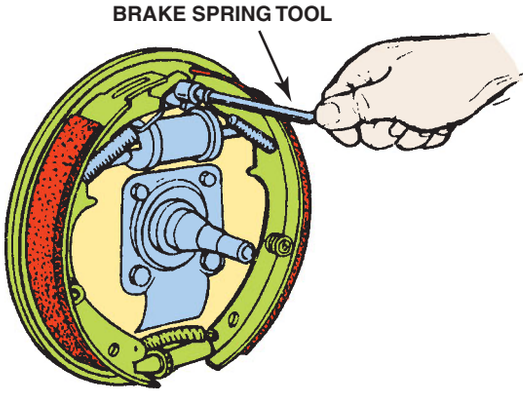

FIGURE 100–6 Using a brake spring tool to release a return (retracting) spring from the anchor pin.

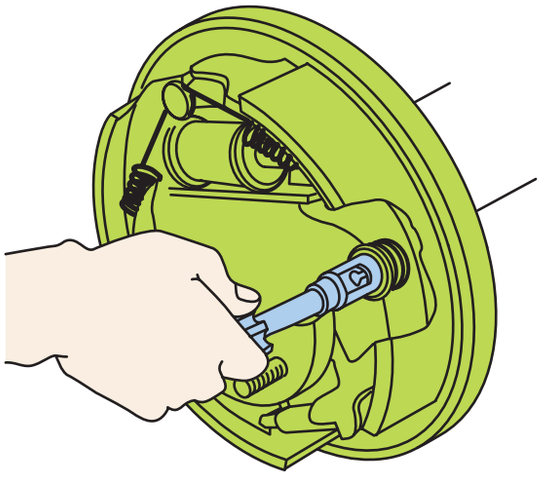

FIGURE 100–7 A special tool, called a hold-down spring tool, being used to depress and rotate the retainer.

After the return springs have been removed, the hold-down springs and other brake hardware can be removed. ● **SEE FIGURE 100–7.**

NOTE: There are generally no "exact" disassembly or reassembly procedures specified by the manufacturer. The order in which the parts are disassembled or reinstalled is based on experience and the personal preference of the technician.

FIGURE 100–8 A typical rusty backing plate shoe pad. This can cause the brakes to squeak when the shoes move outward during a brake application and again when the brake pedal is released.

INSPECTING THE BACKING PLATE

Once all drum brake components have been removed, inspect and service the backing plate. The backing plate supports the parts of the drum brake and helps to keep water from getting onto the brake shoes. The backing plate bolts to the rear axle or spindle and is made from stamped steel. Backing plates are plated (usually with cadmium) or painted to prevent rusting. To inspect the backing plate, follow these steps:

STEP 1 When brakes are serviced, the six raised contact surfaces, called pads, ledges, or shoe contact areas, of the backing plate should be inspected because they rub against the sides of the shoes. If the pads are worn more than 1/16 in. (1.5 mm), the backing plate should be replaced. ● **SEE FIGURE 100–8.**

STEP 2 The backing plate must be inspected for looseness or bending.

STEP 3 Backing plates should also be inspected to ensure that they are parallel with the axle flange.

STEP 4 The raised pads should be cleaned and lubricated. Lithium high-temperature brake grease, synthetic brake grease, silicone grease, or antiseize should be used to lubricate drum brake parts. ● **SEE FIGURE 100–9.**

DRUM BRAKE LINING INSPECTION

Both primary (front facing) and secondary (rear facing) lining material must be thicker than 0.060 in. (1.5 mm). To inspect the drum brake lining, follow these steps:

STEP 1 Some vehicles are equipped with holes in the backing plate that allow for a visual inspection of the thickness of the lining. Most vehicle and brake lining manufacturers recommend replacing worn brake lining when the thickness of the riveted lining reaches 0.060 in. or less. An American nickel is about 0.060 in. thick, so simply remember that you must always have at least "a nickel's worth of lining." ● **SEE FIGURE 100–10.**

FIGURE 100–9 Applying lithium grease to the raised pads on the backing plate.

FIGURE 100–10 A rule of thumb is that the lining should be at least the thickness of a nickel. This applies to both drum brake shoes and disc brake pads.

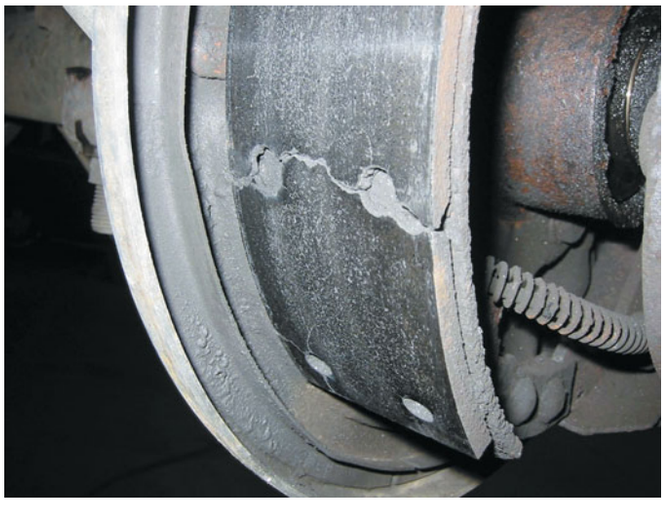

FIGURE 100–11 Cracked brake lining must be replaced.

STEP 2 Most experts agree that the best possible inspection involves removing the brake drum and making a thorough visual inspection of the entire brake instead of just looking at the thickness of the remaining lining. If a riveted brake lining is cracked between rivets, the lining should be replaced. ● **SEE FIGURE 100–11.**

FIGURE 100–12 The top spring is a good-looking spring because all coils of the spring are touching each other. The bottom spring is stretched and should be discarded. The arrow points to the back side of the spring, which goes into a hole in the brake shoe. The open loop of the spring is not strong enough to keep from straightening out during use. Using the back side of the hook provides a strong, long-lasting hold in the brake shoe.

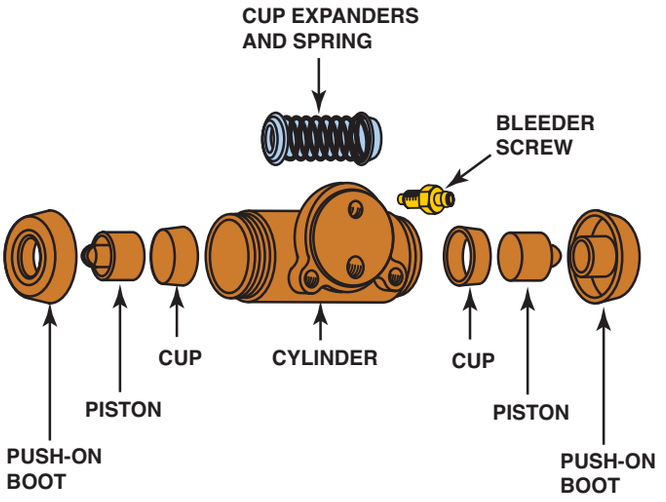

FIGURE 100–13 Exploded view of a typical wheel cylinder. Note how the flat part of the cups touches the flat part of the piston. The cup expander and spring go between the cups.

TECH TIP

The Drop Test

Brake return (retracting) springs can be tested by dropping them to the floor. A good spring should "thud" when the spring hits the ground. This noise indicates that the spring has not stretched and that all coils of the springs are touching each other. If the spring "rings" when dropped, the spring should be replaced because the coils are not touching each other. ● **SEE FIGURE 100–12.**

Although this drop test is often used, many experts recommend replacing all brake springs every time the brake linings are replaced. Heat generated by the brake system often weakens springs enough to affect their ability to retract brake shoes, especially when hot, yet not "ring" when dropped.

BRAKE SPRING INSPECTION

RETURN SPRINGS Each lining has a return spring (retracting spring) that returns the brake shoes back from the drums whenever the brakes are released. The springs are called primary and secondary return springs. The primary return spring attaches to the primary brake shoe and the secondary return spring attaches to the secondary brake shoe. These springs should be tested prior to a brake overhaul, especially when uneven lining wear is discovered.

Some drum brakes use a spring that connects the primary and secondary shoes and is commonly called a shoe-to-shoe spring. Return springs can get weak due to heat and time and can cause the linings to stay in contact with the drum when the brakes are released.

HOLD-DOWN SPRINGS Hold-down springs (one on each shoe) are springs used with a retainer and a hold-down spring pin (or nail) to keep the linings on the backing plate. Other types of hold-down springs include U-shape, flat spring steel type, and the combination return-and-hold spring. These springs still allow the freedom of movement necessary for proper braking operation.

CONNECTING SPRING (ADJUSTING SCREW SPRING) The connecting spring attaches to the lower portion and connects the two shoes together. Check or replace at every brake lining change for best results.

WHEEL CYLINDER INSPECTION

Drum brake wheel cylinders are cast iron that are bored and finished to provide a smooth finish for the wheel cylinder seals and pistons. This special finish is called **bearingized.** The final step in manufacture of the wheel cylinder is to force a hardened steel ball through the bore to bend over the "grain" of the metal and to smooth the inner surface. This process provides a smooth porous-free surface for the sealing caps to travel over. It is this bearingized surface finish on the inside of the wheel cylinder that is often destroyed when a wheel cylinder is honed.

CAUTION: It is because of this bearingized surface finish that most vehicle manufacturers do not recommend that wheel cylinders be honed. Be sure to follow the vehicle manufacturer's recommended procedures. Some manufacturers state that the wheel cylinders can be overhauled using new (replacement) sealing cups and dust shields after cleaning the cylinder bore only.

Outside each wheel cylinder piston are dust boots installed to keep dirt out of the cylinder bore. Between both piston sealing cups there is a spring with piston seal expanders to keep the seals from collapsing toward each other and to keep pressure exerted on the lips of both sealing cups to ensure proper sealing. ● **SEE FIGURE 100–13.**

On the back of each wheel cylinder there is a threaded hole for the brake line and a bleeder valve that can be loosened to remove (bleed) air from the hydraulic system. The wheel cylinder is bolted or clipped to the backing plate. ● **SEE FIGURES 100–14 AND 100–15.**

WHEEL CYLINDER SERVICE Most repair procedures involve replacement of the wheel cylinder assembly. However, overhauling the wheel cylinder can be done if recommended by the vehicle

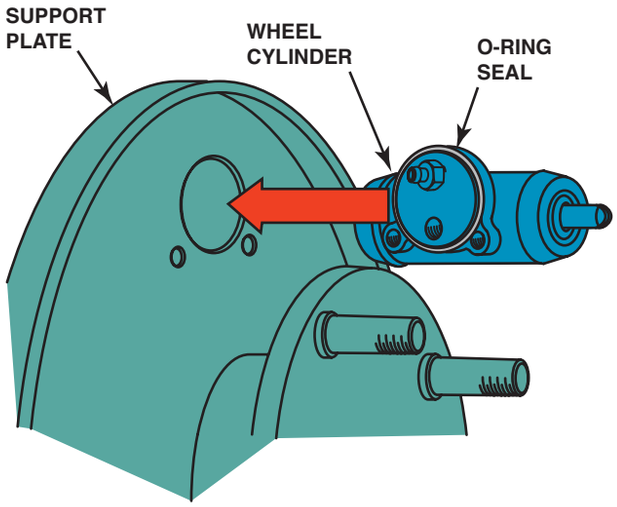

FIGURE 100–14 Many wheel cylinders are bolted to the support plate (backing plate). The O-ring seal helps keep water and dirt out of the drum brake.

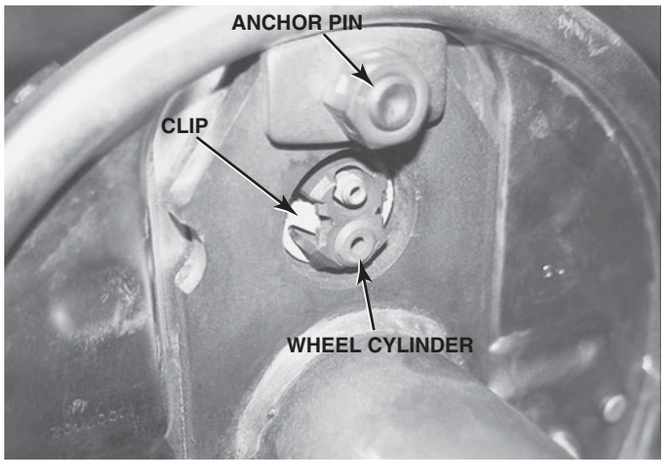
TECH TIP

Wet Is OK—Dripping Is Not OK

When inspecting a wheel cylinder, use a blunt nose tool and pry up the dust boot. If the inside of the seal is wet, this means that some seepage has occurred, which is normal. If, however, brake fluid drips from the dust seal, this indicates that the wheel cylinder sealing cups have failed and the wheel cylinder should be replaced. Also check to see if the internal pistons can move easily by pushing on the pushrods. Replace the wheel cylinder if a piston does not move.

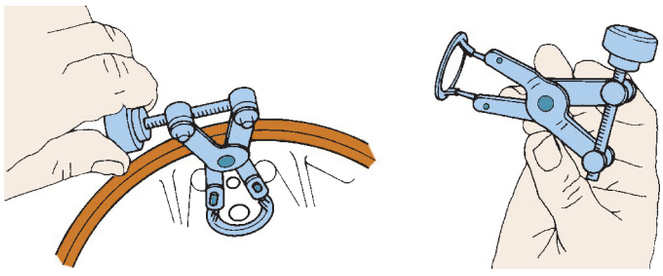
manufacturer and is often the only option on antique or restored muscle cars if the parts are available. The following steps and procedures should be followed:

STEP 1 Loosen the bleeder valve. If unable to loosen the bleeder valve without having it break off, a new replacement wheel cylinder is required. To help prevent broken bleeder valves, attempt to tighten the bleeder valve while tapping on the valve to loosen the rust before loosening the valve.



STEP 2 To remove the wheel cylinder, the brake line must first be removed from the wheel cylinder. Unbolt or remove the wheel cylinder retainer clip. Be sure to check that the brake line nut is turning on the brake line to avoid breaking the brake line.

STEP 3 If the bleeder valve can be removed, remove all internal parts of the wheel cylinder.



NOTE: With some vehicles equipped with piston stops, the wheel cylinder must be unbolted from the backing plate to enable removal of the seals and piston.

STEP 4 Clean and/or hone a wheel cylinder as specified by the manufacturer to remove any rust and corrosion. ● **SEE FIGURE 100–16.**

STEP 5 Install the pistons (usually not included in a wheel cylinder overhaul kit), seals, spring, and dust boots. Install on the vehicle and bleed the system.

(a)

(b)

FIGURE 100–15 (a) Some wheel cylinders are simply clipped to the backing plate. (b) This special tool makes it a lot easier to remove the wheel cylinder clip. A socket (1 1/8 in., 12 point) can be used to push the clip back onto the wheel cylinder.

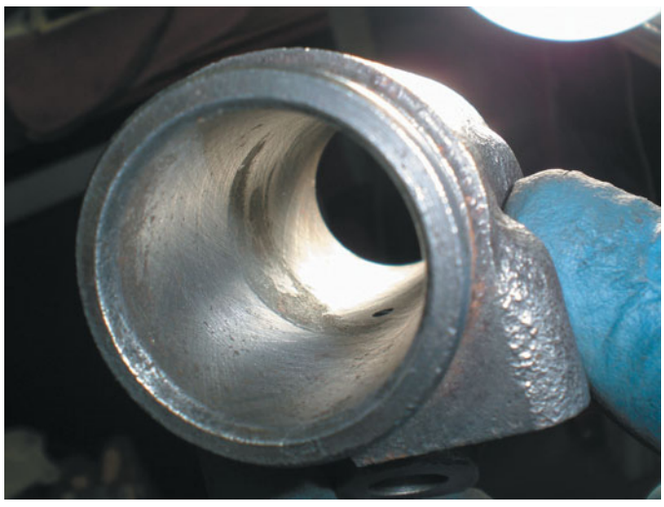


FIGURE 100–16 The rust inside this wheel cylinder will not affect the operation as it is located inside the working area of the sealing cups.

NOTE: Even though the wheel cylinder is not leaking, some brake experts recommend replacing or rebuilding the wheel cylinder every time new replacement linings are installed. Any sludge buildup in the wheel cylinder can cause the wheel cylinder to start to leak shortly after a brake job. When the new, thicker replacement linings are installed, the wheel cylinder piston may be pushed inward enough to cause the cup seals to ride on a pitted or corroded section of the wheel cylinder. As the cup seal moves over this rough area, the seal can lose its ability to maintain brake fluid pressure and an external brake fluid leak can occur. ● **SEE FIGURE 100–17.**

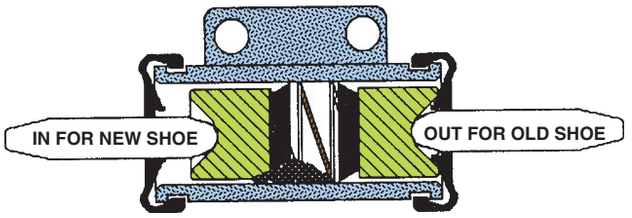

FIGURE 100–17 When new, thicker brake linings are installed, the pistons and cups are forced back into the wheel cylinder and pushed through the sludge that is present in every cylinder.

TECH TIP

Time—Not Mileage—Is Important

Many brake experts recommend rebuilding or replacing wheel cylinders at every other brake job. Some experts recommend that the wheel cylinders be overhauled or replaced every time the brake linings are replaced. If the wheel cylinders are found to be leaking, they must be replaced or overhauled. The most important factor is time, not mileage, when determining when to repair or replace hydraulic components.

The longer the time, the more moisture is absorbed by the brake fluid. The greater the amount of moisture absorbed by the brake fluid, the greater the corrosion to metal hydraulic components. For example, the brakes will probably wear out much sooner on a vehicle that is used all day every day than on a vehicle driven only a short distance every week. In this example, the high-mileage vehicle may need replacement brake linings every year, whereas the short-distance vehicle will require several years before replacement brakes are needed. The service technician should try to determine the amount of time the brake fluid has been in the vehicle. The longer the brake fluid has been in the system, the greater the chances that the wheel cylinders need to be replaced or overhauled.

DRUM BRAKE HARDWARE KIT

If any spring is found to be defective, it is possible to purchase most parts individually or in pairs. However, for best results, many brake suppliers sell drum **brake hardware kits.** These kits usually include the items listed below for two drum brakes (axle set):

1. Primary and secondary return springs
2. Connecting spring
3. Hold-down springs
4. Hold-down spring retainers
5. Hold-down spring pins (nails)

Self-adjuster kits are available if needed. Other brake parts such as adjusters are available separately or as part of a self-adjuster kit. **SEE FIGURE 100–18.**

FIGURE 100–18 This starwheel adjuster is damaged and must be replaced. A lack of proper lubrication can cause the starwheel to become frozen in one place and not adjust properly.

INSPECTING THE DRUM BRAKE SHOES

Carefully inspect the replacement brake shoes. Check all of the following:

1. Check that the replacements are exactly the same size (width and diameter) as the original. Hold the replacement shoes up against the old shoes to make the comparison.
2. Check for sound rivets (if rivet type). The friction material should also be snug against the metal brake shoe backing.

After checking that the replacement brake lining is correct, place the old shoes into the new linings' box. This helps ensure proper credit for the old shoes (called the core) as well as protection against asbestos contamination exposure.

BRAKE PARTS CLEANING

Whenever cleaning brake parts or components always use the following guidelines:

- Denatured alcohol or "brake clean" should only be used to clean brake parts that are disassembled. When individual parts are cleaned, they should be allowed to dry before being assembled.
- Never clean or flush assembled brake components with denatured alcohol or brake clean. Often, the alcohol cannot evaporate entirely from an assembled component. The trapped alcohol will evaporate inside the brake system, causing contamination. The trapped alcohol vapors also act like trapped air in the braking system and can cause a spongy brake pedal.

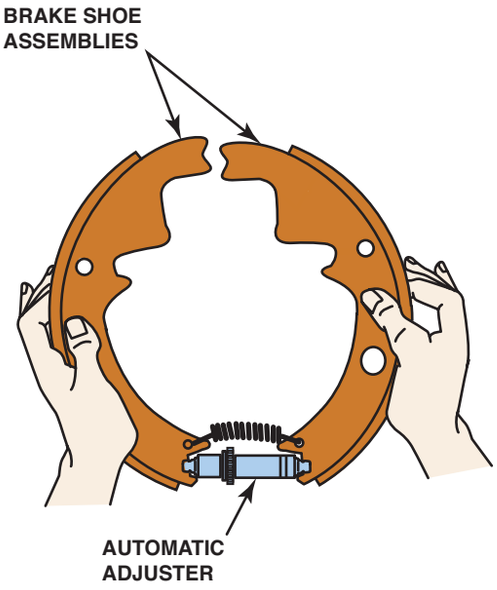

FIGURE 100–19 Pre-assembly of the starwheel adjuster with its connecting spring often helps when reassembling a drum brake.

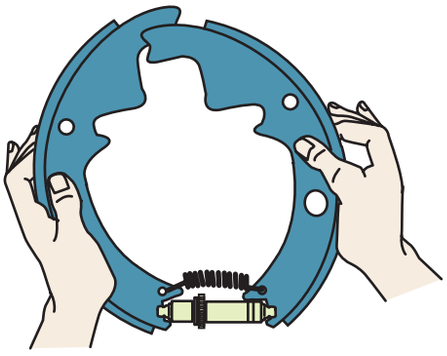

FIGURE 100–20 Sometimes it is necessary to cross the shoes when pre-assembling the starwheel adjuster and connecting spring.

REASSEMBLING THE DRUM BRAKE

Reassembling the drum brake includes the following steps:

STEP 1 Carefully clean the backing plate.

STEP 2 Check the anchor pin for looseness.

STEP 3 Lubricate the shoe contact surfaces (shoe pads) with anti-seize, brake grease, or synthetic grease.

STEP 4 Reassemble the primary and secondary shoes and brake strut, along with all springs.

STEP 5 Finish assembling the drum brake, being careful to note the correct location of all springs and parts.

NOTE: Many technicians preassemble the primary and secondary shoes with the connecting (lower retracting) spring as a unit before installing them onto the backing plate. ● **SEE FIGURES 100–19 AND 100–20.**

Most self-adjusters operate off the rear (secondary) shoe and should therefore be assembled toward the rear of the vehicle. Be sure that the star wheel adjuster is used on the correct side of the vehicle as the threads are different. The self adjuster for one side of the vehicle has right hand threads and the adjuster for the other side has left hand threads. This means that the self adjusters should be marked, if they are not already marked, and kept separated until they are placed on the correct side and then the connecting spring can be installed. ● **SEE FIGURE 100–21.**

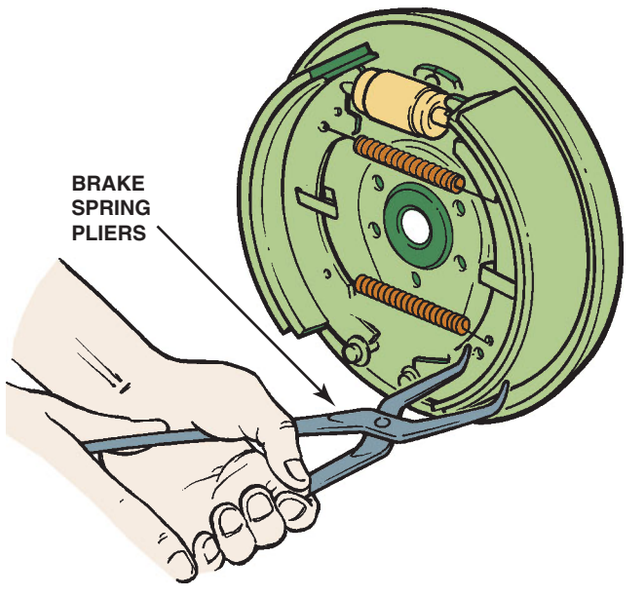

FIGURE 100–21 Brake spring pliers being used to install the connecting spring.

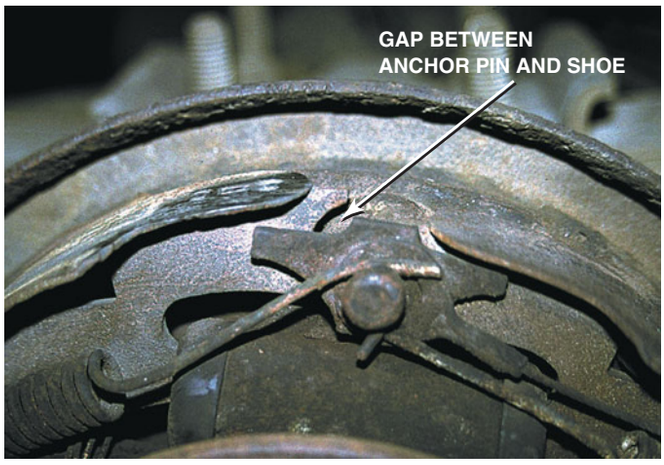

FIGURE 100–22 Notice that the brake shoe is not contacting the anchor pin. This often occurs when the parking brake cable is stuck or not adjusted properly.

ADJUSTING DRUM BRAKES

Most drum brakes are adjusted by rotating a starwheel or rotary adjuster. As the adjuster is moved, the brake shoes move toward the drum. If the brakes have been assembled correctly and with the parking brake fully released, both brake shoes should make contact with the anchor pin at the top. ● **SEE FIGURE 100–22** for an example where one shoe does not make contact with the anchor pin.

If the clearance between the brake shoes and the brake drum is excessive, a low brake pedal results. The wheel cylinder travel may not be adequate to cause the lining to contact the drums. Often, the driver has to pump the brakes to force enough brake fluid into the wheel cylinder to move it enough for braking action to occur.

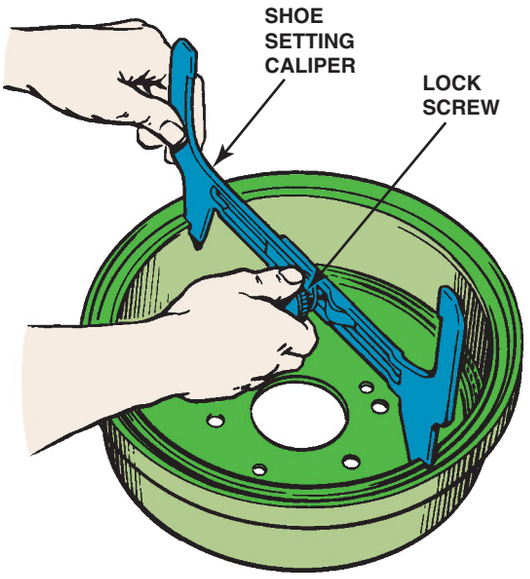

FIGURE 100–23 The first step in using a brake shoe clearance gauge is to adjust it to the drum inside diameter and tighten the lock screw.

Many technicians use a brake shoe setting gauge to adjust the brake shoes before installing the drum. ● **SEE FIGURES 100–23 AND 100–24.**

CAUTION: Before installing the brake drum, be sure to clean any grease off the brake lining. Some experts warn not to use sandpaper on the lining to remove grease. The sandpaper may release asbestos fiber into the air. Grease on the linings can cause the brakes to grab.

LUBRICATION CHECKLIST

For proper operation, the following points should be lubricated with approved brake lubricant:

1. The starwheel adjuster threads and under end caps
2. The backing plate contact areas (pads or ledges)
3. Anchor pins

CAUTION: Do not use wheel bearing or chassis grease on a braking system. Use only approved brake lubricant such as molybdenum disulfide (moly) grease, synthetic grease, lithium-based brake grease, or antiseize compound.

Also, be sure to check and lubricate the parking brake cable, if necessary.

DRUM BRAKE SYMPTOM-BASED GUIDE

LOW PEDAL OR THE PEDAL GOES TO THE FLOOR Possible causes for low pedal include the following:

1. Excessive clearance between the linings and drum
2. Automatic adjusters not working

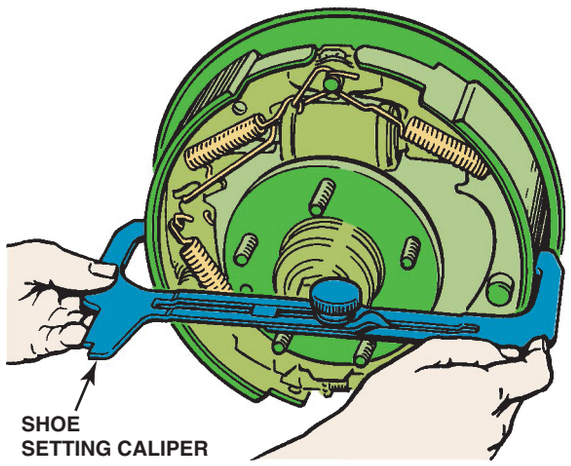

FIGURE 100–24 Place the gauge over the shoes and adjust the brakes until they contact the inside of the gauge.

FIGURE 100–25 To prevent getting grease on the lining, the wise service technician covers the friction material with masking tape. The tape is removed after the brake shoes have been installed.

TECH TIP

The Masking Tape Trick

Some technicians cover the friction material with masking tape to prevent contaminating the linings with dirt or grease during installation. After everything has been installed and double-checked, the masking tape is removed and the brake drums are installed. ● **SEE FIGURE 100–25.**

3. Leaking wheel cylinder
4. Air in the system

SPRINGY, SPONGY PEDAL Possible causes for springy, spongy pedal include the following:

1. Drums worn below specifications
2. Air in the system

EXCESSIVE PEDAL EFFORT REQUIRED TO STOP THE VEHICLE Possible causes for excessive pedal pressure include the following:

1. Grease or fluid-soaked linings
2. Frozen wheel cylinder pistons
3. Linings installed on wrong shoes

LIGHT PEDAL EFFORT—BRAKES TOO SENSITIVE Possible causes for light pedal pressure include the following:

1. Brake adjustment not correct
2. Loose backing plate
3. Lining loose on the shoe
4. Excessive dust and dirt in the drums
5. Scored, bell-mouthed, or barrel-shaped drum
6. Improper lining contact pattern

BRAKE PEDAL TRAVEL DECREASING Possible causes for brake pedal travel decreasing include the following:

1. Weak shoe retracting springs
2. Wheel cylinder pistons sticking

PULSATING BRAKE PEDAL (PARKING BRAKE APPLY PULSATES ALSO) Possible cause for pulsating brake pedal include the following:

1. Drums out-of-round

BRAKES FADE (TEMPORARY LOSS OF BRAKE EFFECTIVENESS WHEN HOT) Possible causes for brake fade include the following:

1. Poor lining contact
2. Drums worn below the discard dimension
3. Charred or glazed linings

SHOE CLICK NOISE Possible causes for shoe click noise include the following:

1. Shoes lift off the backing plate and snap back
2. Hold-down springs weak
3. Shoe bent
4. Grooves in the backing plate pads

THUMPING NOISE WHEN BRAKES ARE APPLIED Possible causes for thumping noise include the following:

1. Cracked drum; hard spots in the drum
2. Retractor springs unequal—weak

GRINDING NOISE Possible causes for grinding noise include the following:

1. Excessively worn braking lining
2. Bent shoe web
3. Brake improperly assembled

ONE WHEEL DRAGS Possible causes for one wheel dragging include the following:

1. Weak or broken shoe retracting springs
2. Brake-shoe-to-drum clearance too tight—brake shoes not adjusted properly
3. Brake assembled improperly
4. Wheel cylinder piston cups swollen and distorted
5. Pistons sticking in the wheel cylinder
6. Drum out-of-round
7. Loose anchor pin/plate
8. Parking brake cable not free
9. Parking brake not adjusted properly

VEHICLE PULLS TO ONE SIDE Possible causes for vehicle pulling to one side include the following:

1. Brake adjustment not correct
2. Loose backing plate
3. Linings not of specified kind; primary and secondary shoes reversed or not replaced in pairs
4. Water, mud, or other material in brakes
5. Wheel cylinder sticking
6. Weak or broken shoe retracting springs
7. Drums out-of-round
8. Wheel cylinder size different on opposite sides
9. Scored drum

WET WEATHER: BRAKES GRAB OR WILL NOT HOLD Possible causes for brakes grabbing or not holding include the following:

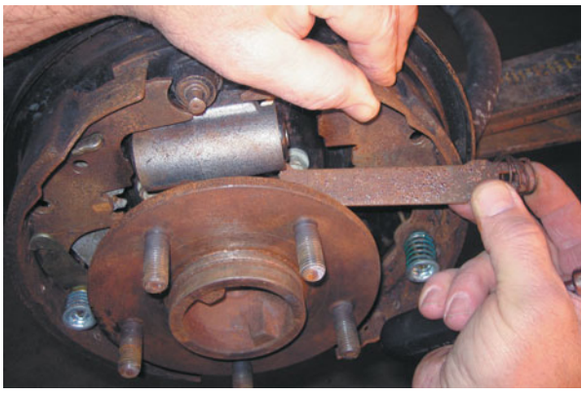
1. Bent backing plate flange
2. Incorrect or abused shoe and linings

BRAKES SQUEAK Possible causes for brakes squeaking include the following:

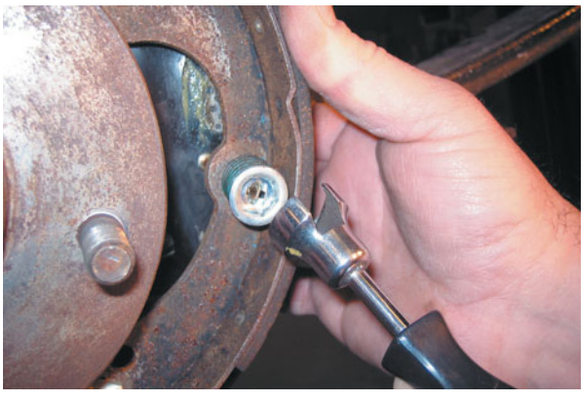
1. Backing plate is bent or shoes twisted
2. Shoes scraping on backing plate pads
3. Weak or broken hold-down springs
4. Loose backing plate, anchor, or wheel cylinder
5. Glazed linings
6. Dry shoe pads and hold-down pin surfaces

BRAKES CHATTER Possible causes for brake chattering include the following:

1. Incorrect lining-to-drum clearance
2. Loose backing plate
3. Weak or broken retractor spring
4. Drums out-of-round
5. Tapered or barrel-shaped drums
6. Improper lining contact pattern



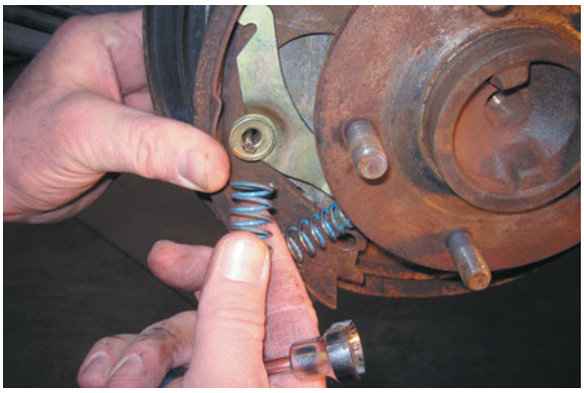
1 Tools needed to service a drum brake assembly include brake tools, silicone grease, wheel lug nut sockets, and torque limiting adapters or a torque wrench.



2 After safely hoisting the vehicle to chest height, remove the brake drum.

3 Remove the primary (forward facing) shoe return spring, using a brake tool. Then, remove the secondary return spring.

4 Remove the parking brake strut along with the antirattle spring.



5 Use a brake tool to depress the hold-down spring, and then rotate it until the slot in the retainer lines up with the flattened part of the hold-down pin.

6 Removing the primary brake shoe plus the starwheel adjuster and connecting spring.

CONTINUED ▶

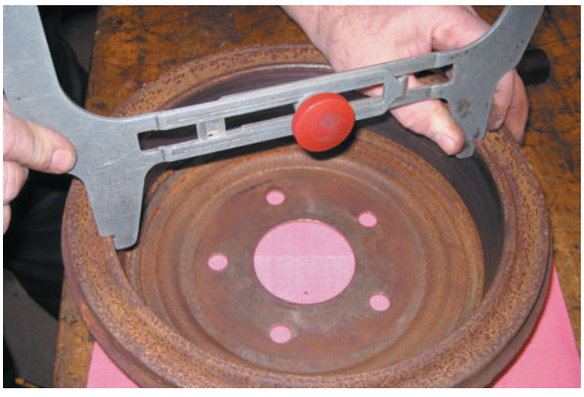
7 When the secondary lining hold-down spring is removed, the adjusting lever and pawl return spring can be removed.

8 The parking brake lever can now be disconnected from the secondary brake shoe.

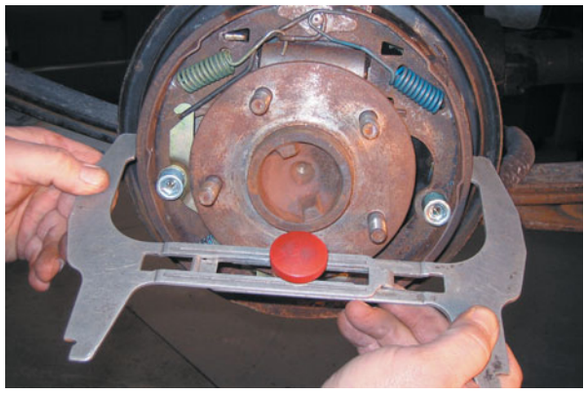
9 Check the wheel cylinder for leakage. Check the pistons to see that they can move too during the inspection. This wheel cylinder is relatively new and not leaking.

10 Clean all six brake shoe ledges. Lubricate the ledges with silicone brake grease.

11 Many technicians prefer to assemble the connecting spring and starwheel adjuster to both shoes to help in the reinstallation.



12 Attaching the parking brake lines to the secondary shoe. The assembled parts at the bottom help keep everything together.



13 Installing the secondary shoe hold-down spring.

14 Installing the secondary shoe return spring. Note that the primary return spring has already been installed.

15 After installing the brake shoes and springs, use a drum/shoe clearance gauge and set it to the inside diameter of the drum.

16 Adjust the starwheel adjuster until the linings contact the drum brake shoe clearance gauge.

17 After installing the drum, it may be necessary to make the final adjustment using a brake adjusting tool (spoon).

18 After completing the brake service, be sure to cover the brake adjustment opening to prevent water from getting into the brake.

REVIEW QUESTIONS

1. Explain how to remove a brake drum.
2. List all items that should be lubricated on a drum brake.
3. List the steps necessary to follow when replacing drum brake linings.
4. Explain why many vehicle manufacturers do not recommend the wheel cylinder be honed.

CHAPTER QUIZ

1. Technician A says that the tinnerman nuts are used to hold the brake drum on and should be reinstalled when the drum is replaced. Technician B says that a drum should be removed inside a sealed vacuum enclosure or washed with water or solvent to prevent possible asbestos dust from being released into the air. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. The backing plate should be replaced if the shoe contact areas (pads or ledges) are worn more than _____.
   a. 1/2 in. (13 mm) **c.** 1/8 in. (4 mm)
   b. 1/4 in. (7 mm) **d.** 1/16 in. (1.5 mm)
3. Technician A says that silicone brake grease can be used to lubricate the shoe contact ledges. Technician B says that synthetic brake grease, lithium brake grease, or antiseize compound can be used as a brake lubricant. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. Most brake experts and vehicle manufacturers recommend replacing brake lining when the lining thickness is _____.
   a. 0.030 in. (0.8 mm) **c.** 0.050 in. (1.3 mm)
   b. 0.040 in. (1.0 mm) **d.** 0.060 in. (1.5 mm)
5. Technician A says that starwheel adjusters use different threads (left- and right-handed) for the left and right sides of the vehicle. Technician B says that the threads and end caps of the adjusters should be lubricated with brake grease before being installed. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
6. Technician A says that many vehicle manufacturers recommend that wheel cylinders not be honed because of the special surface finish inside the bore. Technician B says that some experts recommend that the wheel cylinders be replaced every time the brake linings are replaced. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
7. Most manufacturers recommend that brake parts should be cleaned with _____.
   a. Clean water only **c.** Stoddard solvent
   b. Denatured alcohol **d.** Detergent and water
8. Old brake shoes are often returned to the manufacturer when new friction material is installed. These old shoes are usually called the _____.
   a. Core **c.** Rim
   b. Web **d.** Nib
9. After assembling a drum brake, it is discovered that the brake drum will not fit over the new brake shoes. Technician A says that the parking brake cable may not have been fully released. Technician B says to check to see if both shoes are contacting the anchor pin. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. Technician A says to use masking tape temporarily over the lining material to help prevent getting grease on the lining. Technician B says that grease on the brake lining can cause the brakes to grab. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 101

DISC BRAKES

OBJECTIVES: **After studying Chapter 101, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "C" (Disc Brake Diagnosis and Repair). • Describe how disc brakes function. • Name the parts of a typical disc brake system. • Describe the construction of disc brake pads. • Describe the difference between fixed caliper and floating or sliding caliper. • Explain the difference between a standard caliper and a low-drag caliper.

KEY TERMS: Anchor plate 1122 • Antirattle clips 1117 • Aramid fiber 1121 • Bonded linings 1120 • Brake block 1121 • Brake pad 1118 • CFRC 1121 • Fixed brake caliper 1122 • Floating caliper 1124 • Gas fade 1116 • Integrally molded 1120 • Kevlar 1121 • Lining fade 1115 • Low-drag caliper 1125 • Mechanical fade 1115 • Mold-bonded lining 1120 • NAO 1121 • NAS 1121 • Natural frequency 1117 • Nonasbestos 1121 • Pad wear indicators 1119 • Pin-slider caliper 1124 • Riveted linings 1120 • Semimets 1121 • Sintered metal 1121 • Sintering 1121 • Sliding caliper 1126 • Swept area 1115 • Water fade 1116 • Ways 1126

DISC BRAKES

PARTS AND OPERATION

Disc brakes use a piston(s) to squeeze friction material (pads) on both sides of a rotating disc (rotor). Disc may be spelled *disk* by some manufacturers, but *disc* is the SAE (Society of Automotive Engineers) term and the most commonly used spelling in the industry. The rotor is attached to and stops the wheel.

Disc brakes are used on the front wheels of late-model vehicles, and on the rear wheels of an increasing number of automobiles. Disc brakes were adopted primarily because they can supply greater stopping power than drum brakes with less likelihood of fade. This makes disc brakes especially well suited for use as front brakes, which must provide 60% to 80% of the vehicle's total stopping power.

DISC BRAKE ADVANTAGES

Although increased federal brake performance standards hastened the switch to disc brakes, the front drum brakes would eventually have been eliminated anyway because disc brakes are superior in almost every respect. The disc brake friction assembly has several significant strong points, and only a few relatively minor weak points. ● **SEE FIGURE 101–1.**

The main advantages of the disc brake include the following.

FADE RESISTANCE. The main design features that help disc brakes avoid heat-induced fade is their cooling ability because all of the major parts of a disc brake are exposed to the air flowing over the friction assembly. Many brake rotors also have cooling passages cast into them to further reduce operating temperatures and have greater fade resistance than drum brakes because they have greater swept area. **Swept area** is the amount of brake drum or rotor friction surface that moves past the brake linings every time the drum or rotor completes a rotation. Disc brakes are resistant to all kinds of fade, including the following:

- **Mechanical fade** is not a problem with disc brakes because, unlike a brake drum, the disc brake rotor expands *toward* the brake linings as it heats up rather than *away* from them. This fundamental design difference makes it physically impossible for heat to cause the rotor to expand out of contact with the brake linings. Because of this, there is never the need to move the brake linings out to keep them in contact with the rotor, so brake pedal travel does not increase. If the brake pedal on a vehicle with disc brakes drops toward the floor, it is almost always a sign of vapor lock, a fluid leak, fluid bypassing the seals in the master cylinder, or mechanical fade of the rear *drum* brakes.
- **Lining fade** can and does occur if the brakes become overheated. A little bit of heat brings the brake pads to their operating temperature and actually increases the friction coefficient of the lining material. A warm brake performs better than a cold brake. However, when too much heat is generated by braking, the lining material overheats. Its friction coefficient drops, and lining fade occurs.

  The primary symptom of lining fade is a hard brake pedal that requires the driver to apply greater force to maintain

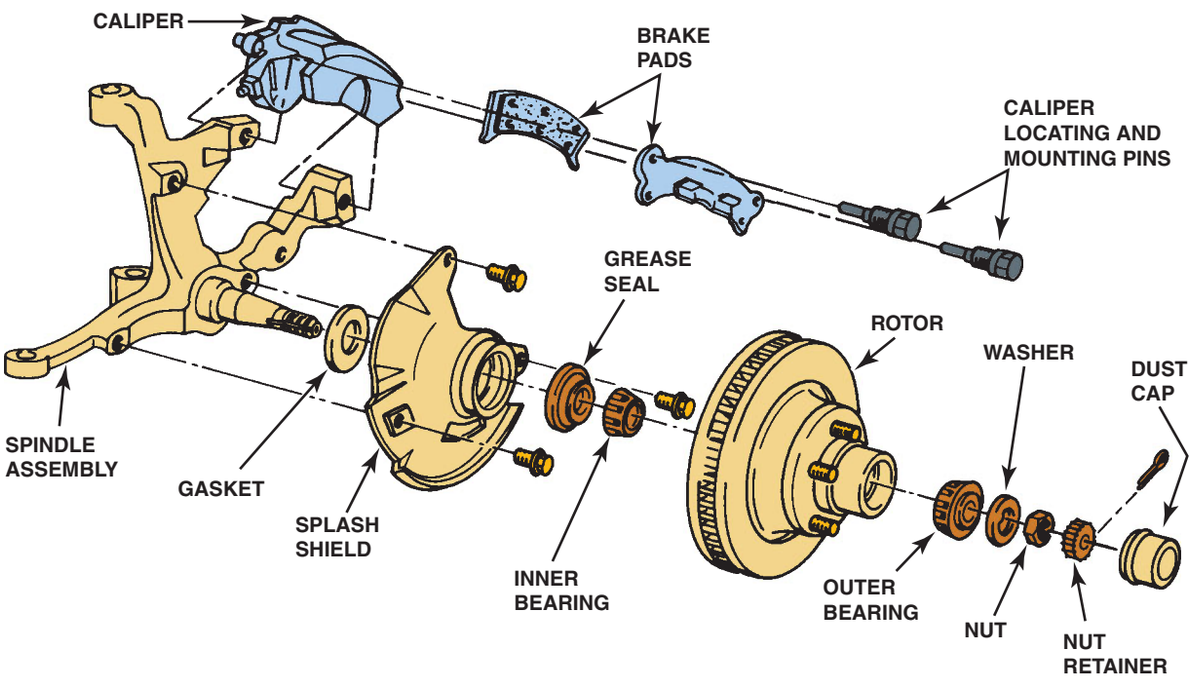


FIGURE 101–1 An exploded view of a typical disc brake assembly.

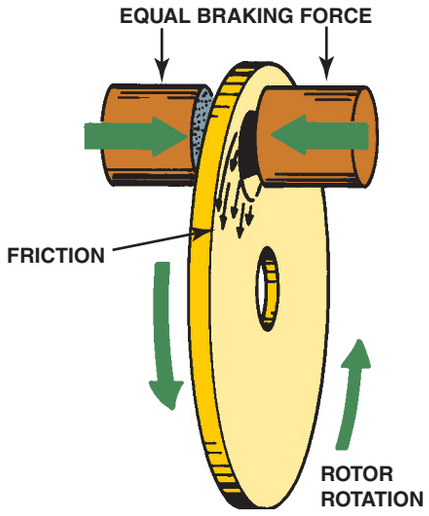

FIGURE 101–2 Braking force is applied equally to both sides of the brake rotor.

FIGURE 101–3 Disc brakes can absorb and dissipate a great deal of heat. During this demonstration, the brakes were gently applied as the engine drove the front wheels until the rotor became cherry red. During normal braking, the rotor temperature can exceed 350°F (180°C), and about 1,500°F (800°C) on a race vehicle.

stopping power. Unlike the similar situation in a drum brake, however, increased application force will not distort the brake rotor because the caliper applies equal force to both sides. ● **SEE FIGURE 101–2.**

Increased pressure will, however, create even more heat, and if brake lining temperatures continue to increase, gas fade and vapor lock of the hydraulic system can occur. If the pads are overheated to the point where the lining material is physically damaged, the brakes will not recover their full stopping power until the pads are replaced. ● **SEE FIGURE 101–3.**

- **Gas fade** is a problem only under severe braking conditions when hot gases and dust particles from the linings are trapped between the brake linings and rotor, where they act as lubricants. The symptoms of gas fade are the same as those for lining fade. The pedal becomes hard and increased force is required to maintain stopping power.

  Even though disc brakes operate at higher temperatures than drum brakes, they have fewer problems with gas fade for a number of reasons.

  1. Disc brakes do not have a drum to contain gases and particles in the area around the brake linings.

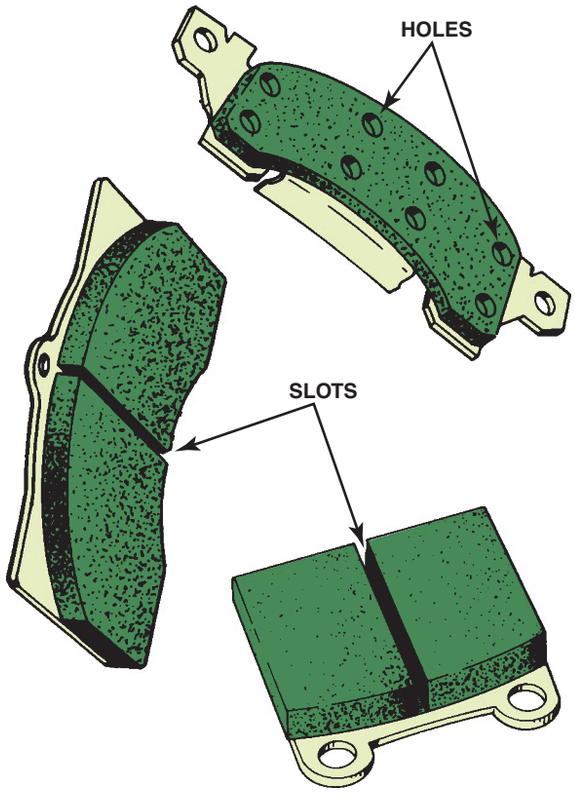

FIGURE 101–4 Slots and holes in the brake linings help prevent gas and water fade.

  2. The constant flow of air over the brake carries away contaminants that might otherwise build up.
  3. The surface area of the brake lining material in a disc brake is smaller than that of a comparable drum brake and this allows gases and particles to escape more easily.

  To help prevent gas fade, many brake pads have slots cut in the lining material. These slots allow gases and dust particles to escape. ● **SEE FIGURE 101–4.** The holes required in riveted linings also perform this function. For even greater protection against gas fade, high-performance vehicles and motorcycles sometimes have holes or slots cut into the rotor. These openings allow gases and water to escape, and their sharp edges continually wipe loose particles off the linings.

- **Water fade** is not a big problem with disc brakes because centrifugal force created by the spinning rotor throws off most moisture, and the brake pads positioned only a few thousandths of an inch away from the rotor continuously wipe it clean. When the brakes are applied, the leading edge of the brake pad lining material wipes the last bit of water from the disc. Once good lining-to-rotor contact is established, water is unable to enter the space between the linings and rotor until the brakes are released.

  Although far more resistant to water fade than drum brakes, disc brakes are not entirely free from its effects. Splash shields and the vehicle's wheels help keep water off of the rotor, and the brake lining materials specified for most vehicles minimize the effects of water fade.

SELF-ADJUSTING ABILITY. Disc brakes are self-adjusting because any wear of the linings is automatically compensated for by the action of the brake caliper.

When the brakes are applied, the caliper pistons move out as far as needed to force the brake pads into contact with the rotor. When

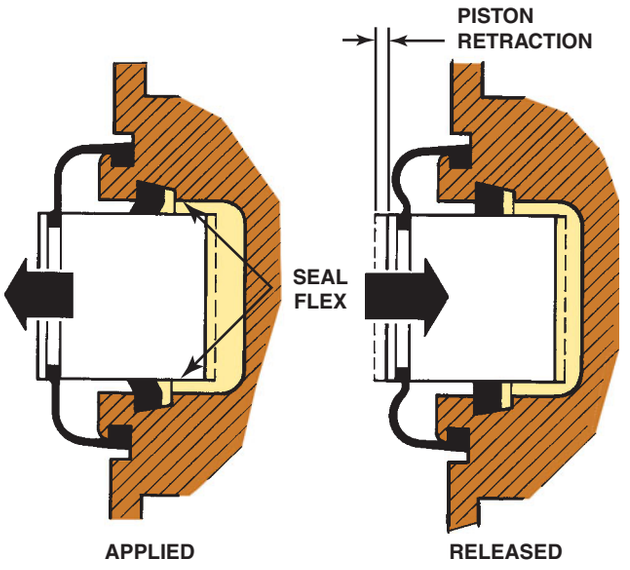

FIGURE 101–5 The square-cut O-ring not only seals hydraulic brake fluid, but also retracts the caliper piston when the brake pedal is released.

the brakes are released, the piston retracts only the small distance dictated by rotor runout and piston seal flex. ● **SEE FIGURE 101–5.** The surface finish on the piston must be clean to allow the piston to slide past this seal. Excessive friction between the caliper piston and the caliper bore can prevent the piston from retracting. If the force of the caliper seal is not strong enough, the piston stays in the applied position. Because the brake pads are still in contact with the rotor, one or both pads will show excessive wear.

FREEDOM FROM PULL. A disc brake will stop straighter under a wider range of conditions than will a drum brake. A disc brake is self-cleaning, will throw off most water, and is less likely to pull.

Disc brakes do not have self-energizing or servo action. Because disc brakes are not self-energizing to increase their braking power, the effects of a loss of friction on one side of the vehicle are far less pronounced than with drum brakes.

DISC BRAKE DISADVANTAGES

The most notable fact about the disadvantages of disc brakes is that there are so few. The weaknesses of disc brakes include the following.

- **No Self-Energizing or Servo Action**—The disc brake's lack of self-energizing or servo action is a disadvantage for two reasons.
  1. It contributes to poor parking brake performance and requires the driver to push harder on the brake pedal for a given stop. However, the problem of high pedal pressures has been eliminated through the use of brake power boosters.
  2. It is easier to control the brakes for the exact amount of stopping power desired.
- **Brake Noise**—Probably the biggest complaint about disc brakes is that they sometimes make various squeaks and squeals during a brake application. As long as the brake linings are not worn down to the backing plate, these noises are usually caused by high-frequency rattling or vibration of the brake pads. Several methods are used to quiet noisy disc brakes. Manufacturers use specific lining materials that dampen vibrations, and most calipers have **antirattle clips** or springs that hold the pads in the caliper under tension to help prevent vibration. ● **SEE FIGURE 101–6.**

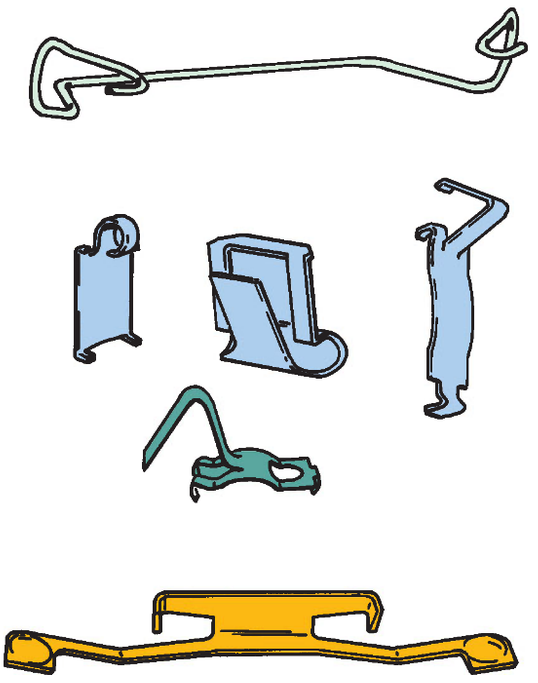

FIGURE 101–6 Antirattle clips reduce brake pad movement and vibration.

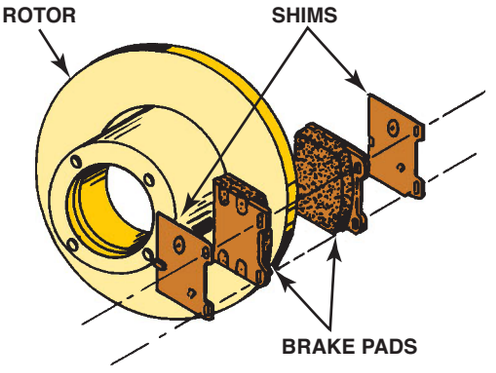

FIGURE 101–7 Antivibration shims are used behind the pads on many disc brake caliper designs.

TECH TIP

Check the Tire Size for a Pulling Problem

If an unequal braking problem is being diagnosed, check that the front tires match and that the rear tires match. Brakes slow and stop wheels. Unequal diameter tires create an unequal braking force. The result may be a pulling toward one side while braking. Tire diameter can vary from one tire manufacturer to another even though the size designation is the same. Even slight differences in the wear or inflation pressure of tires can cause a different tire diameter and, therefore, a different braking force.

Some calipers use special shims between the brake pad and the caliper piston to damp vibrations. ● **SEE FIGURE 101–7.** These shims may be made of metal or fiber. Antinoise sprays and brush-on liquids are available and provide a cushion layer between the pad and the caliper piston. The bond lowers the **natural frequency** of the pad, and the cushion layer dampens any vibration that may still occur.

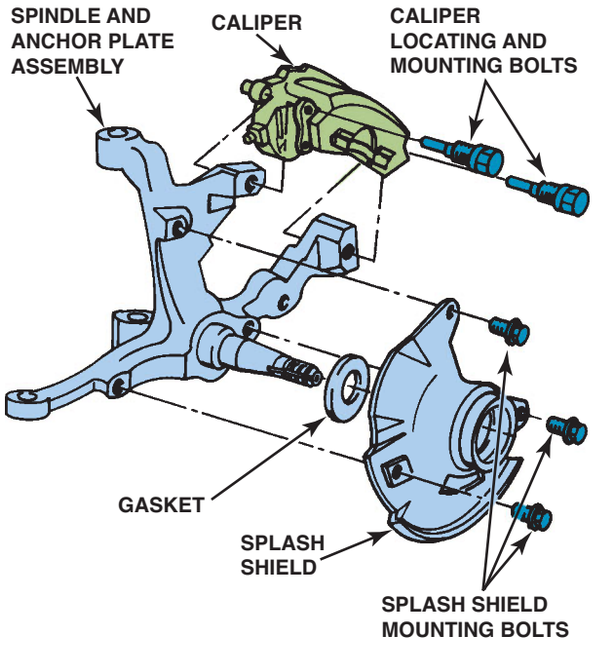

FIGURE 101–8 This brake caliper attaches to the front spindle.

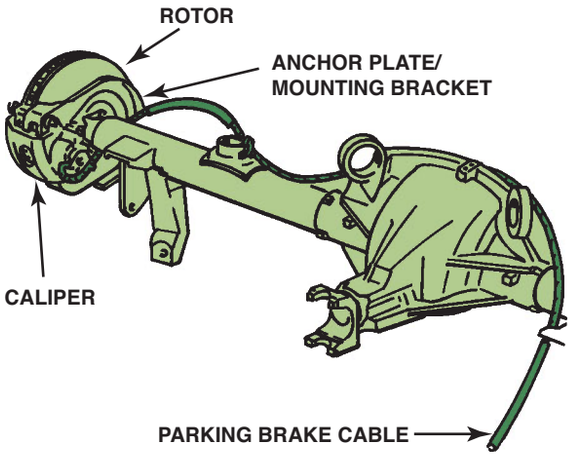

FIGURE 101–9 A rear disc brake caliper often attaches to a mounting bracket on the rear axle housing on this rear-wheel-drive vehicle.

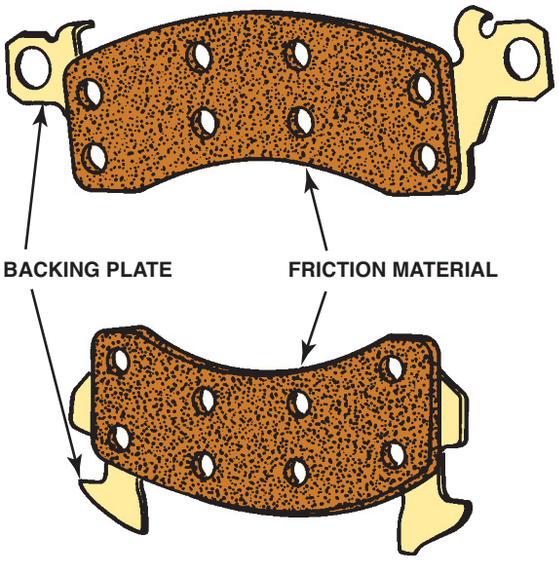

FIGURE 101–10 A typical disc brake pad.

TECH TIP

Wax the Wheels

Brake dust from semimetallic brake pads often discolors the front wheels. Customers often complain to service technicians about this problem, but it is normal for the front wheels to become dirty because the iron and other metallic and nonmetallic components wear off the front disc brake pads and adhere to the wheel covers. A coat of wax on the wheels or wheel covers helps prevent damage and makes it easier to wash off the brake dust.

BRAKE DUST. Because the lining is exposed on a disc brake, rather than being enclosed as on a drum brake, some brake dust can accumulate on the wheels. This brake dust is often dark brown or black and can stain wheels if not cleaned often or protected from the dust.

POOR PARKING BRAKE PERFORMANCE. The lack of self-energizing and servo action plays a large part in poor disc brake parking brake performance. The lining-to-rotor contact area of a disc brake is somewhat smaller than the lining-to-drum contact area of a drum brake. This causes the disc brake to have a lower static coefficient of friction, and therefore less holding power when the vehicle is stopped.

DISC BRAKE CONSTRUCTION

A disc brake is relatively simple compared with a drum brake. The major disc brake friction assembly components include the following.

CALIPER With the exception of the rotor, the caliper is the largest part of a disc brake friction assembly. The brake caliper uses hydraulic pressure to create the mechanical force required to move the brake pads into contact with the brake rotor. At the front axle, the caliper mounts to the spindle, caliper support bracket or steering knuckle. ● **SEE FIGURE 101–8.** Rear disc brake calipers mount to a support bracket on the axle flange or suspension. ● **SEE FIGURE 101–9.**

SPLASH SHIELD The splash shield bolts to the front spindle or steering knuckle, or in rear disc brake applications, to the axle flange or a suspension adapter plate. The job of the splash shield is to protect the inner side of the brake rotor from water and other contaminants, whereas the outer side of the rotor is protected by the wheel. Most splash shields are made of stamped steel or plastic.

DISC BRAKE PADS

BRAKE PAD ASSEMBLY The lining of a disc brake is part of an assembly called the **brake pad.** ● **SEE FIGURE 101–10.** Compared to a brake shoe, a brake pad is a relatively simple part that consists of a block of friction material attached to a stamped steel backing plate. Some pad backing plates have tabs that bend

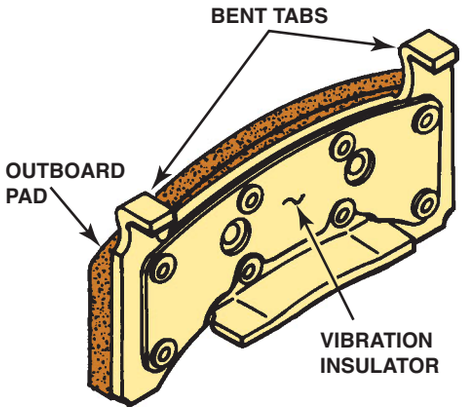

FIGURE 101–11 To prevent noise, bent tabs on the backing plate hold some brake pads to the caliper housing.

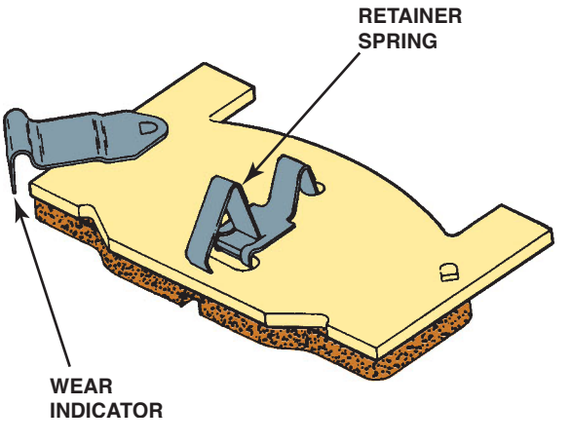

FIGURE 101–13 Retainer springs lock the pad to the caliper piston to prevent brake noise.

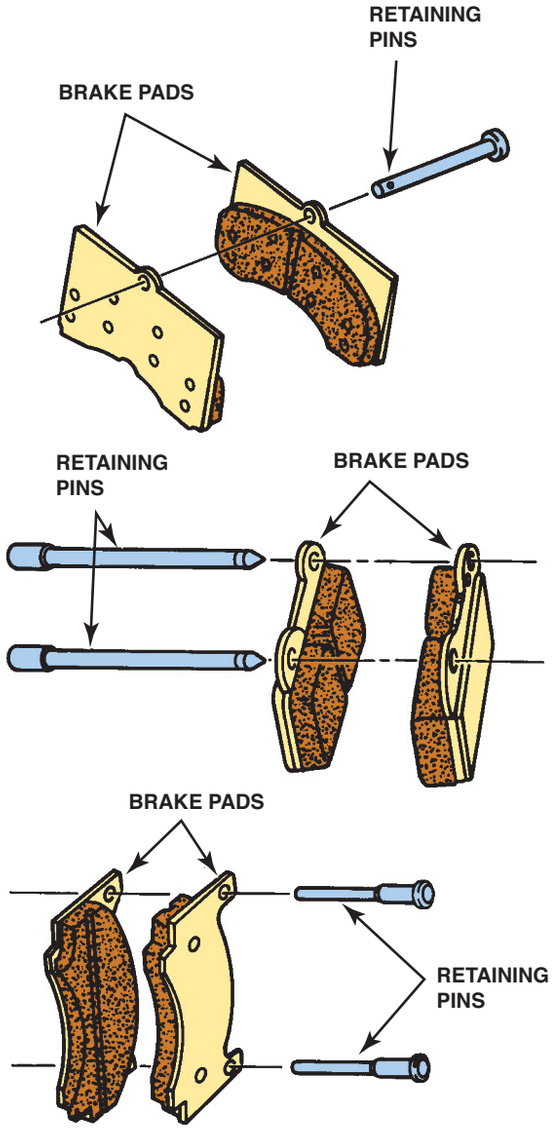

FIGURE 101–12 Holes in the backing plate are a common method of locating a pad in the caliper.

over the caliper to hold the pad tightly in place and help prevent brake noise. ● **SEE FIGURE 101–11.**

Other pad backing plates have tabs with holes in them as shown in ● **FIGURE 101–12.** A pin slips through the holes and fastens to the caliper body to hold the pads in position. Still other pad backing plates have a retainer spring attached that locates the pad in the caliper by locking it to the caliper piston. ● **SEE FIGURE 101–13.**

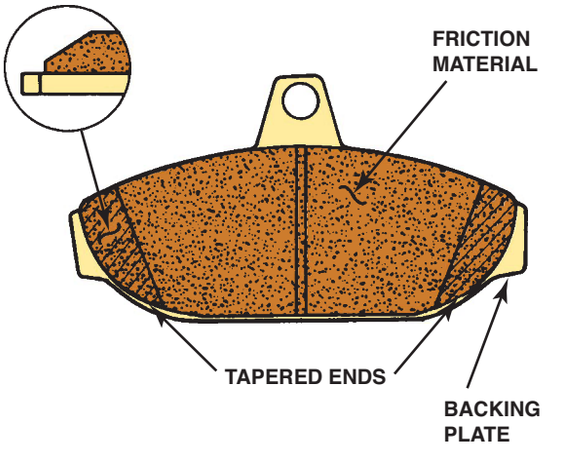

FIGURE 101–14 The lining edges of some brake pads are tapered to help prevent vibration.

As with brake shoes, the lining material of a disc pad can be any one of a number of products that can be fastened to the backing plate in several ways. The edges of the lining material on a brake pad are usually perpendicular to the rotor surface, although a few larger pads do have tapered edges to help combat vibration and noise. ● **SEE FIGURE 101–14.**

PAD WEAR INDICATORS

Although not required by law, a growing number of vehicle manufacturers are fitting **pad wear indicators** to their brakes for safety reasons. Pad wear indicators are either mechanical or electrical, and signal the driver when the lining material has worn to the point where pad replacement is necessary.

A mechanical wear indicator is a small spring-steel tab riveted to the pad backing plate. When the friction material wears to a predetermined thickness, the tab contacts the rotor and makes a squealing or chirping noise (when the brakes are not applied) that alerts the driver to the need for service. ● **SEE FIGURE 101–15.**

Electrical wear indicators, such as those shown in ● **FIGURE 101–16,** use a coated electrode embedded in the lining material to generate the warning signal. The electrode is wired to a warning light in the instrument panel and when the lining wears sufficiently, the electrode grounds against the rotor to complete the circuit and turn on the warning light.

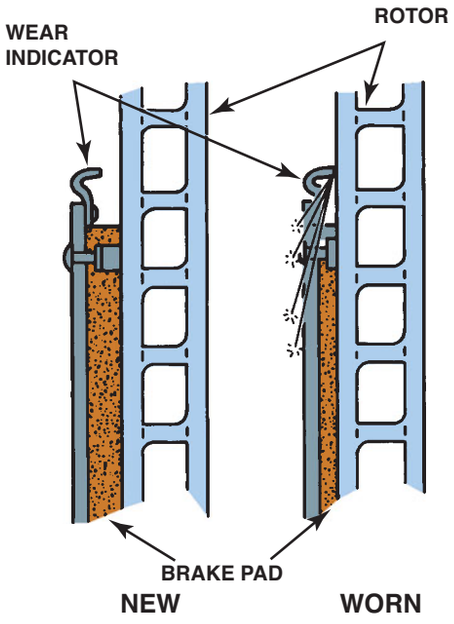

FIGURE 101–15 Typical pad wear sensor operation. It is very important that the disc brake pads are installed on the correct side of the vehicle to be assured that the wear sensor will make a noise when the pads are worn. If the pads with a sensor are installed on the opposite side of the vehicle, the sensor tab is turned so that the rotor touches it going the opposite direction. Usually the correct direction is where the rotor contacts the sensor before contacting the pads when the wheels are being rotated in the forward direction.

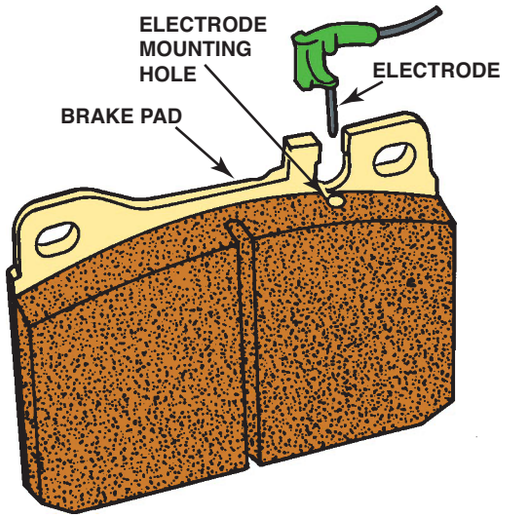

FIGURE 101–16 Electrical wear indicators ground a warning light circuit when the pads need replacement.

PAD ASSEMBLY METHODS

As mentioned previously, there are several methods that are used to mount brake linings, including:

- **Riveted linings** take advantage of the oldest method of lining attachment still in use. In this system, the brake block is attached to the backing plate with copper or aluminum rivets.

  The major advantage of riveting is that it allows a small amount of flex between the brake block backing plate. This play enables the assembly to absorb vibration, and the result is that riveted linings operate more quietly than bonded linings. However the rivet holes create stress points in the lining where cracks are likely to develop.

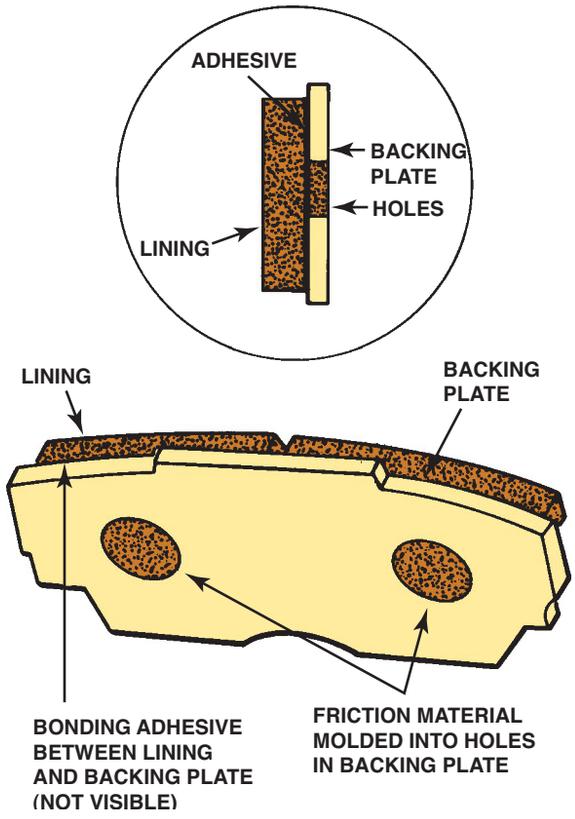

FIGURE 101–17 Mold-bonded linings are commonly used in many applications.

- **Bonded linings** use high-temperature adhesive to glue the brake block directly to the shoe pad backing plate. Heat and pressure are then applied to cure the assembly. Bonding is a common form of shoe and pad assembly, and is most often used to mount organic friction materials.

  Bonding offers several advantages. Without rivets, bonded linings can wear closer to the backing plate and provide a longer service life. If the linings wear too far, bonding adhesive is not as destructive to rotors as rivets. Bonded linings also have fewer problems with cracking because they have no rivet holes to weaken the brake block. The primary disadvantage of bonded linings is a limited ability to withstand high temperatures. If a bonded lining gets too hot, the bonding adhesive will fail and allow the brake block to separate from the backing plate. Bonded linings are also more prone to be noisy because they do not allow any vibration absorbing flex between the brake block and backing plate.

- **Mold-bonded linings** are found on some disc brake pads. Mold bonding is a manufacturing process that combines the advantages of bonding with some of the mechanical strength of riveting. Instead of riveting and/or bonding a cured brake block to a separate backing plate, the friction material in a mold-bonded pad is cured on the backing plate during manufacture. This process is also called **integrally molded.** Most high-performance disc brake pads are made in this way.

  To make a mold-bonded pad, one or more holes are punched in the pad backing plate, and a high-temperature adhesive is applied to it. The backing plate is then installed in a molding machine where uncured friction material is formed onto the plate and forced into the holes. ● **SEE FIGURE 101–17.** Once the pad is cured under heat and pressure, the bonding adhesive combines with the portions of the lining that extend into the backing plate holes to solidly lock the brake block in place.

INGREDIENT	TYPICAL FORMULA RANGE
Phenolic resin (binder)	9–15%
Asbestos fiber	30–50%
Organic friction modifiers (rubber scrap)	8–19%
Inorganic friction modifiers (barites, talc, whiting)	12–26%
Abrasive particles (alumina)	4–20%
Carbon	4–20%

CHART 101–1

Typical compositions for asbestos (organic) lining used on older vehicles.

INGREDIENT	FORMULA RANGE
Phenolic resin	15–40%
Graphite or carbon particles	15–40%
Steel fibers	10–30%
Ceramic powders	2–10%
Steel, copper, brass metal powders	15–40%
Other modifiers (rubber scrap)	0–20%

CHART 101–2

Typical compositions for semimetallic disc brake pads

BRAKE LINING COMPOSITION

Shoes and pads operate under the most extreme conditions in the entire brake system and are subject to a great deal of wear. The replacement of worn brake shoes and pads is a common part of brake service.

Friction materials such as disc brake pads or drum brake shoes contain a mixture of ingredients. These materials include a binder such as a thermosetting resin, fibers for reinforcement, and friction modifiers to obtain a desired coefficient of friction (abbreviated μ—Greek letter mu).

The various ingredients in brake lining are mixed and molded into the shape of the finished product. The fibers in the material are the only thing holding this mixture together. A large press is used to force the ingredients together to form a **brake block,** which eventually becomes the brake lining. ● **SEE CHART 101–1.**

SEMIMETALLIC FRICTION MATERIAL. The term *semimetallic* refers to brake lining material that uses metal rather than asbestos in its formulation. It still uses resins and binders and is, therefore, not 100% metal, but rather, semimetallic. Semimetallics are commonly called **semimets.** The metal in most metallic linings is made from metal particles that have been fused together without melting. This process is called **sintering** and the result is called **sintered metal** linings. ● **SEE CHART 101–2.**

Most semimetallic linings do not contain asbestos. Semimetallic linings require a very smooth finish on the rotor because the metal in the lining does not conform to the surface of the rotor, as does asbestos lining.

NOTE: If a magnet sticks the lining material, it is semimetallic.

TECH TIP

Competitively Priced Brakes

The term *competitively priced* means lower cost. Most brake manufacturers offer "premium" as well as lower-price linings, to remain competitive with other manufacturers or with importers of brake lining material produced overseas by U.S. or foreign companies. In fact, according to warehouse distributors and importers, the box often costs more than the brake lining inside.

Professional brake service technicians should only install brake linings and pads that will give braking performance equal to that of the original factory brakes. For best results, always purchase high-quality brake parts from a known brand-name manufacturer.

FREQUENTLY ASKED QUESTION

What Does "D³EA" Mean?

Original equipment brake pads and shoes are required to comply with the Federal Motor Vehicle Safety Standard (FMVSS) 135, which specifies maximum stopping distances. There is also a requirement for fade resistance, but no standard for noise or wear. Aftermarket (replacement) brake pads and shoes are not required to meet the FMVSS standard. However, several manufacturers of replacement brake pads and shoes are using a standardized test that closely matches the FMVSS standard and is called the "Dual Dynamometer Differential Effectiveness Analysis" or D³EA. This test is currently voluntary and linings that pass the test can have a "D³EA certified" seal placed on the product package.

NONASBESTOS FRICTION MATERIAL. Brake pads and linings that use synthetic material such as aramid fibers instead of steel are usually referred to as **nonasbestos, nonasbestos organic (NAO),** or **nonasbestos synthetic (NAS).** Linings are called *synthetic* because synthetic (man-made) fibers are used. These linings use **aramid fiber** instead of metal as the base material. Aramid is the generic name for aromatic polyamide fibers. **Kevlar** is the Dupont brand name of aramid and a registered trademark of E.I. Dupont de Nemours and Company. Nonasbestos linings are often quieter than semimetallics and do not cause as much wear to brake rotors as do semimetallic pads.

CARBON FIBER FRICTION MATERIAL. Carbon fiber brake lining is the newest and most expensive of the lining materials. Carbon fiber material is often called **CFRC (carbon fiber-reinforced carbon).** It is composed of a carbon mix into which reinforcing carbon fibers are embedded. CFRC is commonly used in the brakes of jet aircraft and racing cars. CFRC brakes provide constant friction coefficient whether cold or hot, low wear rates, and low noise development.

CERAMIC FRICTION MATERIAL. Some vehicle manufacturers use friction materials that contain ceramic fibers. These ceramic fibers are usually potassium titanite. Most pads today are ceramic and use little, if any steel. One way to check to see which type of pad is used is to use a magnet. If a magnet sticks to the pad, it has a high steel content but a magnet will not stick to a ceramic pad.

Code C	0.00 to 0.15
Code D	0.15 to 0.25
Code E	0.25 to 0.35
Code F	0.35 to 0.45
Code G	0.45 to 0.55
Code H	0.55 and above
Code Z	ungraded

CHART 101–3

The SAE brake pad edge codes are used to indicate the coefficient of friction of the pad material.

EDGE CODES As explained previously, the lining edge codes help identify the coefficient of friction. These codes were established by the SAE (Society of Automotive Engineers) and published as Standard J886a. ● **SEE CHART 101–3.**

The first letter, which is printed on the side of most linings, indicates its coefficient of friction when brakes are cold, and the second letter indicates the coefficient of friction of the brake lining when the brakes are hot. For example, FF indicates that the brake lining material has a coefficient of friction between 0.35 and 0.45 when both cold and hot.

BRAKE ROTORS

The brake rotor provides the friction surfaces for the brake pads to rub against. The rotor, the largest and heaviest part of a disc brake, is usually made of cast iron because that metal has excellent friction and wear properties. There are two basic types of rotors:

- **Solid**—Solid rotors are most often used on the rear of vehicles equipped with four-wheel disc brakes.
- **Vented**—Vented rotors have radial cooling passages cast between the friction surfaces. ● **SEE FIGURE 101–18.**

CALIPER DESIGNS

There are basically three types of calipers: fixed, floating, and sliding designs.

FIXED CALIPER DESIGN The **fixed brake caliper** is the earliest design. ● **SEE FIGURE 101–19.** The fixed caliper has a body manufactured in two halves, and uses two, four, or six pistons to apply the brake pads. The fixed caliper gets its name from the fact that the caliper is rigidly mounted to the suspension. When the brakes are applied, the pistons extend from the caliper bores and apply the brake pads with equal force from both sides of the rotor. No part of the caliper body moves when the brakes are applied.

FIXED CALIPER ADVANTAGES Fixed calipers are relatively large and heavy, which enables them to absorb and dissipate great amounts of heat. This allows the brake rotor and pads to run cooler, and reduce the amount of heat transferred to the brake fluid. Compared with other caliper designs, a fixed caliper is able to withstand a greater number of repeated hard stops without heat-induced fade or vapor lock of the hydraulic system.

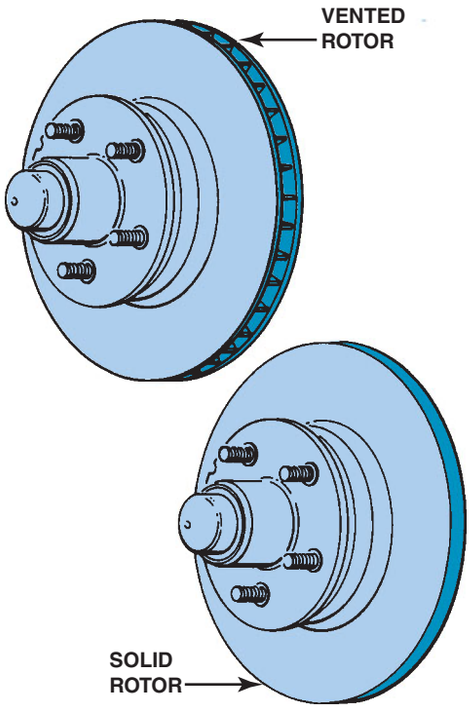

FIGURE 101–18 Disc brake rotors can be either solid or vented.

The size and rigid mounting of a fixed caliper also means it does not flex as much as other designs. A caliper that is flexing is usually felt by the driver as a spongy brake pedal. Fixed calipers are very strong and provide a firm and linear brake pedal feel.

The strength and heat-dissipating abilities of fixed calipers make them best suited for heavy-duty use such as in most race vehicles.

FIXED CALIPER DISADVANTAGES The size and weight of fixed calipers are advantages in heavy-duty use, but they add weight to the vehicle.

Another disadvantage of fixed calipers is that, with multiple pistons and split bodies, service is more difficult and allows greater opportunity for leaks. The drilled passages that route fluid through the inside of the caliper body also contribute to cracking as miles accumulate and the caliper goes through hundreds of thousands of heating and cooling cycles.

FLOATING AND SLIDING CALIPER DESIGN The front brakes of most vehicles are fitted with either floating or sliding calipers, which are *not* rigidly mounted. The caliper is free to move within a limited range on an **anchor plate** that *is* solidly mounted to the vehicle suspension. The anchor plate may be cast into a suspension member (often the front spindle) or it can be a separate piece that bolts to the suspension. ● **SEE FIGURE 101–20.**

When the brakes are applied, the caliper piston moves out of its bore and applies the inner brake pad. At the same time, the caliper body moves in the opposite direction on the anchor plate and applies the outer brake pad. With a floating or sliding caliper, the caliper body moves every time the brakes are applied. ● **SEE FIGURE 101–21.**

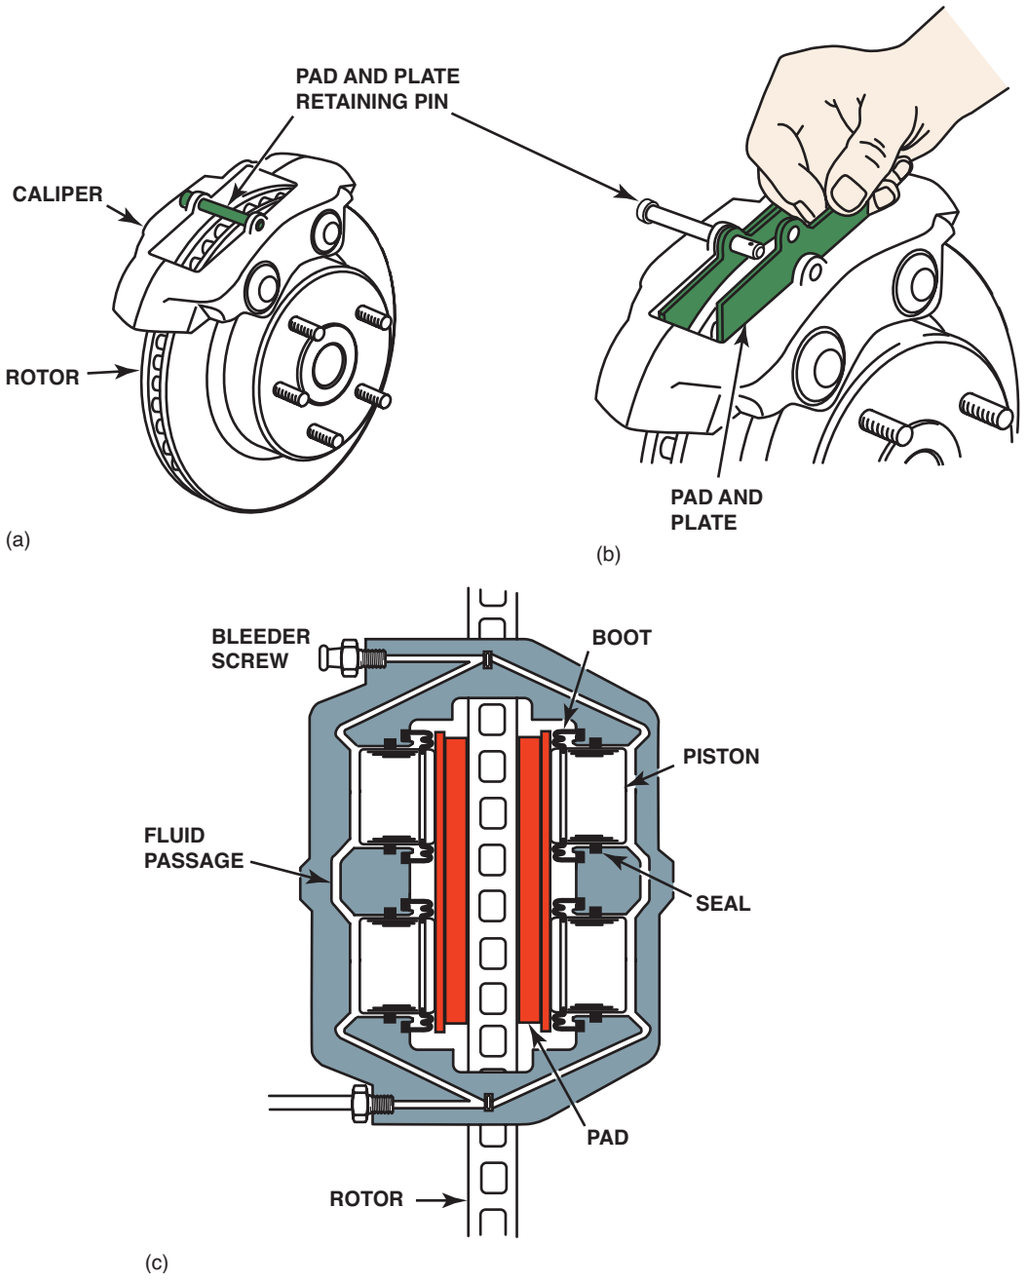

FIGURE 101–19 (a) Many fixed caliper disc brakes use a simple retaining pin to hold the disc brake pads. (b) Removing the retainer pin allows the brake pads to be removed. (c) Notice the cross-over hydraulic passage that connects both sides of the caliper.

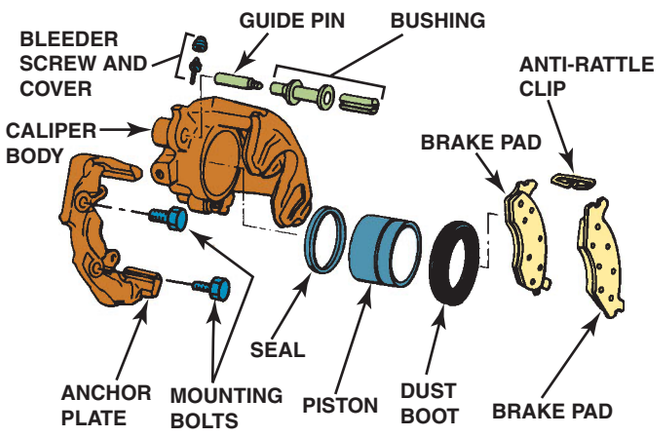

FIGURE 101–20 This floating caliper mounts on a separate anchor plate that bolts to the vehicle suspension.

NORMAL CALIPER OPERATION

The piston moves just enough to distort the caliper seal and returns to the original position when the brake pedal is released.

WEAR COMPENSATION. The piston moves more than the caliper seal can distort. The piston moves through the seal until the pad contacts the rotor. The caliper piston returns to the released position by the seal distortion, the same as during normal operation, except now in a different, more applied position.

As the wear occurs and the piston moves, additional brake fluid is needed behind the piston. This additional brake fluid comes from the master cylinder and the brake fluid level drops as the disc brake pads wear.

FLOATING AND SLIDING CALIPER ADVANTAGES

The biggest advantages of floating and sliding calipers are lower cost, simple construction, and compact size. Most floating and sliding

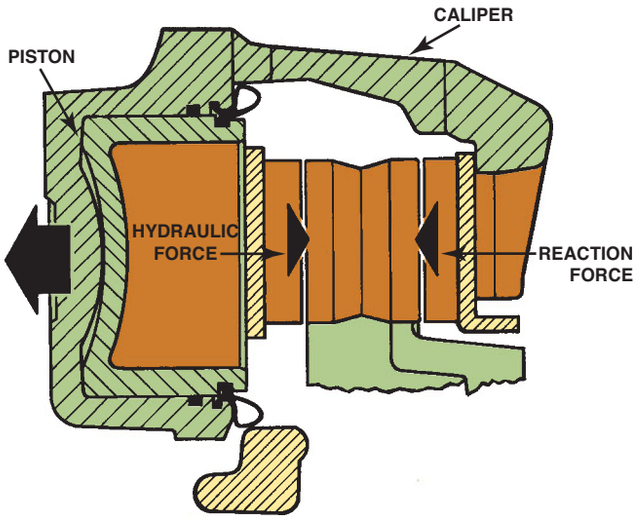

FIGURE 101–21 Hydraulic force on the piston (left) is applied to the inboard pad and the caliper housing itself. The reaction of the piston pushing against the rotor causes the entire caliper to move toward the inside of the vehicle (large arrow). Since the outboard pad is retained by the caliper, the reaction of the moving caliper applies the force of the outboard pad against the outboard surface of the rotor.

calipers are single-piston designs. Because they have fewer pieces, floating and sliding calipers are cheaper to build and service, and have fewer places where leaks can develop.

The smaller size of floating and sliding calipers also allows better packaging of the caliper on the vehicle. A single-piston caliper with the piston located on the inboard side of the brake rotor fits easily within the diameter of a small wheel. The inboard position of the caliper piston also contributes to better cooling because the bulk of the caliper body is exposed to the passing airflow.

Like any disc brake, floating and sliding calipers have poor parking brake performance. Unlike a fixed caliper, a floating or sliding caliper can be mechanically actuated by applying the single piston with a cable and lever mechanism.

FLOATING AND SLIDING CALIPER DISADVANTAGES

The movable caliper body allows a certain degree of flex, which can contribute to a spongy brake pedal. Caliper flex also allows the caliper body to twist slightly when the brakes are applied, causing tapered wear of the brake pad lining material. ● **SEE FIGURE 101–22.**

Although the inboard piston location of floating and sliding calipers provides good cooling, these designs can never absorb as much heat (and therefore have the fade resistance) as a fixed caliper with similar stopping power. Floating and sliding calipers simply do not have the mass of fixed calipers, and their flexible mounting systems slow the transfer of heat from the caliper body to the anchor plate and other suspension components that aid in the cooling process.

FLOATING CALIPER OPERATION

The body of a **floating caliper** does not make direct metal-to-metal contact with the anchor plate. ● **SEE FIGURE 101–23.** Instead, the caliper body is supported by bushings and/or O-rings that allow it to "float" or slide on metal guide pins or locating sleeves attached to the anchor plate. For this reason, some automakers call the floating caliper a **pin-slider caliper.**

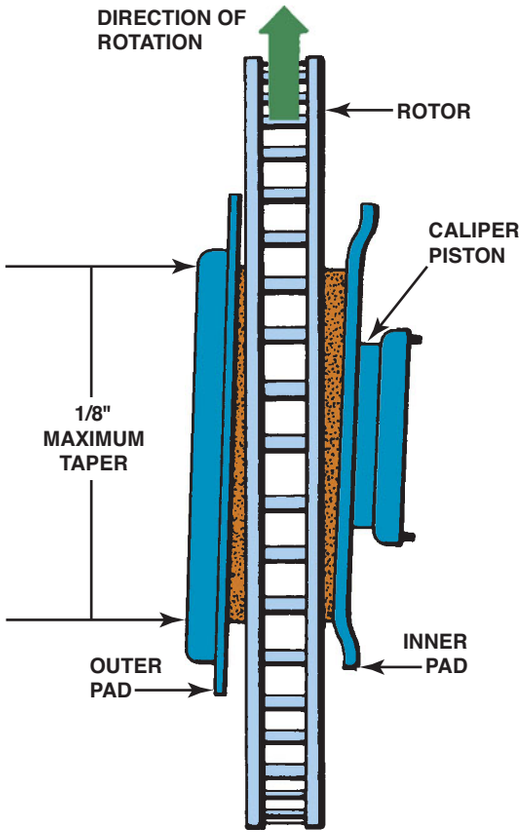

FIGURE 101–22 Caliper flex can cause tapered wear of the brake lining.

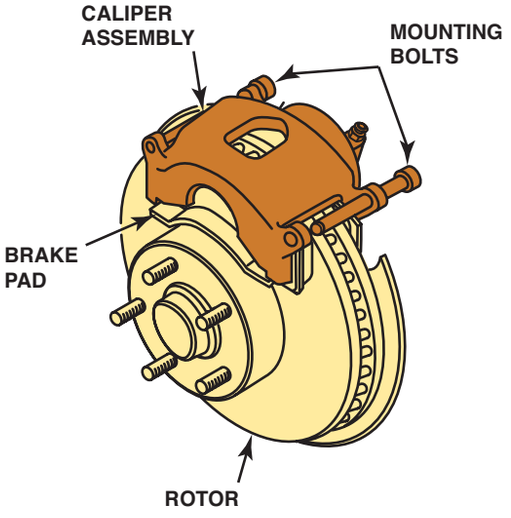

FIGURE 101–23 A typical single-piston floating caliper. In this type of design, the entire caliper moves when the single piston is pushed out of the caliper during a brake application. When the caliper moves, the outboard pad is applied against the rotor.

The bushings that support floating calipers are made from a number of materials including rubber, Teflon, and nylon. The O-rings are generally made from high-temperature synthetic rubber. ● **SEE FIGURE 101–24.** The guide pins and sleeves are made of steel and come in a variety of shapes and sizes for different caliper designs. ● **SEE FIGURE 101–25.**

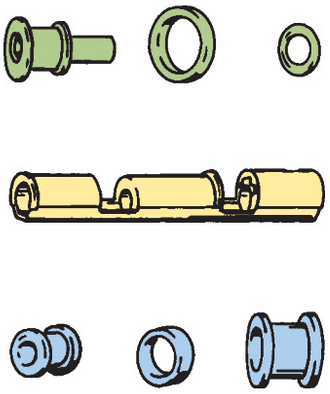

FIGURE 101–24 Floating calipers are supported by rubber O-rings or plastic bushings.

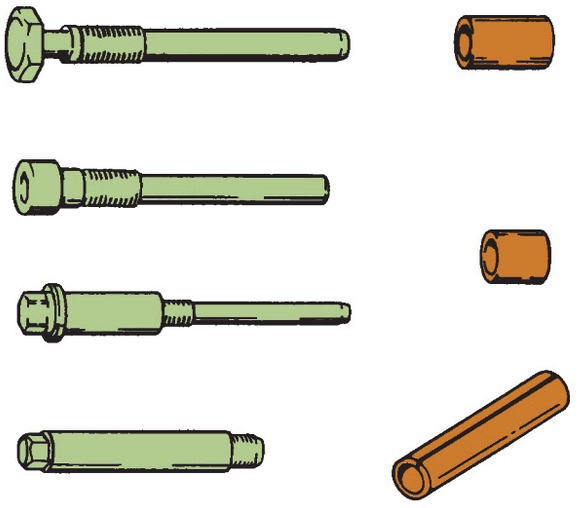

FIGURE 101–25 Metal guide pins and sleeves are used to retain and locate floating calipers.

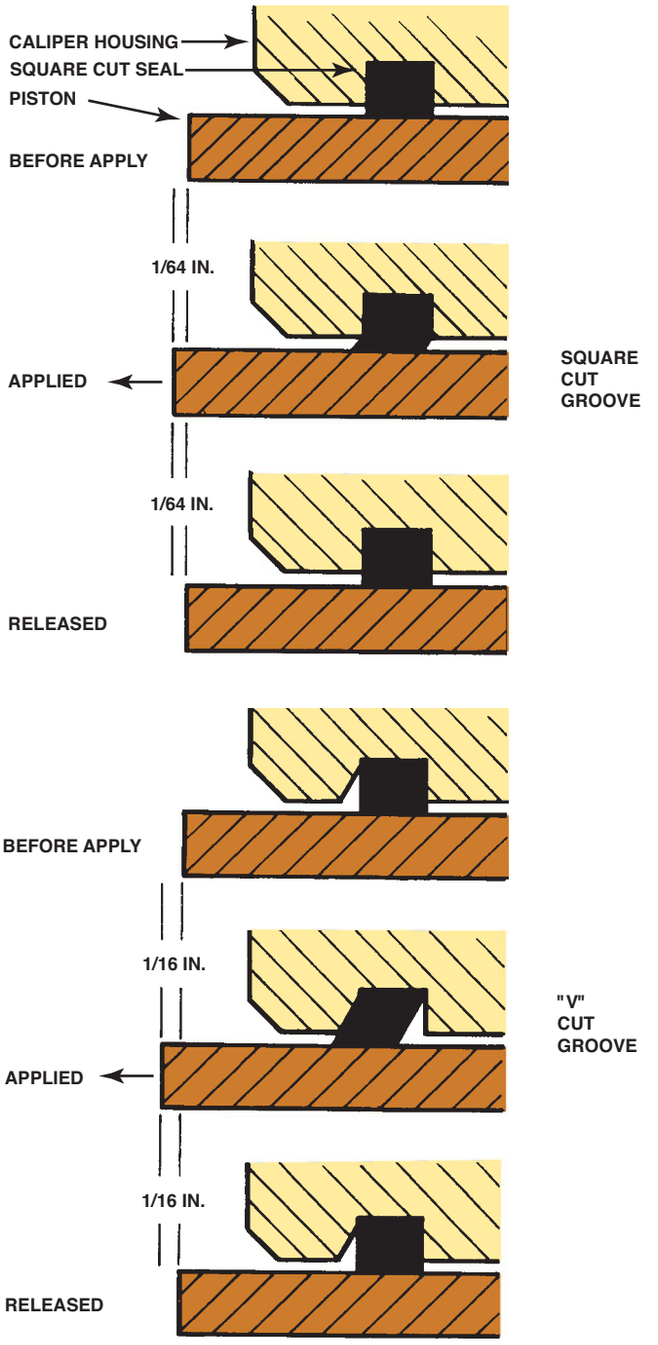

FIGURE 101–26 In a standard disc brake caliper, the square-cut O-ring deforms when the brakes are applied and returns the piston to its original (released) position due to the elastic properties of the rubber seal. In a low-drag caliper design, the groove for the square-cut O-ring is V-shaped, allowing for more retraction. When the brake pedal is released, the piston is moved away from the rotor farther, resulting in less friction between the disc brake pads and the rotor when the brakes are released.

? FREQUENTLY ASKED QUESTION

What Is a Low-Drag Caliper?

A **low-drag caliper** differs from a standard caliper in the area of the square-cut O-ring. A V-shaped cutout allows the O-ring to deflect more and, as a result, is able to pull the caliper piston back into the bore when the brakes are released. Because of this further movement, the brake pads are pulled farther from the rotor and are less likely to drag. The negative aspect of this design is that greater volume of brake fluid is needed to achieve a brake application. To compensate for this need for greater brake fluid volume, a quick-take-up master cylinder was designed and is used whenever low-drag calipers are used.

● **SEE FIGURE 101–26.**

Floating calipers depend on proper lubrication of their pins, sleeves, bushings, and O-rings for smooth operation. If these parts become rusted or corroded, the caliper will bind and stick, causing loss of braking power that is usually accompanied by rapid and unusual wear of brake pads. Special high-temperature brake grease must be used to lubricate these parts any time the caliper is

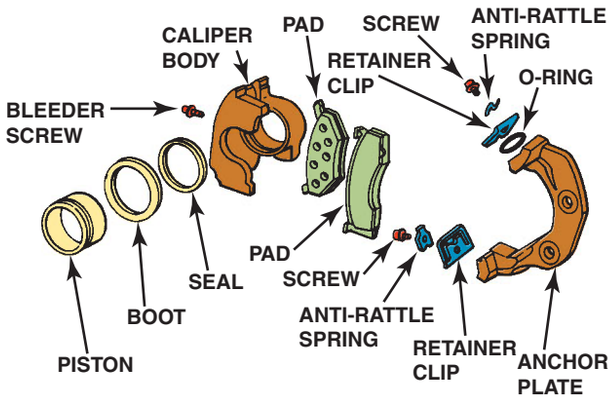

FIGURE 101–27 Exploded view of a typical sliding brake caliper.

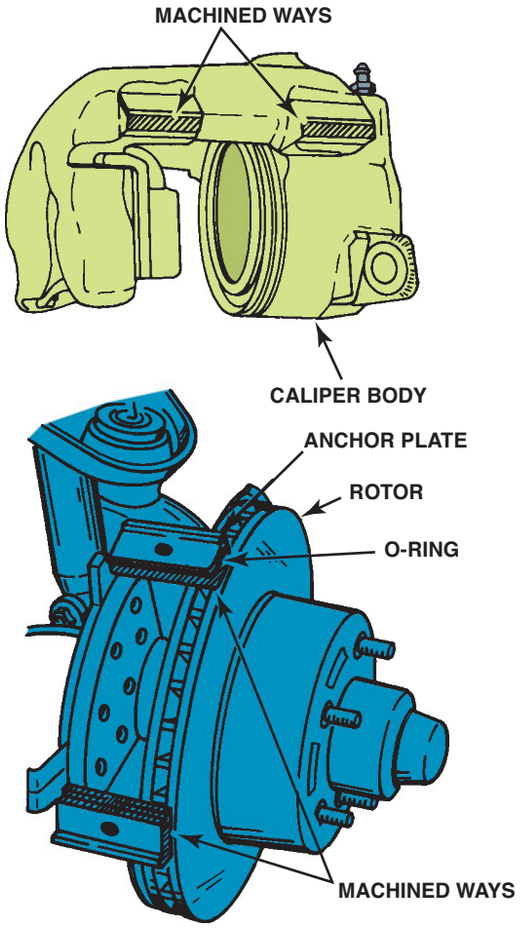

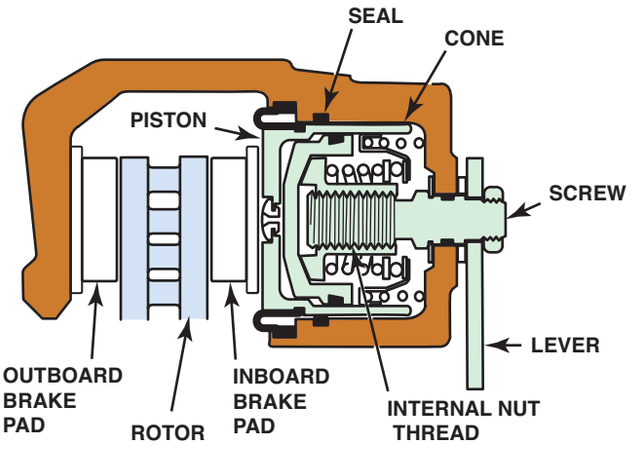

FIGURE 101–28 Sliding calipers move on machined ways.

disassembled. Many manufacturers recommend that floating caliper pins, sleeves, bushings, and O-rings be replaced whenever the caliper is serviced. These parts come in a "small parts kit" available from brake part suppliers.

SLIDING CALIPERS Unlike a floating caliper, the body of a **sliding caliper** mounts in direct metal-to-metal contact with the anchor plate. ● **SEE FIGURE 101–27.**

Instead of pins and bushings, sliding calipers move on **ways** cast and machined into the caliper body and anchor plate. ● **SEE FIGURE 101–28.** Retaining clips and the design of the caliper prevent the body from coming out of the ways once the caliper is assembled. On some calipers, the ways may have to be filed for proper

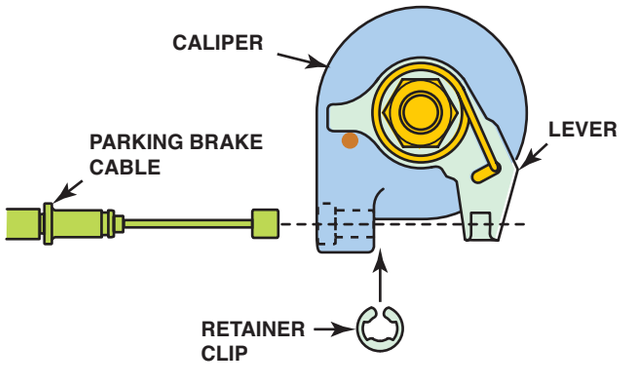

FIGURE 101–29 Exploded view of a typical rear disc brake with an integral parking brake. The parking brake lever mechanically pushes the caliper piston against the rotor.

clearance between the caliper body and anchor plate if the caliper is replaced.

Like floating calipers, sliding calipers depend on good lubrication of their ways for proper operation. If not properly coated with high-temperature brake grease, the ways can rust or corrode, causing the caliper to drag or seize.

REAR DISC BRAKES

In recent years, four-wheel disc brake systems have become more common. In most rear-wheel applications, drum brakes are adequate to provide the relatively small portion of a vehicle's total braking power required of them. Because rear drum brakes are lightly loaded, fade is a problem only in extreme conditions when the front brakes fade and force the rear brakes to take on a larger part of the braking load. The automatic adjusting ability of disc brakes is also less of an advantage in slow-wearing rear brakes.

REAR DISC PARKING BRAKES There are two methods of providing parking brakes when rear discs are installed on a vehicle.

1. Adapt the disc brake to also function as the parking brake. This is done by installing a series of cables, levers, and internal parts to mechanically actuate the brake caliper. ● **SEE FIGURES 101–29 AND 101–30.**
2. Use mechanically actuated drum brakes inside the rear rotors. ● **SEE FIGURE 101–31.**

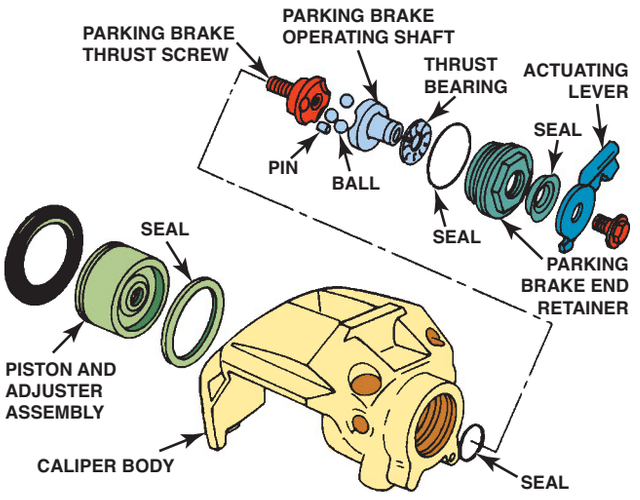

FIGURE 101–30 This single-piston brake caliper is mechanically actuated to serve as a parking brake.

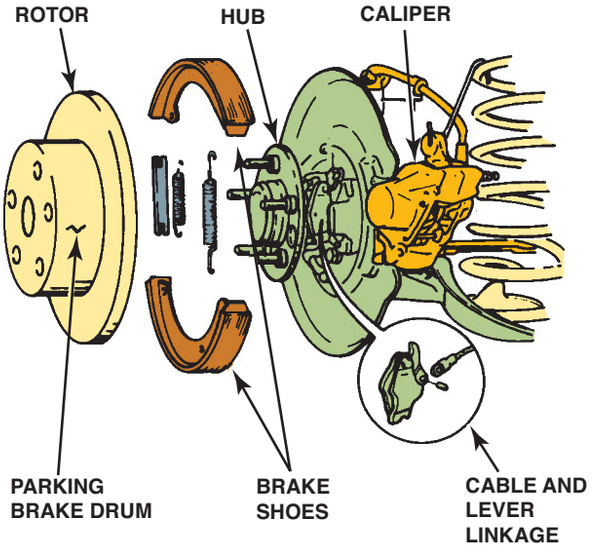

FIGURE 101–31 Drum parking brakes are fitted inside the rotors on this vehicle equipped with rear disc brakes.

REVIEW QUESTIONS

1. What are the advantages and disadvantages of disc brakes?
2. What parts are included in a typical disc brake?
3. How does a low-drag caliper work?
4. What mechanism is used to apply the parking brake on a vehicle equipped with rear disc brakes?
5. What do the abbreviations NAO, NAS, and CFRC mean?

CHAPTER QUIZ

1. What part causes the disc brake caliper piston to retract when the brakes are released?
   a. Return (retracting) spring
   b. The rotating rotor (disc) that pushes the piston back
   c. The square-cut O-ring
   d. The caliper bushings
2. Two technicians are discussing the reason that the brake fluid level in the master cylinder drops. Technician A says that it may be normal due to the wear of the disc brake pads. Technician B says that a low brake fluid level may indicate a hydraulic leak somewhere in the system. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Two technicians are discussing a floating-type disc brake caliper. Technician A says that if the caliper slides are corroded, one pad may wear more than the other pad on the same wheel brake. Technician B says that if a caliper slide is corroded, reduced braking may occur. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. Technician A says that disc brakes are self-adjusting and the brake pedal height should not become lower as the disc brake pads wear. Technician B says that as the disc brake pads wear, the level of brake fluid in the master cylinder reservoir drops. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. Which type of disc brake caliper may leak brake fluid more often?
   a. Sliding
   b. Fixed
   c. Floating
   d. Single-piston
6. A quick-take-up master cylinder is required when what type of caliper design is used on a vehicle?
   a. Fixed
   b. Two-piston
   c. Sliding
   d. Low-drag
7. Technician A says that all vehicles equipped with rear disc brakes use a parking brake that is integrated in the caliper. Technician B says that all vehicles equipped with rear disc brakes use a small drum brake inside the rear rotor for a parking brake. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
8. The brake pad edge code letters “FF” mean _____.
   a. Brand name
   b. Coefficient of friction rating
   c. Quality factor
   d. Noise level rating
9. Semimetallic brake pads are made by a process called _____.
   a. Sintering
   b. Melting
   c. Grating
   d. Composition
10. Technician A says that riveted disc brake pads are often quieter than bonded disc brake pads. Technician B says integrally molded disc brake pads are molded into holes in the steel backing of the pads. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 102

DISC BRAKE DIAGNOSIS AND SERVICE

OBJECTIVES: **After studying Chapter 102, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "C" (Disc Brake Diagnosis and Repair). • List the items that should be checked during a visual inspection. • Describe the caliper disassembly procedure. • Describe the caliper assembly procedure. • List the steps necessary to reduce brake noise.

KEY TERMS: Abutments 1134 • Antiseize compound 1137 • Bedded-in 1136 • Brake assembly fluid 1133 • Burnished 1136 • Constrained layer shims (CLS) 1137 • Lithium-based brake grease 1137 • Loaded calipers 1134 • Minimum thickness 1129 • MOS_2 (molybdenum disulfide) grease 1137 • Phenolic caliper pistons 1130 • Polyalphaolefin (PAO) 1137 • Reaction pads 1134 • Silicone grease 1137 • Synthetic grease 1137 • Ways 1134

DISC BRAKE DIAGNOSTIC PROCEDURES

When diagnosing disc brake concerns, perform the following steps:

STEP 1 The first step is to verify the customer complaint. This step usually includes test driving the vehicle to see if the complaint can be duplicated. If the problem cannot be duplicated, then the repair or service cannot be verified.

CAUTION: Do not test drive the vehicle on public roads if the red brake warning light is on. Perform a visual inspection to determine the reason for the warning light being on and correct before test driving the vehicle.

STEP 2 Check the brake pedal height and verify proper operation. If the brake pedal is low, count the number of "clicks" it takes to apply the parking brake. There should be 3 to 7 clicks. If there are over 10 clicks, check the rear brakes.

STEP 3 Safely hoist the vehicle and remove the wheels. Visually check the following:

- Flexible brake hoses for wear or damage
- Disc brake rotors for excessive rust or scoring
- Disc brake calipers for leakage or damage

STEP 4 Remove disc brake calipers and check the disc brake pads for proper lining thickness and check for cracks or other damage.

STEP 5 Replace all components that do not meet factory specifications.

STEP 6 Test drive the vehicle to verify that the repairs did correct the customer concern.

TECH TIP

Let the Owner Drive

When verifying the customer complaint, ask the owner or driver of the vehicle to drive. Often, the problem is best discovered if the vehicle is being driven exactly the same way as when the complaint first occurred. For example, the technician may brake harder or softer than the driver so the problem may not be detected.

VISUAL INSPECTION

Even with operating wear-indicating sensors, a thorough visual inspection is very important. ● **SEE FIGURE 102–1.** A lining thickness check alone should not be the only inspection performed on a disc brake. *A thorough visual inspection can only be accomplished by removing the friction pads.* ● **SEE FIGURE 102–2** for an example of a disc brake pad that shows usable lining thickness, but is severely cracked and *must* be replaced.

NOTE: Some disc brake pads use a heat barrier (thermo) layer between the steel backing plate and the friction material. The purpose of the heat barrier is to prevent heat from transferring into the caliper piston where it may cause the brake fluid to boil. Do not confuse the thickness of the barrier as part of the thickness of the friction lining material. The barrier material is usually a different color and usually can be distinguished from the lining material.

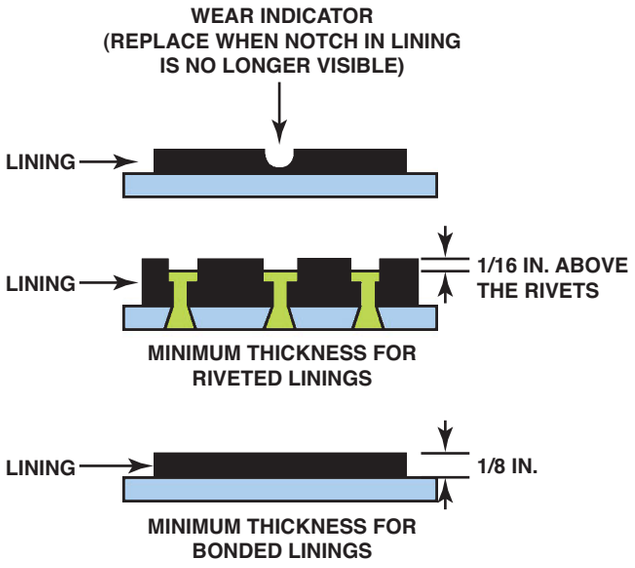

FIGURE 102–1 Minimum thickness for various types of disc brake pads. Pad wear sensors often make a "chirping" sound when the vehicle is moving if the pads are worn. Do not confuse that noise for a defective wheel bearing or other fault.

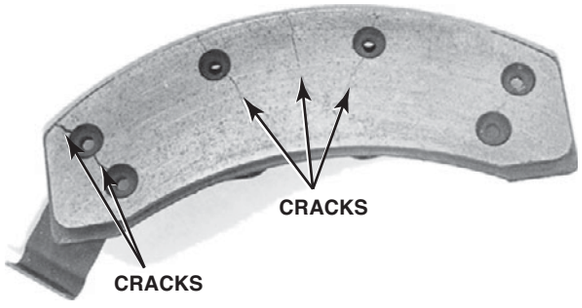

FIGURE 102–2 This cracked disc brake pad must be replaced even though it is thicker than the minimum allowed by the vehicle manufacturer and the wear sensor was not close to the rotor.

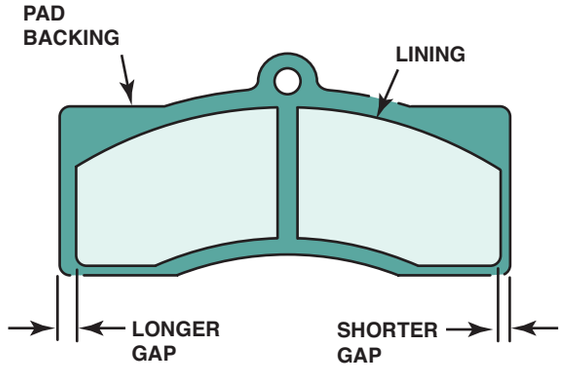

FIGURE 102–3 Be careful to observe the direction in which replacement linings are facing. Some vehicle manufacturers offset the friction material on the steel backing to help prevent or minimize tapered pad wear. Check service information for details as to which direction the pads should be installed.

Some disc brake pads may show more wear on the end of the pad that first contacts the rotor as compared to the trailing end of the pad. This uneven wear is caused by the force between the pad and the abutment (slide area). In designs that place the caliper piston exactly in the center of the leading edge of the pad that first contacts the rotor as it is revolving through the caliper, pressures are often one-third higher than the average pressure exerted on the entire pad. The result of this higher pressure is greater wear.

Brake engineers design brakes to minimize or eliminate tapered pad wear by offsetting the piston more toward the trailing edge of the shoe or by other caliper/pad mounting designs.

One method used to help reduce tapered pad wear is the design that offsets the friction material off center. Be certain to position the pads correctly or severe tapered pad wear will occur. ● **SEE FIGURE 102–3.**

Many calipers are equipped with a brake inspection opening that allows the technician to view the thickness of the brake pads. ● **SEE FIGURE 102–4.**

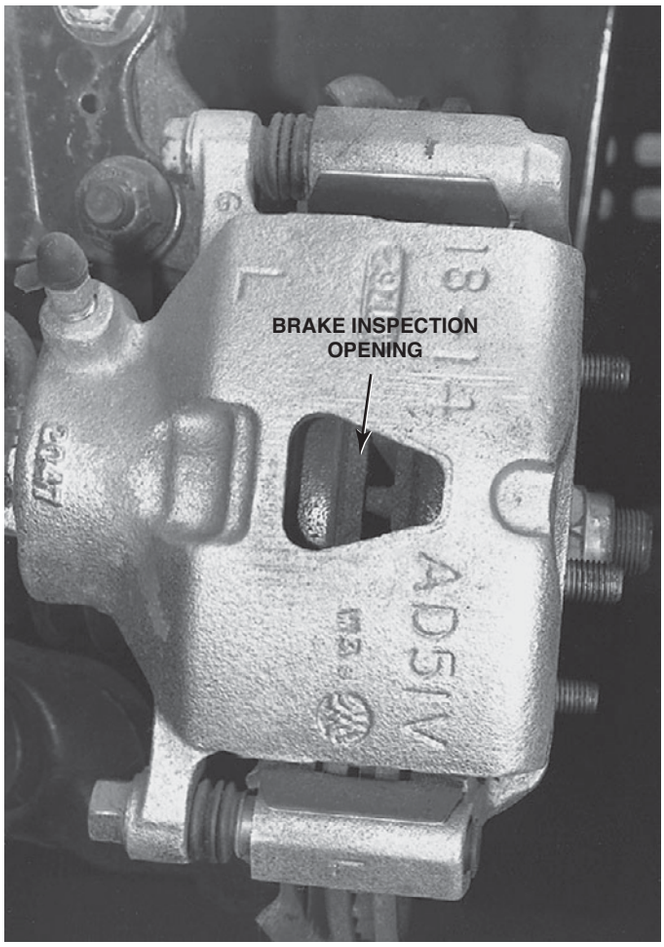

FIGURE 102–4 Most disc brake calipers have a brake inspection opening. For a thorough inspection, however, the caliper should be removed and the entire braking system thoroughly inspected.

TECH TIP

The Bleed and Squirt Test

If you suspect a brake is not being fully released, simply loosen the bleeder valve. If brake fluid squirts out under pressure, then the brake is being kept applied. Look for a defective flexible brake hose.

If the vehicle is off the ground, the wheels should be able to be rotated with the brakes off. If a wheel is difficult or hard to turn by hand and is easy to turn after opening the bleeder valve, then there is a brake fluid restriction between the master cylinder and the brake.

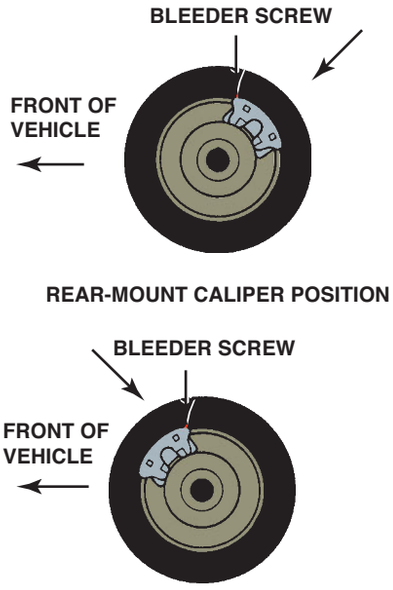

FIGURE 102–5 Both rear- and forward-mounted calipers have the bleeder valve at the top. Some calipers will fit on the wrong side of the vehicle, yet not be able to be bled correctly because the bleeder valve would point down, allowing trapped air to remain inside the caliper bore. If both calipers are being removed at the same time, mark them "left" and "right."

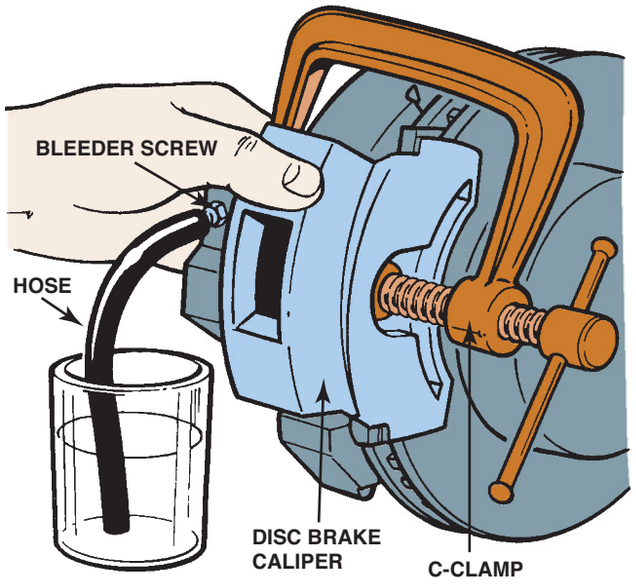

FIGURE 102–7 Most manufacturers recommend that the bleeder valve be opened and the brake fluid forced into a container rather than back into the master cylinder reservoir. This helps prevent contaminated brake fluid from being forced into the master cylinder where the dirt and contamination could cause problems.

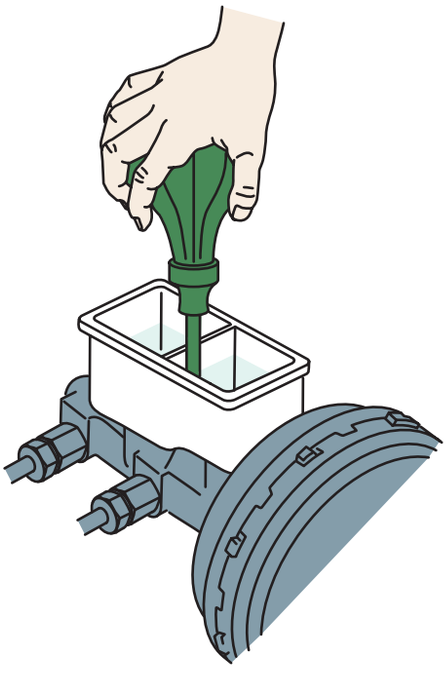

FIGURE 102–6 Many manufacturers recommend removing one-half of the brake fluid from the master cylinder before servicing disc brakes. Use a squeeze bulb and dispose of the used brake fluid properly.

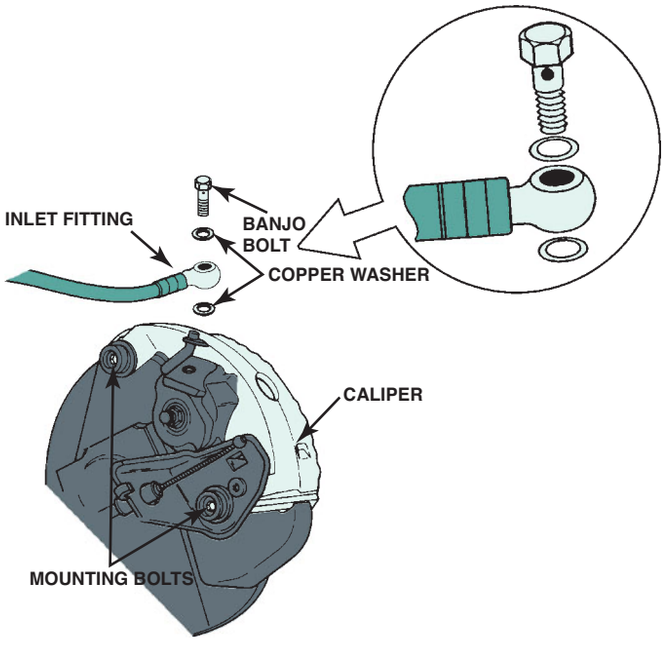

FIGURE 102–8 Many calipers use a hollow "banjo bolt" to retain the flexible brake line to the caliper housing. The fitting is usually round like a banjo. The copper washers should always be replaced and not reused.

DISC BRAKE CALIPER SERVICE

REMOVAL Hoist the vehicle and remove the wheel(s). Note the caliper mount position as shown in ● **FIGURE 102–5** before removing the caliper. Knowing whether the caliper is "rear-mount" position or "forward-mount" position is often needed when purchasing replacement calipers. Remove the caliper following the steps shown in ● **FIGURES 102–6 THROUGH 102–10.**

INSPECTION AND DISASSEMBLY Check for brake fluid in and around the piston boot area. If the boot is damaged or a fluid leak is visible, then a caliper assembly repair or replacement is required. ● **SEE FIGURES 102–11 AND 102–12.**

PHENOLIC CALIPER PISTONS. **Phenolic caliper pistons** are made from a phenol-formaldehyde resin combined with various reinforcing fibers. When phenolic brake caliper pistons were first used, the results were not good and the problem was blamed on "those *darn* plastic pistons." What was happening was that the pistons were

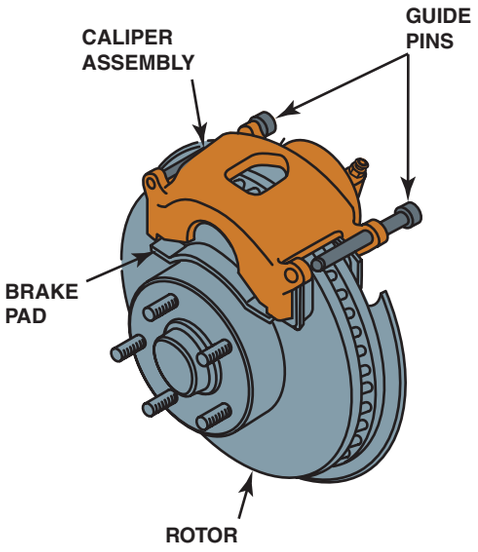

FIGURE 102–9 Caliper retaining bolts are often called guide pins. These guide pins are used to retain the caliper to the steering knuckle. These pins also slide through metal bushings and rubber O-rings.

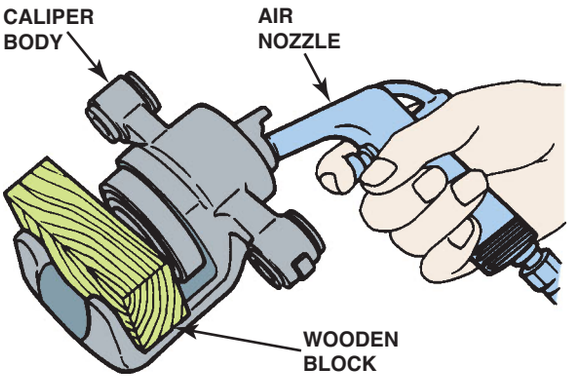

FIGURE 102–11 A wooden block or a folded shop cloth helps prevent damage when caliper pistons are removed. Use extreme care when removing a caliper piston using compressed air. The pressure applied can force the piston out of the caliper with tremendous force. Always follow service information instructions.

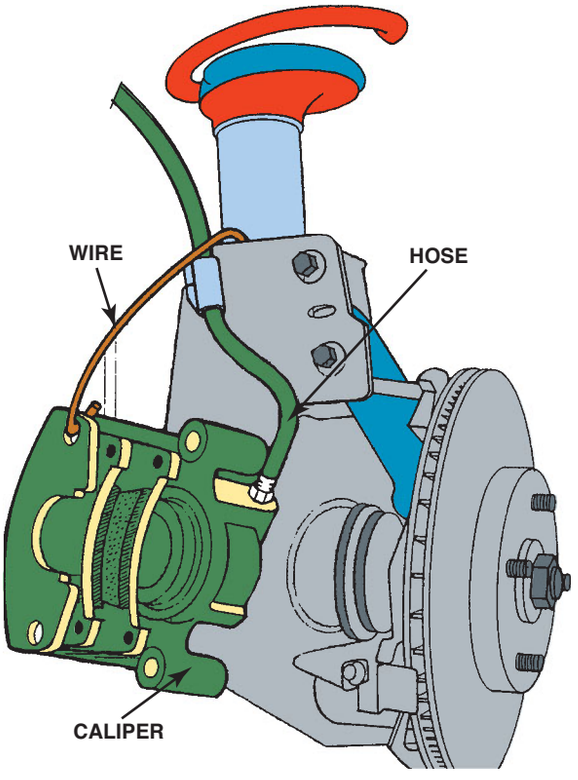

FIGURE 102–10 If the caliper is not being removed, it must be supported properly so that the weight of the caliper is not pulling on the flexible rubber brake line. A suitable piece of wire, such as a coat hanger, may be used.

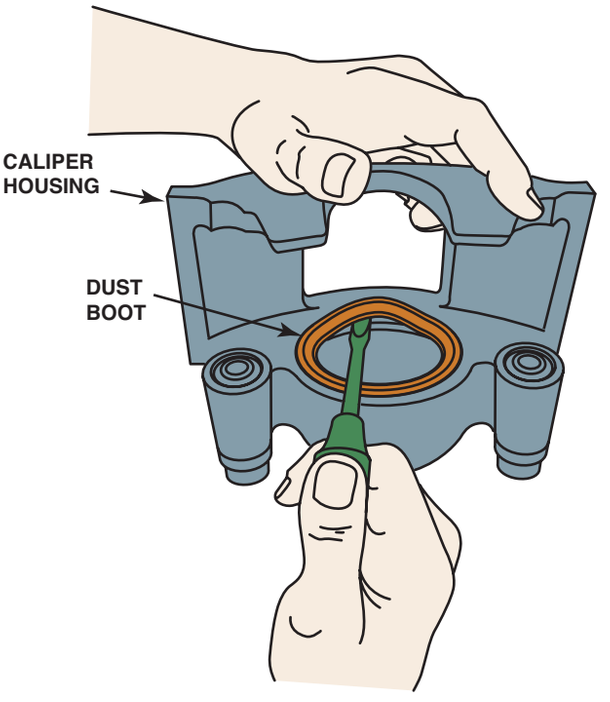

FIGURE 102–12 After the piston is removed from the caliper housing, the dust boot can often be removed using a straight-blade screwdriver.

becoming stuck in the caliper, which caused the brake pads to remain applied. This caused the brake pads to wear out very rapidly. The problem occurred because the phenolic pistons absorbed moisture and swelled in size.

NOTE: Uneven disc brake pad wear (inside pad compared to the outside pad) can be caused by a stuck caliper piston or if the caliper is unable to "float."

Phenolic caliper pistons are natural thermal insulators and help keep heat generated by the disc brake pads from transferring through the caliper piston to the brake fluid. Phenolic brake caliper pistons are also lighter in weight than steel caliper pistons and are usually brown in color. ● **SEE FIGURE 102–13.**

STEEL CALIPER PISTONS. Many manufacturers still use steel pistons. The stamped steel pistons are plated first with nickel, then chrome to achieve the desired surface finish. ● **SEE FIGURE 102–14.** Unlike phenolic caliper pistons, steel pistons can transfer heat from the brake pads to the brake fluid. The surface finish on a steel piston is critical. Steel can rust and corrode. Any surface pitting can cause the piston to stick.

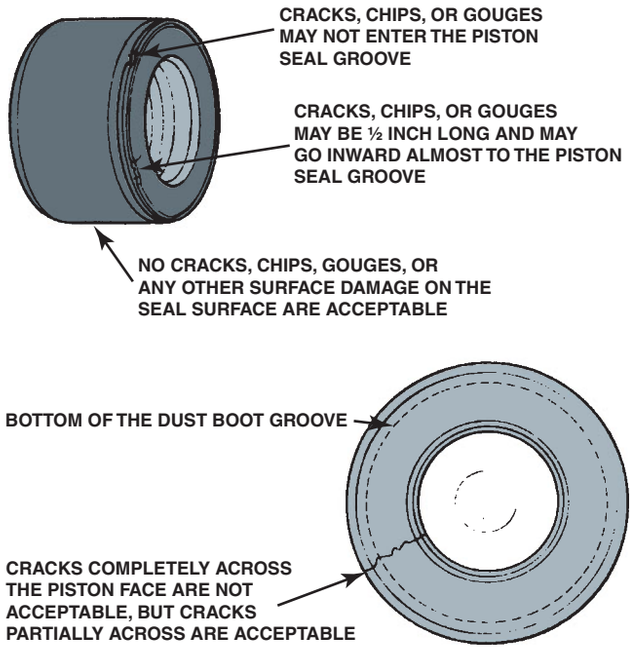

FIGURE 102–13 Phenolic (plastic) pistons should be carefully inspected.

FIGURE 102–14 If there are any surface flaws such as rust pits on the piston, it should be replaced.

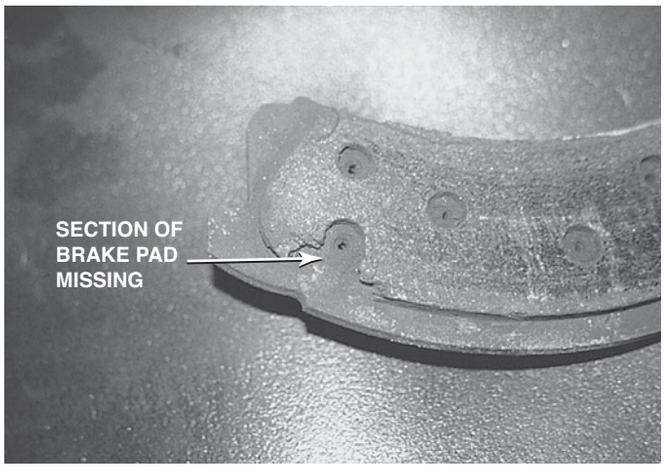

FIGURE 102–15 These pads were found to be cracked and a section was missing from a part of one pad.

REAL WORLD FIX

Three Brake Jobs in 40,000 Miles

A service technician was asked to replace the front disc brake pads on a Pontiac Grand Am because the sensors were touching the rotors and making a squealing sound. This was the third time that the front brakes needed to be replaced. Previous brake repairs had been limited to replacement of the front disc brake pads only.

When the caliper was removed and the pads inspected, it was discovered that a part of one pad had broken and a piece of the lining was missing. ● **SEE FIGURE 102–15.**

Then the technician spotted something at the rear of the vehicle that told the whole story—a trailer hitch.

The owner confirmed that a heavy jet ski was towed in hilly terrain. The technician recommended overhauling the front disc brake calipers to prevent the possibility of the front pads dragging. The technician also recommended an inspection of the rear brakes. The rear brakes were glazed and out-of-adjustment. The technician received permission to replace the rear brakes, overhaul both front calipers, and install quality disc brake pads. When the customer returned, the technician advised the customer to use the transmission on long downhill roads to help keep the brakes from overheating and failing prematurely.

NOTE: Care should be taken when cleaning steel pistons. Use crocus cloth to remove any surface staining. Do not use sandpaper, emery cloth, or any other substance that may remove or damage the chrome surface finish.

SERVICING DISC BRAKE CALIPERS

INSPECTION After removing the caliper piston then remove the square-cut O-ring. ● **SEE FIGURE 102–16.** Then the caliper should be thoroughly cleaned in denatured alcohol and closely examined. If the caliper bore is rusted or pitted, some manufacturers recommend that a special hone be used, as shown in ● **FIGURE 102–17.**

Some manufacturers do *not* recommend honing the caliper bore because the actual sealing surface in the caliper is between the piston seal and the piston itself. This is the reason why the surface condition of the piston is so important.

CALIPER ASSEMBLY To assemble the disc brake caliper, perform the following steps:

STEP 1 Carefully clean the caliper bore with clean brake fluid from a sealed container. Coat a new piston seal with clean brake fluid and install it in the groove inside the caliper bore, as shown in ● **FIGURE 102–18**.

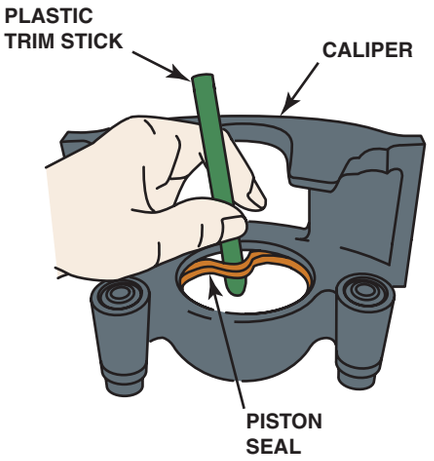

FIGURE 102–16 Removing the square-cut O-ring seal from the caliper bore. Use a wooden or plastic tool to prevent damage to the seal groove.

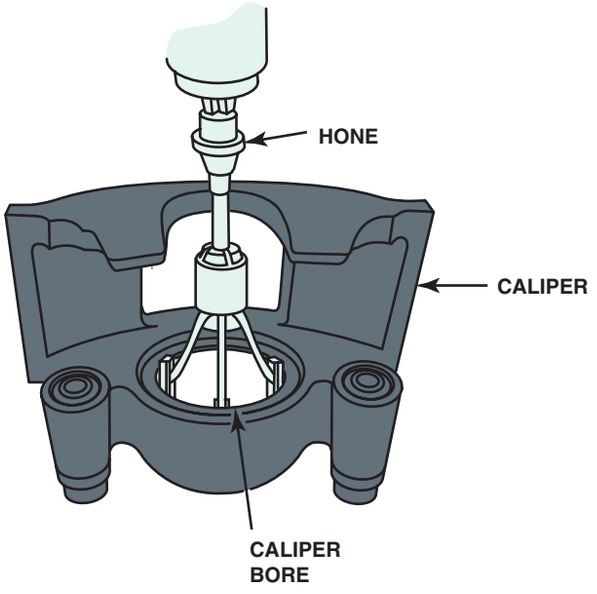

FIGURE 102–17 Some manufacturers recommend cleaning the inside of the caliper bore using a honing tool as shown. Even though the caliper piston does not contact the inside of this bore, removing any surface rust or corrosion is important to prevent future problems. If the honing process cannot remove any pits or scored areas, the caliper should be replaced.

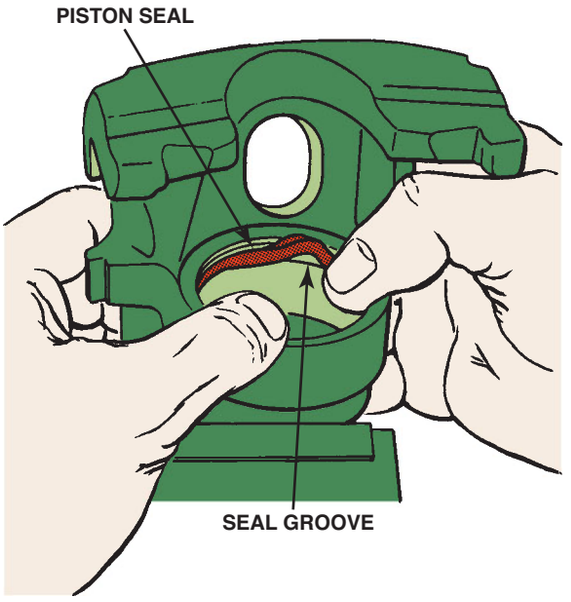

FIGURE 102–18 Installing a new piston seal. Never reuse old rubber parts. A caliper overhaul kit includes just two items: the square-cut piston seal O-ring and dust boot.

FIGURE 102–19 Brake assembly fluid or clean brake fluid from a sealed container can be used to lubricate the caliper seal and caliper pistons before assembly.

STEP 2 Check the piston-to-caliper bore clearance. Typical piston-to-caliper bore clearance is as follows.

- steel piston 0.002–0.005 in. clearance (0.05–0.13 mm)
- phenolic piston 0.005–0.010 in. clearance (0.102–0.25 mm)

STEP 3 Coat a new piston boot with brake fluid or **brake assembly fluid.** ● **SEE FIGURE 102–19**. Brake assembly fluid is similar to brake fluid but has antiwear additives.

STEP 4 Install the piston into the caliper piston, as shown in ● **FIGURES 102–20 AND 102–21**.

STEP 5 Some caliper boots require a special boot-seating tool, as shown in ● **FIGURE 102–22**.

STEP 6 Always lubricate caliper bushings, shims, and other brake hardware as instructed by the manufacturer. ● **SEE FIGURE 102–23**.

STEP 7 The pads should also be securely attached to the caliper as shown in ● **FIGURES 102–24 AND 102–25**.

CAUTION: Installing disc brake pads on the wrong side of the vehicle (left versus right) will often prevent the sensor from making noise when the pads are worn down.

CALIPER MOUNT SERVICE When the hydraulic force from the master cylinder applies pressure to the disc brake pads, the entire caliper tends to be forced in the direction of rotation of the

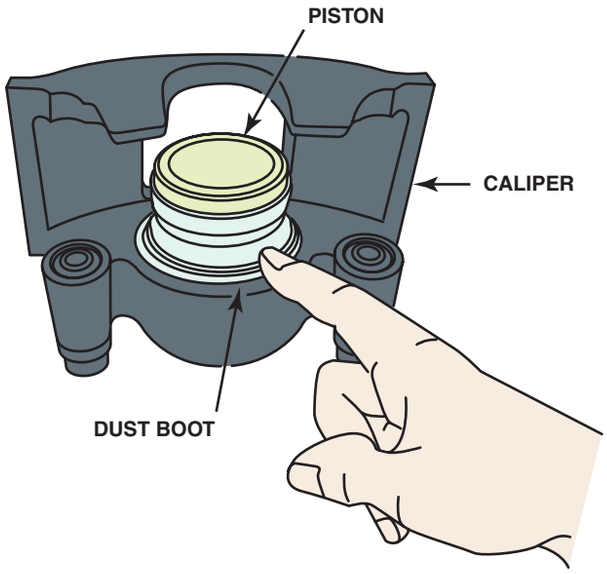

FIGURE 102–20 Installing the caliper piston. Many calipers require that the dust boot be installed in the groove of the piston and/or caliper before installing the piston.

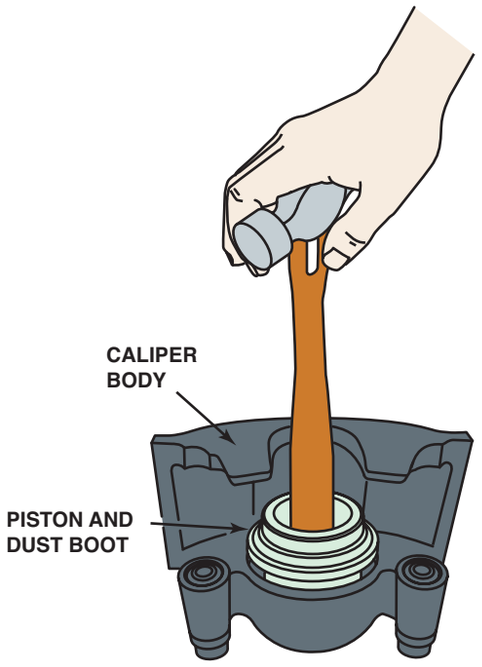

FIGURE 102–21 Installing a piston into a caliper. Sometimes a C-clamp is needed to install the piston. Both the piston and the piston seal should be coated in clean brake fluid before assembly.

TECH TIP

Using "Loaded Calipers" Saves Time

Many technicians find that disassembly, cleaning, and rebuilding calipers can take a lot of time. Often the bleeder valve breaks off or the caliper piston is too corroded to reuse. This means that the technician has to get a replacement piston, caliper overhaul kit (piston seal and boot), plus the replacement friction pads and hardware kit.

To save time (and sometimes money), many technicians are simply replacing the old used calipers with "loaded calipers." **Loaded calipers** are remanufactured calipers that include (come loaded with) the correct replacement friction pads and all the necessary hardware. ● **SEE FIGURE 102–26.**

Therefore, only one part number is needed for each side of the vehicle for a complete disc brake overhaul.

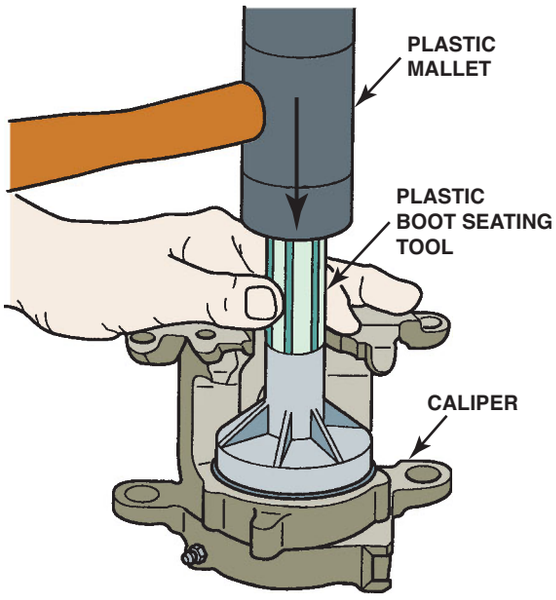

FIGURE 102–22 Seating the dust boot into the caliper housing using a special plastic seating tool.

rotor. All calipers are mounted to the steering knuckle, caliper support bracket, or axle housing. ● **SEE FIGURE 102–27.**

All braking force is transferred through the caliper to the mount. The places where the caliper contacts the caliper mount are called the **abutments, reaction pads,** or **ways.** The sliding surfaces of the caliper support should be cleaned with a wire brush and coated with a synthetic grease or antiseize compound according to manufacturers' recommendations. ● **SEE FIGURE 102–28.**

ROTATING PISTONS BACK INTO THE CALIPER

Many disc brake calipers used on the rear wheels require that the piston be rotated to reseat the pistons. When the parking brake is applied, the actuating screw moves the piston outward, forcing the pads against the disc brake rotor. The piston is kept from rotating because of an antirotation device or notches on the inboard pad and piston.

When the disc brake pads are being replaced, use a special tool to rotate the piston back into the brake calipers. Insert the tip of the tool in the holes or slots in the piston. Exert inward pressure while turning the piston. Make sure that the piston is retracting into the caliper and continue to turn the piston until it bottoms out.

NOTE: Some pistons are activated with left-handed threads.

After replacing the pads back into the caliper, check that the clearance does not exceed 1/16 in. (1.5 mm) from the rotor. Clearance greater than 1/16 in. may allow the adjuster to be pulled out of the piston when the service brake is applied. If the clearance

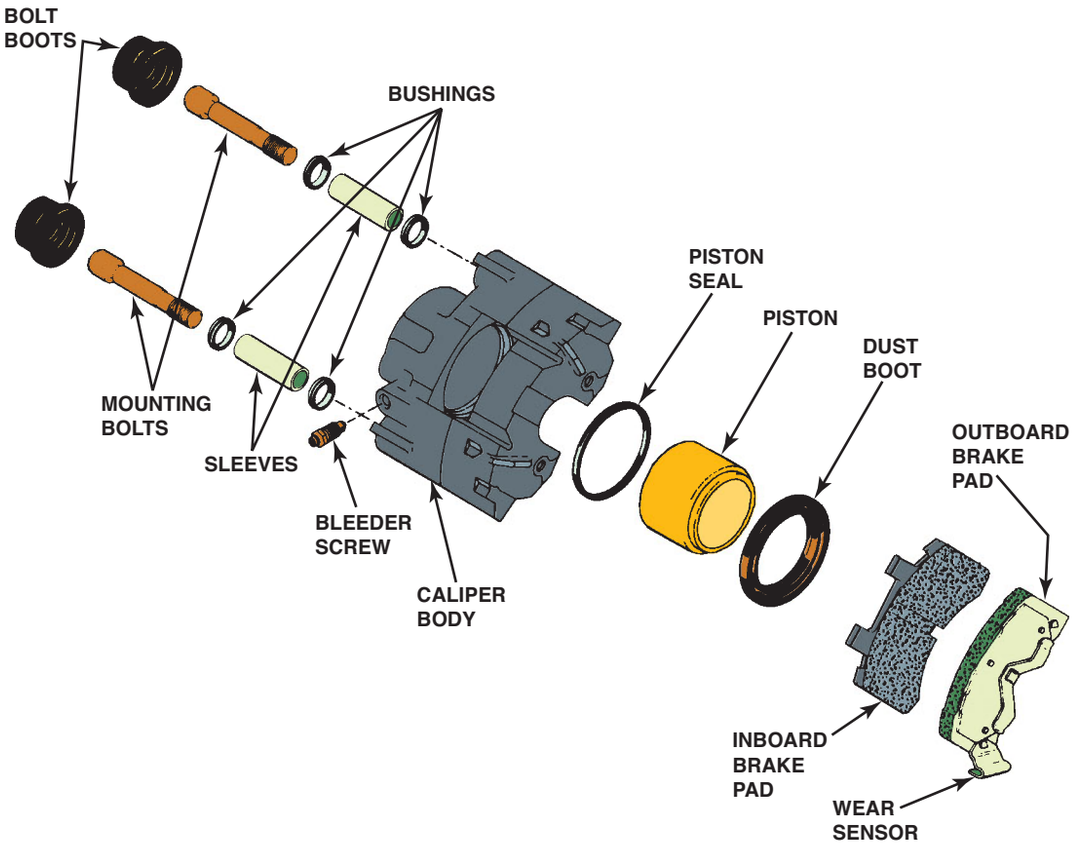

FIGURE 102–23 All rubber bushings should be lubricated with silicone brake grease for proper operation.

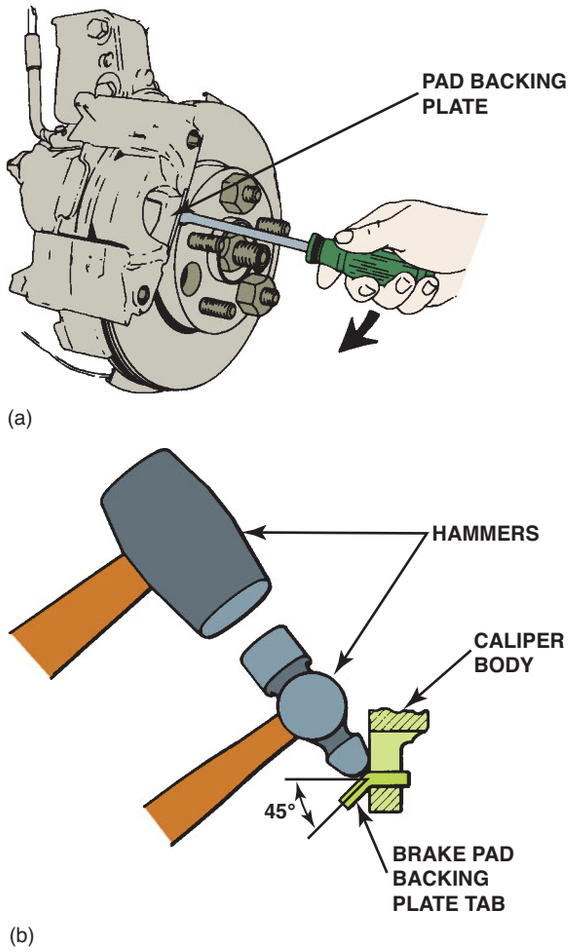

FIGURE 102–24 (a) Using a screwdriver to force the outboard pad into proper position before bending the retaining tabs. (b) Use two hammers to bend the tab where it extends through the hole in the caliper body.

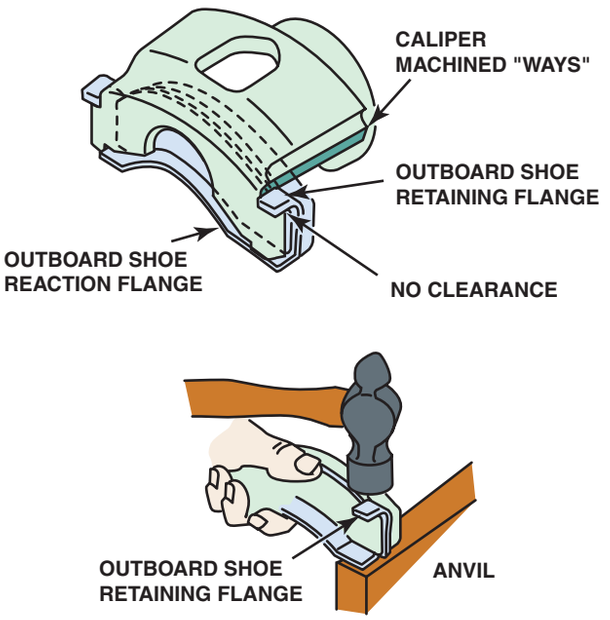

FIGURE 102–25 Often, a hammer is necessary to bend the retainer flange to make certain that the pads fit tightly to the caliper. If the pads are loose, a "click" may be heard every time the brakes are depressed. This click occurs when the pad(s) move and then hit the caliper or caliper mount. If the pads are loose, a clicking noise may be heard while driving over rough road surfaces.

is greater than 1/16 in., readjust by rotating the piston outward to reduce the clearance. ● **SEE FIGURE 102–29.**

TEST DRIVE AFTER BRAKE REPLACEMENT After installing replacement disc brake pads or any other brake work, depress the brake pedal several times before driving the vehicle. This is a very important

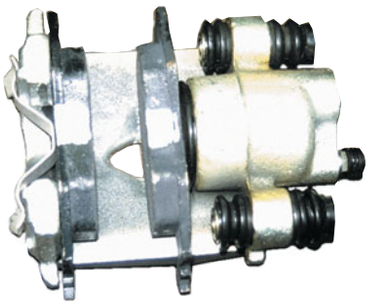

FIGURE 102–26 A loaded caliper includes all hardware and shims with the correct pads all in one convenient package, ready to install on the vehicle.

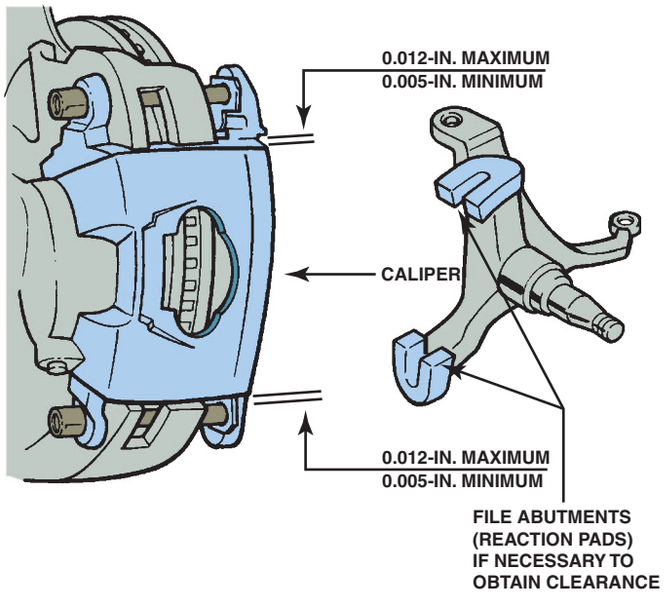

FIGURE 102–27 Floating calipers must be able to slide during normal operation. Therefore, there must be clearance between the caliper and the caliper mounting pads (abutments). Too little clearance will prevent the caliper from sliding and too much clearance will cause the caliper to make a clunking noise when the brakes are applied.

FIGURE 102–28 Using an air-powered sanding disc to clean the caliper mount pads.

step! New brake pads are installed with the caliper piston pushed all the way into the caliper. The first few brake pedal applications usually result in the brake pedal going all the way to the floor. The brake pedal must

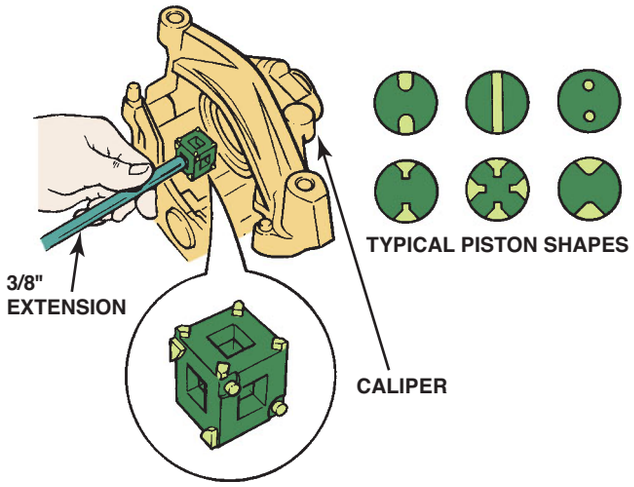

FIGURE 102–29 Determine which face of the special tool best fits the holes or slots in the piston. Sometimes needle-nose pliers can be used to rotate the piston back into the caliper bore.

FIGURE 102–30 Note the twisted flexible brake line. This was caught by an automotive instructor before the brake work on the vehicle was completed. The twisted brake line can cause brake hose failure if not corrected.

TECH TIP

Always Double-Check Your Work

Whenever reassembling brakes, it is easy to twist the flexible brake hose as shown in ● **FIGURE 102–30.** To prevent possible brake hose failure and possibly an accident, always double-check that the ribs on the brake hose are straight. The ribs allow the service technician to easily spot if the hose has been twisted.

be depressed ("pumped") several times before enough brake fluid can be moved from the master cylinder into the calipers to move the piston tight against the pads and the pads against the rotors.

CAUTION: Never allow a customer to be the first to test drive the vehicle after brake work has been performed.

BEDDING-IN REPLACEMENT BRAKE PADS Some manufacturers recommend that their replacement brake pads be **bedded-in** or **burnished** before returning the vehicle to the owner. This break-in

TECH TIP

Increasing Pad Life

Many vehicles seem to wear out front disc brakes more often than normal. Stop-and-go city-type driving is often the cause. Driving style, such as rapid stops, also causes a lot of wear to occur.

The service technician can take some actions to increase brake pad life that are easier than having to cure the driver's habits. These steps include the following.

1. Make sure the rear brakes are properly adjusted and working correctly. If the rear brakes are not functioning, all of the braking is accomplished by the front brakes alone.

   NOTE: Remind the driver to apply the parking brake regularly to help maintain proper rear brake clearance on the rear brakes.

2. Use factory brake pads or premium brake pads from a known manufacturer. Tests performed by vehicle manufacturers show that many aftermarket replacement brake pads fail to deliver original equipment brake pad life.

FIGURE 102–31 For best braking performance, purchase replacement disc brake pads that include all clips and shims specified by the vehicle manufacturer. Some pads even come with a package of the specified grease to use on the shims to reduce the possibility of brake noise.

process varies with the manufacturer, but usually involves stopping the vehicle from 30 mph (48 km/h) up to 30 times, allowing the brakes to cool 2 to 3 minutes between stops. This break-in procedure helps the replacement pads to conform to the rotor and helps cure the resins used in the manufacture of the pads. Failure to properly break in new pads according to the manufacturer's recommended procedure could result in a hard brake pedal complaint from the driver and/or reduced braking effectiveness.

Even if the brake pad manufacturer does not recommend a break-in procedure, high-speed stops and overheating of the brakes should be avoided as much as possible during the first 50 to 100 stops.

DISC BRAKE SQUEAL CORRECTION

CAUSES OF BRAKE SQUEAL Disc brakes tend to create brake noise (squeal). The cause and correction of brake noise is a major concern for both the vehicle manufacturers and the service technicians. The greatest customer complaint about brake work involves brake noise. Noise is caused by moving air, which is a result of moving brake components.

CORRECTING DISC BRAKE SQUEAL Brake squeal can best be *prevented* by careful attention to details whenever servicing any disc brake. Some of these precautions include the following:

- **Keep the Disc Brake Pads Clean.** Grease on brake lining material causes the friction surface to be uneven. When the brakes are applied, this uneven brake surface causes the brake components to move.
- **Use Factory-Type Clips and Anti-Squeal Shims.** The vehicle manufacturer has designed the braking system to be as quiet as possible. To assure that the brakes are restored to like-new performance, all of the original hardware should be used. Many original equipment brake pads use **constrained layer shims (CLS)** on the back of the brake pads. These shims are constructed with dampening material between two layers of steel. ● **SEE FIGURE 102–31.**

  NOTE: Many aftermarket disc brake pads do *not* include replacement hardware that usually includes noise-reducing shims and clips. One of the advantages of purchasing original equipment (OE) disc brake pads is that they usually come equipped with all necessary shims and often with special grease that is recommended to be used on metal shims.

- **Lubricate All Caliper Slide Points as per Manufacturer's Recommendation.** Lubrication of moving or sliding components prevents noise from being generated as the parts move over each other. Many vehicle manufacturers recommend one or more of the following greases:
  1. **Lithium-based brake grease**
  2. **Silicone grease**
  3. **Molybdenum disulfide (MOS_2) grease** ("Molykote") often referred to as "moly" grease
  4. **Synthetic grease** (usually **polyalphaolefin [PAO]**) sometimes mixed with graphite, Teflon, and/or MOS_2
  5. **Antiseize compound**

  The lubricant should be applied on both sides of shims used between the pad and the caliper piston.

CAUTION: Lubricant should only be applied to the non-friction (steel) side of the disc brake pads.

- **Machine the Brake Rotor as Little as Possible and with the Correct Surface Finish.** Machining the brake rotor reduces its thickness. A thinner rotor will vibrate at a different frequency than a thicker rotor. For factors that can help or hurt brake squeal, ● **SEE CHART 102–1.**

Vehicle manufacturers also change brake pad (lining) composition and the shape of the pads to help eliminate brake noise. The change of shape changes the frequency of the sound. Noise is vibration, but much of the vibration generated is not heard because the noise is beyond the normal frequency to be heard. Most people can hear from 20 to 20,000 cycles per second (called hertz). To stop brake noise, the manufacturer can change the frequency of the vibration to above or below the hertz range that can be heard. ● **SEE FIGURE 102–32.**

NOTE: All metal-to-metal contacts *must* be lubricated to help prevent brake noise.

FACTOR	INCREASE NOISE	REDUCE NOISE
Brake pad thickness	Thinner (worn) pads	Thicker (new) pads
Rotor (disc) thickness	Thinner (worn) rotor	Thicker (new) rotor
Brake pad material	Harder	Softer
Lubrication of parts	Dry—not lubricated	Properly lubricated
Dampening	No dampening	Dampening material behind the pads
Pad mounting	Pad tabs not bent over	Pad tabs securely crimped
Antirattle clips	Worn, defective, or not lubricated	New and properly lubricated

CHART 102–1

The causes of brake noise can have many reasons and corrections.

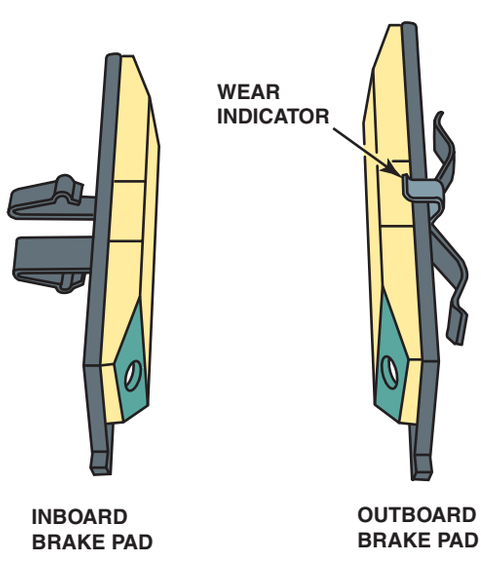

FIGURE 102–32 Notice the beveled pads. The shape of the pad helps reduce brake noise.

DISC BRAKE SYMPTOM GUIDE

PULLS TO ONE SIDE DURING BRAKING

Possible causes of this include the following:

1. Incorrect or unequal tire pressures
2. Front end out of alignment
3. Unmatched tires on the same axle

TECH TIP

The Screwdriver Trick

A low brake pedal on GM vehicles equipped with rear disc brakes is a common customer complaint. Often the reason is a lack of self-adjustment that *should* occur whenever the brake pedal (or parking brake) is released. During brake release, the pressure is removed from the caliper piston and the spring inside the caliper piston is free to adjust. Often this self-adjustment does not occur and a low brake pedal results.

A common trick that is used on the vehicle assembly line is to use a screwdriver to hold the piston against the rotor while an assistant releases the brake pedal. ● **SEE FIGURE 102–33.**

As the brake pedal is released, the adjusting screw inside the caliper piston is free to move. Sometimes, it may be necessary to tap on the caliper itself with a dead-blow hammer to free the adjusting screw. Repeat the process as necessary until the proper brake pedal height returns.

If this method does not work, replace the caliper assembly.

In summary, recall these steps.

STEP 1 Have an assistant depress the brake pedal.

STEP 2 Using a screwdriver through the hole in the top of the caliper, hold the piston against the rotor.

NOTE: Be careful not to damage the dust boot.

STEP 3 While still holding the piston against the rotor, have the assistant release the brake pedal. The adjusting screw adjusts when the brake pedal is *released* and a slight vibration or sound will be noticed as the brake is released. This vibration or sound is created by the self-adjusting mechanism inside the caliper piston taking up the excess clearance.

STEP 4 Repeat as necessary until normal brake pedal height is achieved.

4. Restricted brake lines or hoses
5. Stuck or seized caliper or caliper piston
6. Defective or damaged shoe and lining (grease or brake fluid on the lining, or a bent shoe)
7. Malfunctioning rear brakes
8. Loose suspension parts
9. Loose calipers

BRAKE ROUGHNESS OR CHATTER (PEDAL PULSATES)

Possible causes of this include the following:

1. Excessive lateral runout of rotor
2. Parallelism of the rotor not within specifications
3. Wheel bearings not adjusted correctly
4. Rear drums out-of-round
5. Brake pads worn to metal backing plate

EXCESSIVE PEDAL EFFORT

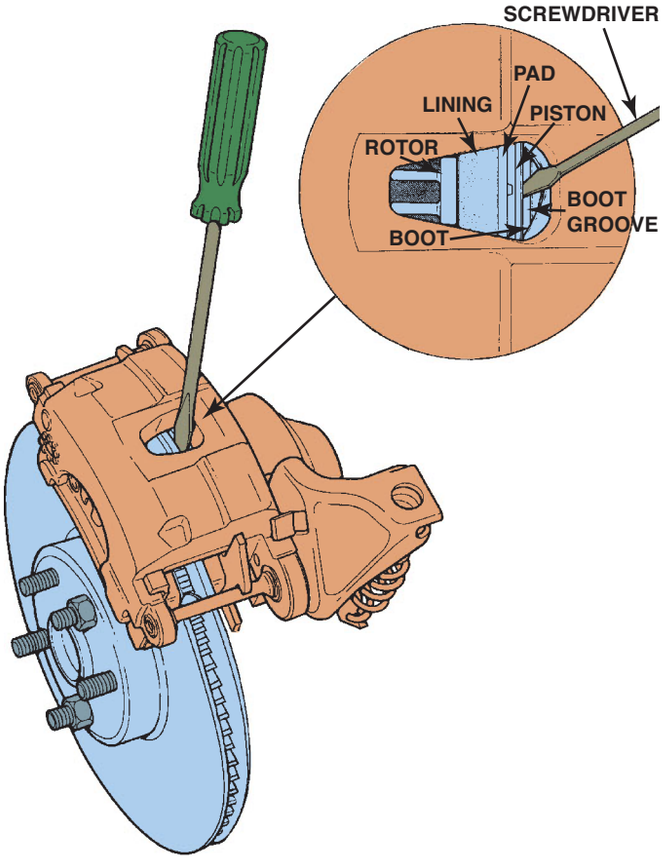
Possible causes of this include the following:

1. Binding or seized caliper mounting
2. Binding brake pedal mechanism
3. Improper rotor surface finish
4. Malfunctioning power brake
5. Partial system failure
6. Excessively worn shoe and lining
7. Piston in the caliper stuck or sluggish
8. Fading brakes due to incorrect lining

EXCESSIVE PEDAL TRAVEL

Possible causes of this include the following:

1. Partial brake system failure
2. Insufficient fluid in the master cylinder
3. Air trapped in the system
4. Bent shoe and lining
5. Excessive pedal effort
6. Excessive parking brake travel (four-wheel disc brakes, except Corvette)



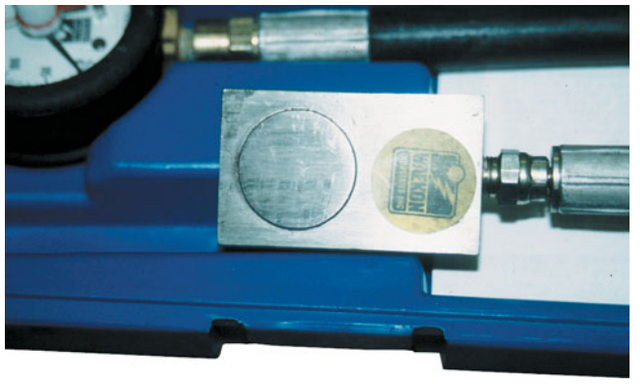


FIGURE 102–33 The screwdriver blade is used to keep the piston applied to allow self-adjustment to occur when the brake pedal is released.

(a)

(b)

FIGURE 102–34 (a) A brake pressure tester. (b) The small "pads" can be placed between the caliper piston and the rotor to check for applied pressure and inserted between the caliper and the rotor on the outside of the rotor to test the pressure—the pressure should be the same if the caliper is able to slide on its pins or slides.

TECH TIP

Pressure Testing Can Help Find Problems

A stuck caliper or caliper slide is often difficult to see or diagnose as a problem because the movement of the broken pads is so little. Using a pressure gauge between the caliper piston and the rotor (inboard) or between the rotor and the caliper (outboard) can tell the service technician if there is a difference between the left and the right side brakes. ● **SEE FIGURE 102–34.**

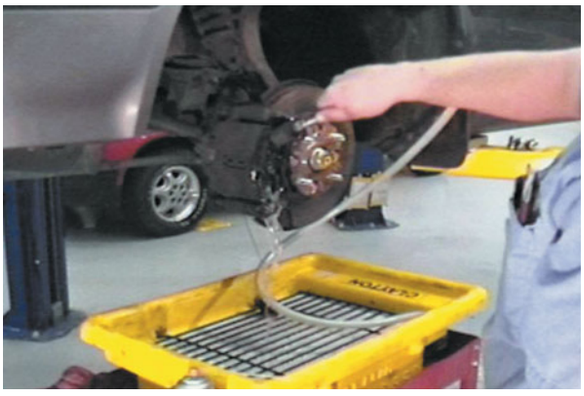
DRAGGING BRAKES Possible causes of this include the following:

1. Pressure trapped in the brake lines (to diagnose, momentarily open the caliper bleeder valve to relieve the pressure)
2. Restricted brake tubes or hoses
3. Improperly lubricated caliper mounting system
4. Improper clearance between the caliper and torque abutment surfaces
5. Check valve installed in the outlet of the master cylinder to the disc brakes
6. Stuck caliper caused from rusted sliding points or rusty mounting bolts/bushings.
7. Stuck caliper piston

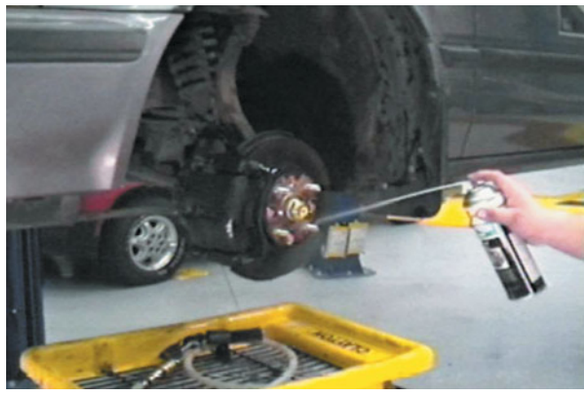
FRONT DISC BRAKES VERY SENSITIVE TO LIGHT BRAKE APPLICATIONS Possible causes of this include the following:

1. Metering valve not holding off the front brake application
2. Incorrect lining material
3. Improper rotor surface finish
4. Check other causes listed under “PULLS”
5. Contaminated brake pad lining material from wheel bearing grease.

REAR DRUM BRAKES SKIDDING UNDER HARD BRAKE APPLICATIONS Possible causes of this include the following:

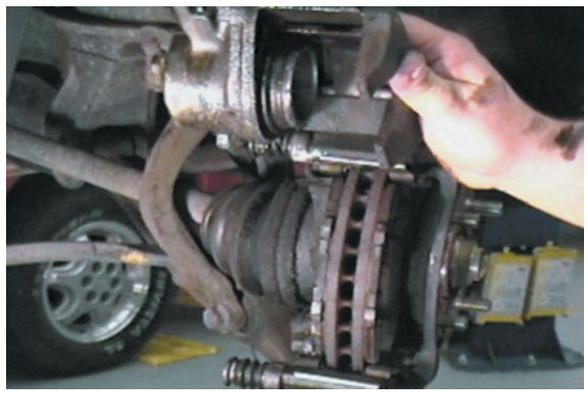


1. Proportioning valve
2. Contaminated rear brake lining
3. Caliper or caliper piston stuck or corroded



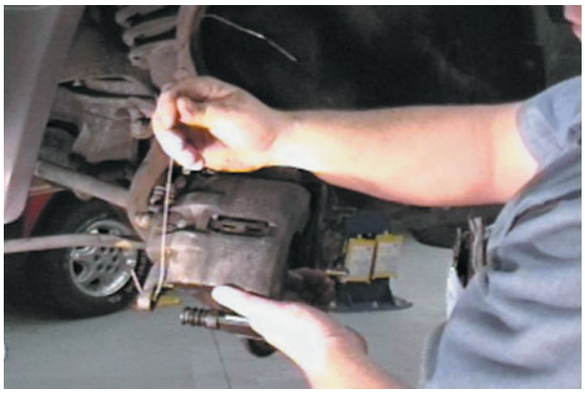
1 After properly setting the hoist pads under the vehicle, raise the vehicle to chest level and remove the lug nuts.

2 Remove the wheel/tire assembly and place it where it will not get in the way or be damaged.

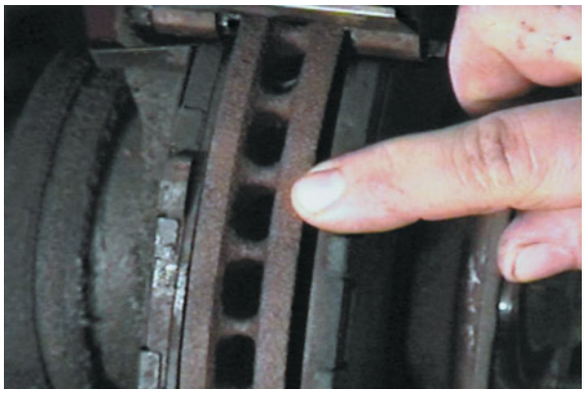


3 It is recommended that the entire brake assembly be washed using a commercially available cleaner to avoid the possibility of allowing brake dust from becoming airborne.

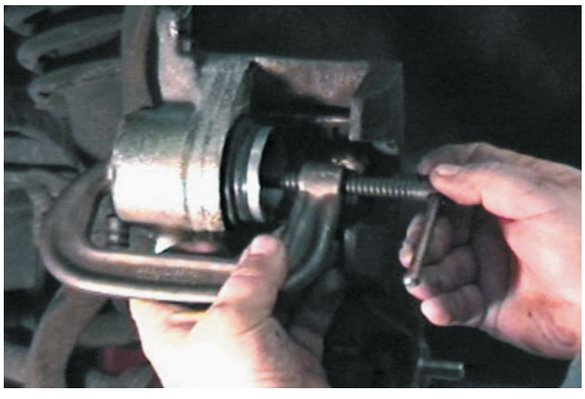
4 If a commercial brake cleaning unit is not available, use brake cleaner from an aerosol or pressurized container.



5 To service the front disc brake pads on this vehicle, loosen the upper caliper retainer bolt and remove the lower bolt.



6 After the lower caliper bolt has been removed, the caliper assembly can be lifted upward by pivoting on the upper retaining bolt.

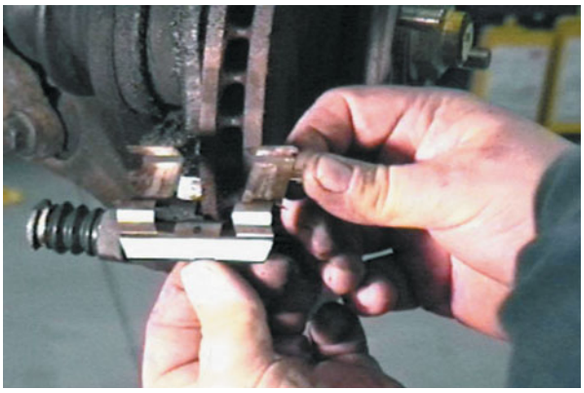


CONTINUED ▶

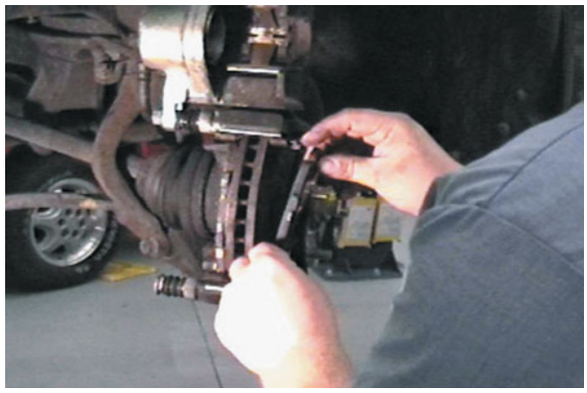
7 Use mechanic's wire to hold the caliper in the raised position to allow access to the disc brake pads.

8 Notice that both the inboard and outboard pad remain attached to the steering knuckle. The pads and shims can be lifted off.

9 A C-clamp can be used to push the piston into the caliper, but be sure to open the bleeder valve first.

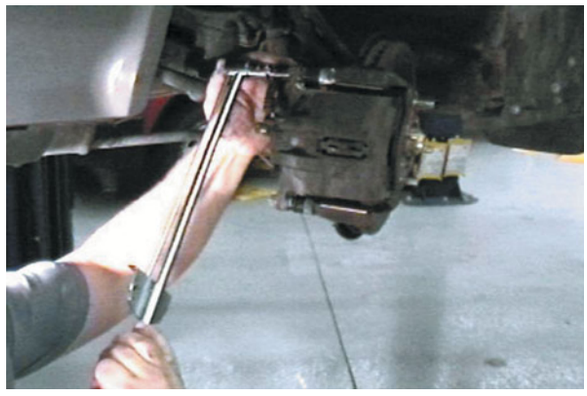


10 The bleeder valve should be opened to allow the old brake fluid to flow out of the caliper and not be forced up into the ABS hydraulic unit or master cylinder.



11 Often factory replacement disc brake pads include noise-dampening shims, antirattle clips, and special "moly" disc brake grease that is to be used on the shims.

12 All hardware, including this anchor shim, should be replaced.



13 Install new shims after thoroughly cleaning the steering knuckle area of any rust using a wire brush or other suitable tool.

14 The replacement disc brake pads are installed next to the rotor and held in place by the tension of the anchor shims.

15 After double-checking that all shims, clips, and spacers are correctly installed, lower the calipers and install this lower attaching bolt.

16 Torque the retaining bolts to factory specifications. Repeat the process on the other side and bleed the hydraulic system.

17 Reinstall the wheel/tire assembly.

18 Torque the lug nuts to factory specifications or use a torque-limiting adapter. Test drive the vehicle before returning it to the customer.

REVIEW QUESTIONS

1. List what parts are included in a typical overhaul kit for a single-piston floating caliper.
2. Describe how to remove caliper pistons and perform a caliper overhaul.
3. Explain what causes disc brake squeal and list what a technician can do to reduce or eliminate the noise.

CHAPTER QUIZ

1. Uneven disc brake pad wear is being discussed. Technician A says the caliper piston may be stuck. Technician B says the caliper may be stuck on the slides and unable to "float." Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. A "chirping" noise is heard while the vehicle is moving forward, but stops when the brakes are applied. Technician A says that the noise is likely caused by the disc brake pad wear sensors. Technician B says the noise is likely a wheel bearing because the noise stops when the brakes are applied. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Technician A says that disc brake pads should be replaced when worn to minimum allowable thickness. Technician B says the pads should be removed and inspected whenever there is a brake performance complaint. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. A typical disc brake caliper overhaul (OH) kit usually includes what parts?
   a. Square-cut O-ring seal and dust boot
   b. Replacement caliper piston and dust boot
   c. Dust boot, return spring, and caliper seal
   d. Disc brake pad clips, dust boot, and caliper piston assembly
5. Technician A says that a lack of lubrication on the back of the disc brake pads can cause brake noise. Technician B says that pads that are not correctly crimped to the caliper housing can cause brake noise. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
6. Two technicians are discussing ways of removing a caliper piston. Technician A says to use compressed air. Technician B says to use large pliers. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. Which is *not* a recommended type of grease to use on brake parts?
   a. Silicone grease
   b. Wheel bearing (chassis) grease
   c. Synthetic grease
   d. Antiseize compound
8. Technician A says that a loaded caliper includes an overhauled caliper assembly but no brake pads or hardware. Technician B says that a loaded caliper includes the pads and all needed hardware. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
9. A vehicle is hoisted during routine service and the service technician discovers that the left front wheel does not turn when force is applied. Technician A says that the hoist (lift) pads could be against the left front tire. Technician B says that there could be a brake fluid restriction between the master cylinder and the brake. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. Technician A says that a steel piston should be cleaned with sandpaper to remove rust. Technician B says that the brake assembly fluid or clean brake fluid should be used to lubricate the caliper pistons before installing in the caliper. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 103

PARKING BRAKE OPERATION, DIAGNOSIS, AND SERVICE

OBJECTIVES: **After studying Chapter 103, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "E" (Miscellaneous Systems Diagnosis and Repair). • Describe what is required of a parking brake. • Describe the parts and operation of the parking brake as used on a rear drum brake system. • Describe how a parking brake functions when the vehicle is equipped with rear disc brakes. • Explain how to adjust a parking brake properly.

KEY TERMS: Application cables 1148 • Control cables 1148 • Electric parking brake (EPB) 1156 • Equalizer 1148 • Intermediate lever 1148 • Red brake warning lamp 1147 • Transfer cable 1148 • Vacuum servo 1147

PARKING BRAKE STANDARDS

BACKGROUND Before 1967, most vehicles had only a single master cylinder operating all four brakes. If the fluid leaked at just one wheel, the operation of all brakes was lost. This required the use of a separate method to stop the vehicle in case of an emergency. This alternative method required that a separate mechanical method be used to stop the vehicle using two of the four wheel brakes. After 1967, federal regulations required the use of dual or tandem master cylinders where half of the braking system has its own separate hydraulic system. In case one-half of the system fails, a dash brake warning lamp lets the driver know that a failure has occurred and the vehicle stops with one-half of the brake system operating. The term *parking brake* has replaced the term *emergency brake* since the change to dual master cylinder design.

FMVSS 135 According to Federal Motor Vehicle Safety Standard (FMVSS) 135, the parking brake must hold a fully loaded (laden) vehicle stationary on a slope of 20% up or down grade. The hand force required cannot exceed 80 lb (18 N) or a foot force greater than 100 lb (22 N). ● **SEE FIGURE 103–1** for a typical parking brake system.

PEDALS, LEVERS, AND HANDLES

Parking brakes are applied by a pedal, a lever, or a handle from inside the vehicle. Foot pedals and floor-mounted levers are the most common means of applying parking brakes. ● **SEE FIGURES 103–2 AND 103–3.** All parking brake controls incorporate a *ratchet* mechanism to lock the brake in the applied position. ● **SEE FIGURE 103–4.**

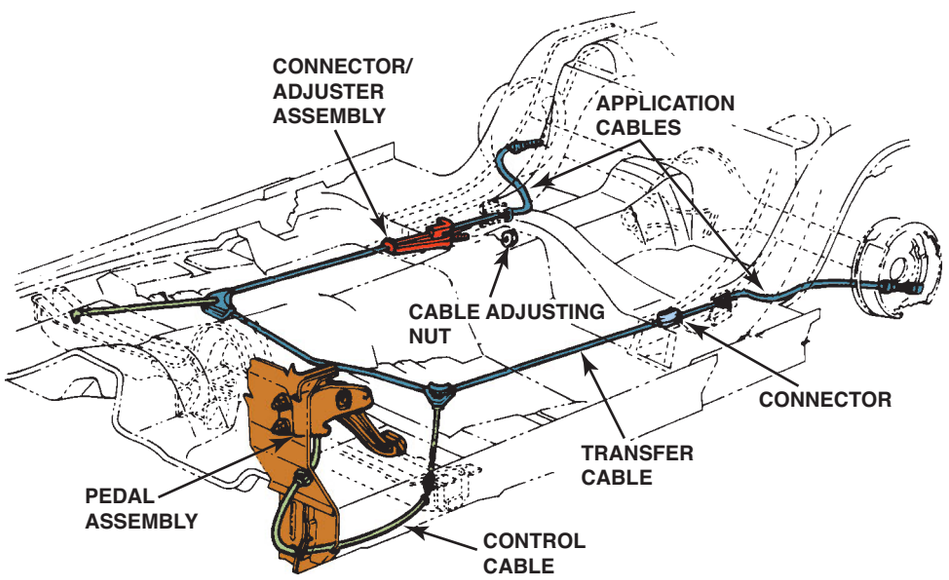


FIGURE 103–1 Typical parking brake cable system showing the foot-operated parking brake lever and cable routing.

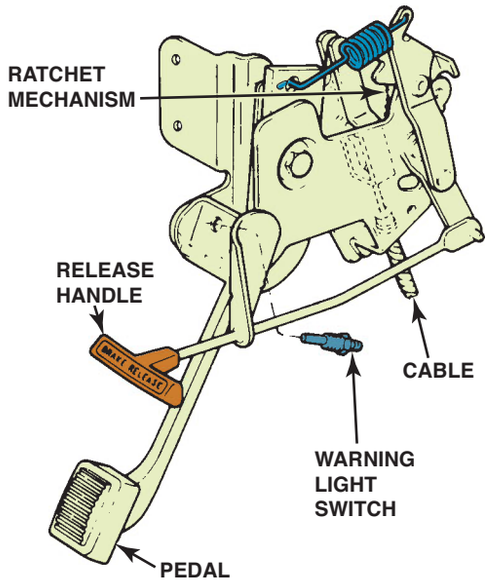

FIGURE 103–2 A typical parking brake pedal assembly.

All parking brakes are applied manually and the release procedure varies with the design of the parking brake control.

PARKING BRAKE PEDALS A parking brake pedal is applied by depressing it with a foot. The ratchet engages automatically and the pedal remains in the depressed position. The pedal is released by a pull or a small T-handle or lever under the dash. This disengages the ratchet mechanism, and allows a return spring to move the pedal to the unapplied position. On some vehicles, the release lever is integrated into the underside of the dash and connects to the release mechanism through a rod or cable. ● **SEE FIGURE 103–5.**

Some vehicles were equipped with a special pedal design that enabled them to meet federal regulations on parking brake holding power while keeping maximum pedal application force within legal limits. This type of pedal had a high leverage ratio and a special ratchet mechanism that locked the brake pedal in the applied position, but allowed the pedal to return after it had been depressed. Two full pedal strokes, or several partial strokes, were required to fully apply the parking brake. The brake was released by a single pull on a T-handle or release lever.

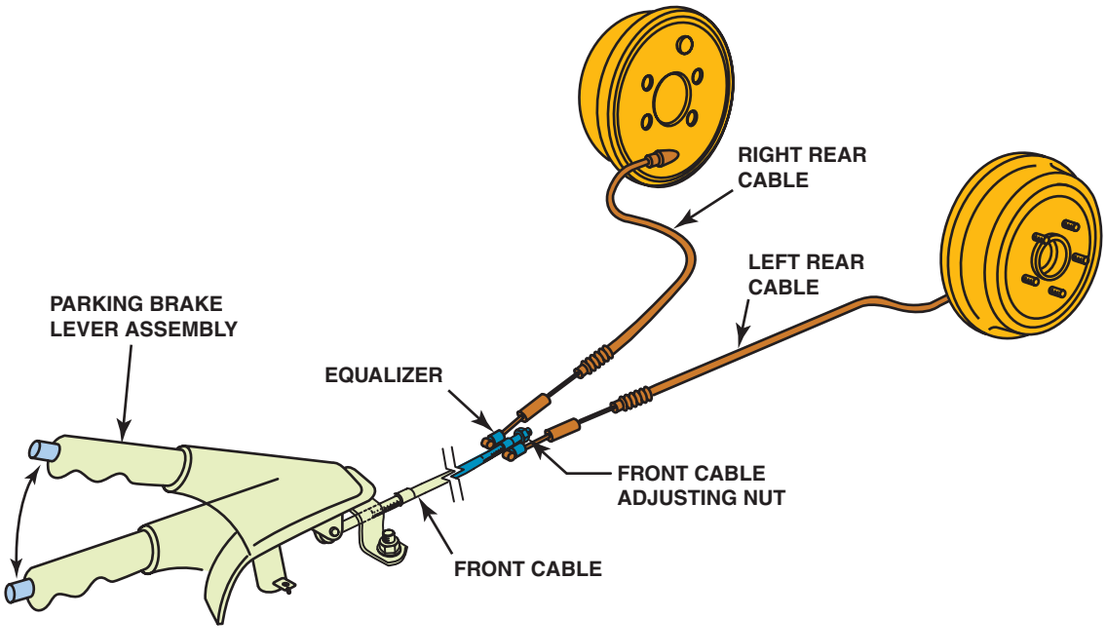

FIGURE 103–3 Typical hand-operated parking brake. Note that the adjustment for the cable is underneath the vehicle at the equalizer.

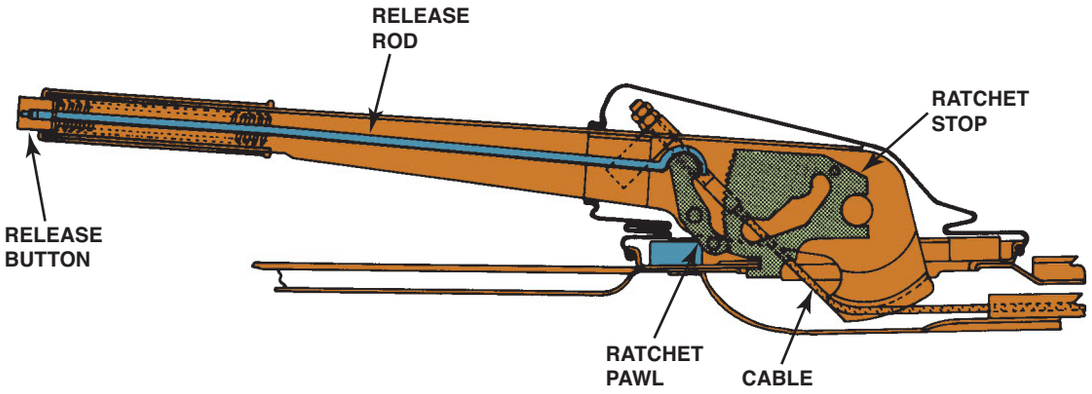

FIGURE 103–4 A ratchet mechanism is used to lock parking brakes in the applied position.

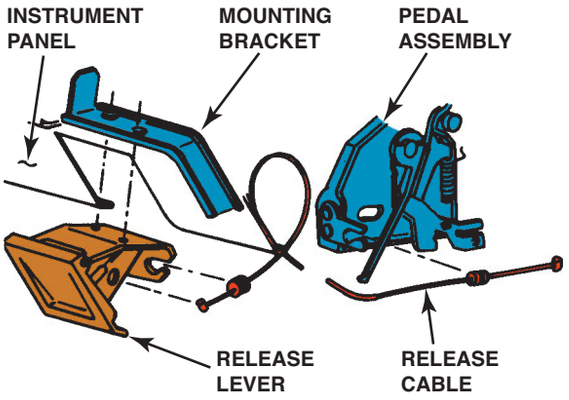

FIGURE 103–5 A remote-mounted parking brake release lever.

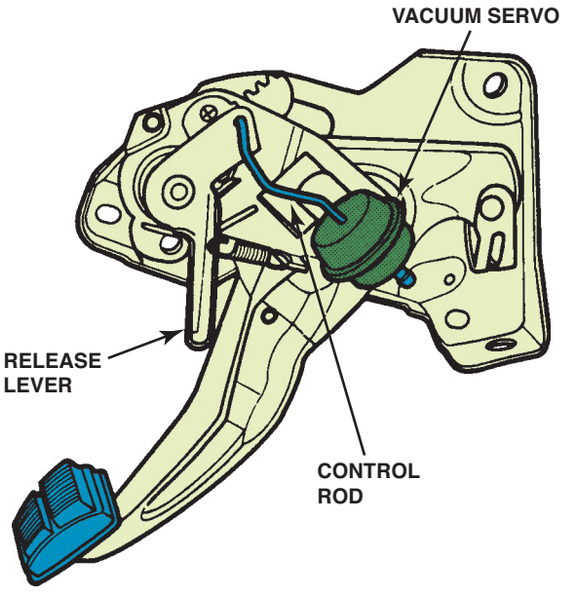

FIGURE 103–6 Automatic parking brake release mechanisms usually use a vacuum servo to operate the release lever.

REAL WORLD FIX

Pump to Release?

A customer called and asked a dealer for help because the parking brake could not be released. The service technician discovered that the customer was attempting to release the parking brake by depressing the parking brake pedal, as was done on the customer's previous vehicle. The service technician simply pulled on the release lever and the parking brake was released.

Some vehicles were equipped with a system that required the driver to depress the parking brake pedal to release the parking brake once it was set. The rubber pad on the parking brake pedal usually states "push to release."

AUTOMATIC PARKING BRAKE RELEASE Some vehicles with pedal-operated parking brakes have an automatic release mechanism that disengages the parking brake using a **vacuum servo** controlled by an electrical solenoid. ● **SEE FIGURE 103–6.**

A metal rod connects the vacuum servo to the upper end of the parking brake release lever. When the engine is running (to provide vacuum) and the shifter is placed in gear, an electrical contact closes to energize the solenoid and route vacuum to the servo. The servo diaphragm then retracts the rod, which releases the parking brake. ● **SEE FIGURE 103–7.**

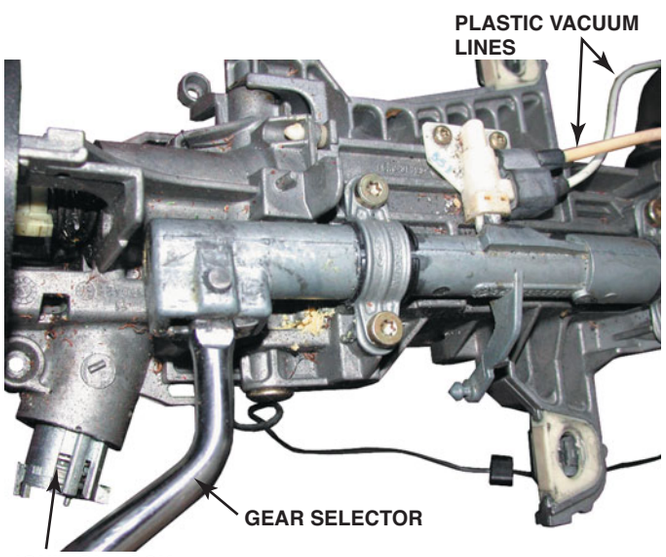

FIGURE 103–7 The two plastic vacuum tubes on the steering column are used to release the parking brake when the gear selector is moved from park into a drive gear.

PARKING BRAKE WARNING LAMP

A **red brake warning lamp** lights on the dash if any of the following events occur.

- On most vehicles, this is the same lamp that lights when there is a hydraulic or brake fluid level problem.
- The warning lamp for the parking brake warns the driver that the parking brake is applied or partially applied. This warning helps prevent damage or overheating to the brake drums and linings or rear discs and pads that could occur if the vehicle was driven with the parking brake applied.

If the red BRAKE warning lamp is on, check the parking brake to see if it is fully released. If the BRAKE lamp is still on, the parking brake switch may be defective, out of adjustment, or there may be a hydraulic problem.

PARKING BRAKE LINKAGES

Parking brake linkages transmit force from the pedal, lever, or handle inside the vehicle to the brake friction assemblies.

LINKAGE RODS Parking brake linkage rods made from solid steel are commonly used with floor-mounted actuating levers to span the short distance to an intermediate lever or an equalizer.

LINKAGE CABLES

The typical parking brake cable is made of woven-steel wire encased in a reinforced rubber or plastic housing. The housing is fixed in position at both ends, and is routed under the vehicle through mounting brackets that hold the cable in position, yet allow a small amount of movement. The cable slides back and forth inside the housing to transmit application force, and depending on the linkage design, the outer housing may play a part in parking brake application as well.

Parking brake linkages use control cables, transfer cables, and application cables.

- **Control cables** attach to the parking brake pedal, lever, or handle inside the vehicle.
- A **transfer cable** transmits force to an intermediate lever or equalizer to the application cables.
- The **application cables** use the force passed through the linkage to apply the rear wheel brake assembly. ● **SEE FIGURE 103–8.**

Parking brake cables are subject to damage from water, dirt, and other debris thrown up under the vehicle by the tires. Most parking brake cables do not require lubrication because they are lined with nylon or Teflon, and any cable housing ends located under the vehicle are protected by rubber or nylon seals.

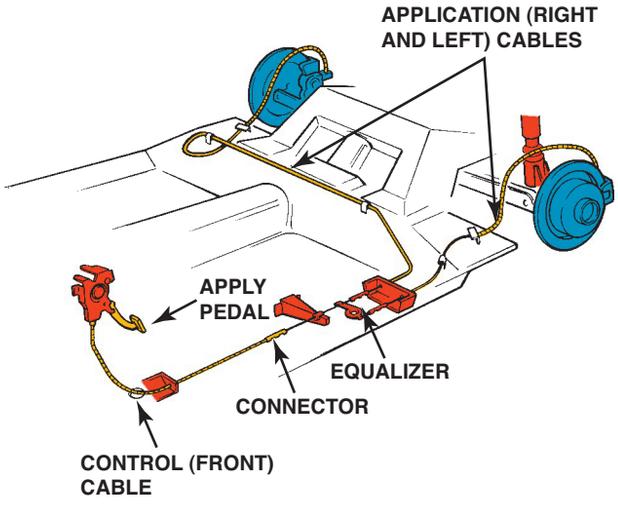

FIGURE 103–8 The cable from the activating lever to the equalizer is commonly called the control cable. From the equalizer, the individual brake cables are often called application cables. These individual cables can usually be purchased separately.

TECH TIP

Look for Swollen Parking Brake Cables

Always inspect parking brake cables for proper operation. A cable that is larger in diameter in one section indicates that it is rusting inside and has swollen. ● **SEE FIGURE 103–9.**

A rusting parking brake cable can keep the rear brake applied even though the parking brake lever has been released. This can cause dragging brakes, reduced fuel economy, and possible vehicle damage due to overheated brakes.

LINKAGE LEVERS

Unfortunately, the amount of physical force a driver can apply to the parking brake control is often not enough to apply the parking brake. For this reason, all parking brake linkages contain one or more levers that increase application force.

The parking brake pedals, floor-mounted levers, and pivoting under dash handles described earlier are all types of levers used to increase parking brake application force. A lever in the parking brake linkage under the vehicle is called an **intermediate lever.** ● **SEE FIGURE 103–10.**

To further increase parking brake application force, intermediate levers provide leverage in addition to that supplied by the parking brake control.

LINKAGE EQUALIZERS

In some parking brake linkages, the rods or cables to the two friction assemblies are adjusted separately. If the adjustments are unequal, one brake will apply before the other, preventing full lining-to-drum contact at the opposite wheel and greatly reducing the holding power of the parking brake. To prevent unequal application, most parking brake linkages use an **equalizer** to balance the force from the parking brake control, and transmit an equal amount to each friction assembly.

Equalizers come in many shapes and sizes, but the simplest is the cable guide attached to a threaded rod. ● **SEE FIGURE 103–11.**

FIGURE 103–9 Notice how rust inside the covering of this parking brake cable has caused the cable to swell.

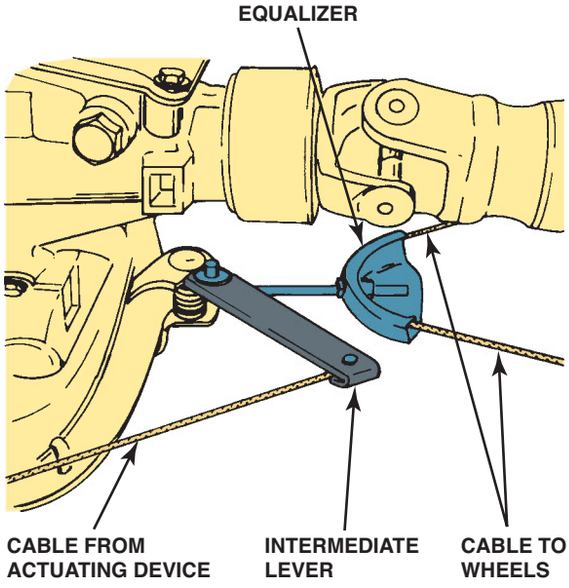

FIGURE 103–10 Intermediate levers in the parking brake linkage increase the application force.

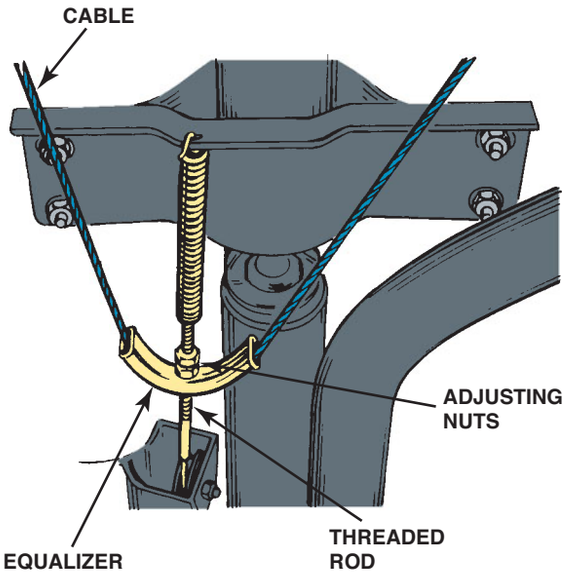

FIGURE 103–11 A cable guide is a common type of parking brake linkage equalizer.

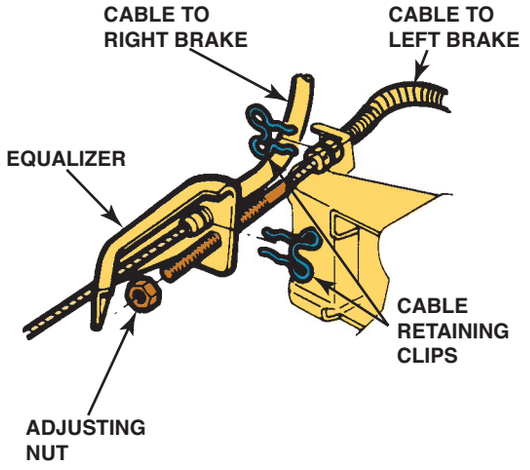

FIGURE 103–12 Some parking brake equalizers are installed in the brake cable.

This type of equalizer pivots or allows the inner cable to slide back and forth to even out application force.

Another type of equalizer installs in a long application cable that runs from the linkage at the front of the vehicle to one rear brake. ● **SEE FIGURE 103–12.**

LINKAGE DESIGN The number of different parking brake linkage designs is almost as great as the number of vehicle models on the road. Most linkages combine intermediate levers and equalizers in various ways and use from one to four cables to actuate the friction assemblies. ● **SEE FIGURE 103–13.**

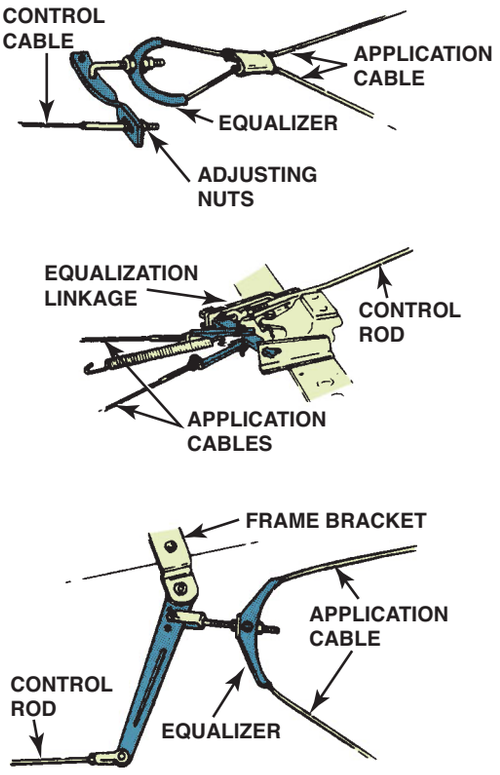

FIGURE 103–13 Many parking brake linkages use both an intermediate lever and an equalizer.

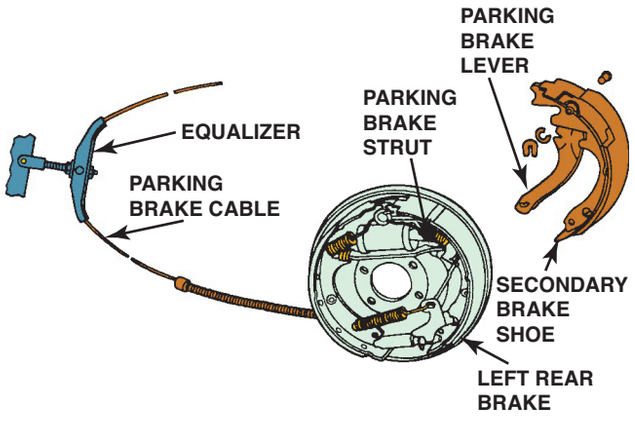
FRONT AND REAR ENTRY PARKING BRAKE CABLES



The parking brake standard requires that the vehicle be held stationary on a 20% grade facing either uphill or downhill. Many drum parking brake systems attach the parking brake lever on the secondary (rearward) shoe and push the primary (forward facing) brake shoe against the drum. The parking brake cable enters the backing plate from the front of the vehicle (front entry). Because the primary shoe is attached to the secondary shoe on dual-servo brakes, any forward motion of the vehicle tends to wedge the primary shoe into the brake drum *and* force the rear secondary lining also against the drum.

Applying only the forward brake shoe tends to hold the vehicle best when the vehicle is being held on a hill with the front pointing downward. To help provide the same holding power for a vehicle being held from backing up, some vehicles reverse the parking brake arrangement for the right side. Instead of having the parking brake cable enter the backing plate from the front, this style has the cable entering from the rear (rear entry). In this case, the right rear brake has the parking brake lever installed on the *primary* shoe. This creates a reverse servo action when the vehicle is parked with the rear facing downward.

NOTE: An easy way to remember how to reassemble a drum brake is to realize that the parking brake lever is usually attached to the secondary (rearward) brake shoe. The parking brake strut attaches between the shoes with the spring toward the front of the vehicle (remember, "spring forward").

DRUM PARKING BRAKES

Drum parking brakes are the most common types on vehicles and light trucks. Drum brakes make excellent parking brakes because they have a high static coefficient of friction combined with self-energizing action and, in the case of dual-servo brakes, servo action that increases their application force.

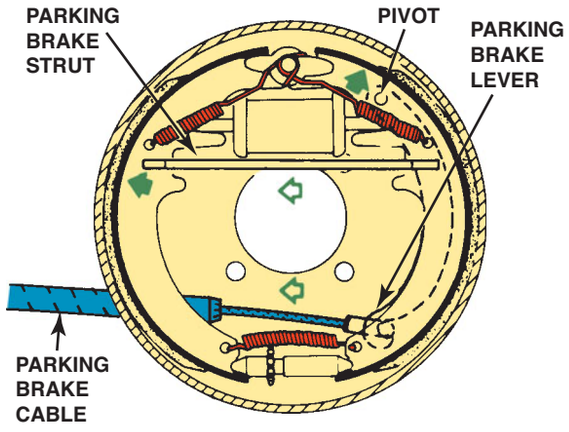


FIGURE 103–15 The parking brake cable pulls on the parking brake lever, which in turn forces the brake shoe against the drum.

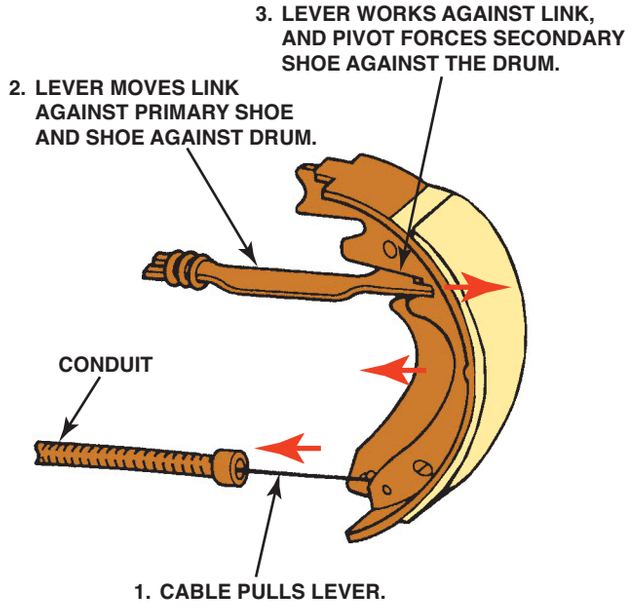

FIGURE 103–14 Notice the spring at the end of the parking brake strut. This antirattle spring keeps tension on the strut. The parking brake lever is usually attached with a pin and spring (wavy) washer and retained by a horseshoe clip.

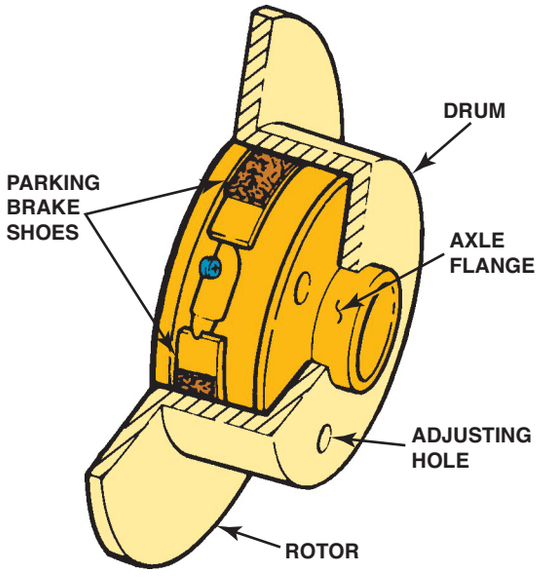

FIGURE 103–16 The inside "hat" of the disc brake rotor is the friction surface for the parking brake shoes.

INTEGRAL DRUM PARKING BRAKES

Integral drum parking brakes mechanically apply the rear drum service brakes to serve as the parking brakes. ● **SEE FIGURE 103–14.**

Integral drum parking brakes are the most common type not only because of their natural superiority in this application, but because it is simple and inexpensive to design a parking brake linkage into a drum brake.

The typical integral drum parking brake has a pivoting lever mounted on one brake shoe, and a strut placed between the lever and the other shoe. The strut may be fitted with a spring that takes up slack to prevent noise when the parking brake is not applied. The end of the lever opposite the pivot is moved by the parking brake cable, which enters through an opening in the backing plate. All integral drum parking brakes operate in essentially the same manner. ● **SEE FIGURE 103–15.**

When the parking brake control is operated, the cable pulls the end of the lever away from the shoe it is attached to. The lever pivots at the attaching point and moves the strut to apply the forward shoe. Once the forward brake shoe lining contacts the drum, the strut can travel no farther. The lever then pivots on the strut and forces the lining of the reverse shoe against the drum.

REAR DISC AUXILIARY DRUM PARKING BRAKES

Rear disc service brakes with fixed calipers commonly have a parking brake drum formed into the hub of the brake rotor. ● **SEE FIGURE 103–16.** Inside the drum is a small dual-servo drum brake friction assembly that serves as the parking brake. The rotor splash shield, or a special mounting bracket, provides the backing plate for the friction assembly. Rear disc auxiliary drum parking brakes use the dual-servo friction assembly design because it provides the most holding power, and does so equally in both forward and reverse directions. Dual-servo parking brake friction assemblies operate in essentially the same manner as service brakes except that the wheel cylinder is eliminated and the friction assembly is actuated mechanically. ● **SEE FIGURE 103–17.**

CALIPER-ACTUATED DISC PARKING BRAKES

BASIC OPERATION

Caliper-actuated disc parking brakes are used on vehicles whose rear disc brakes are equipped with floating or sliding brake calipers. The single-piston construction of these

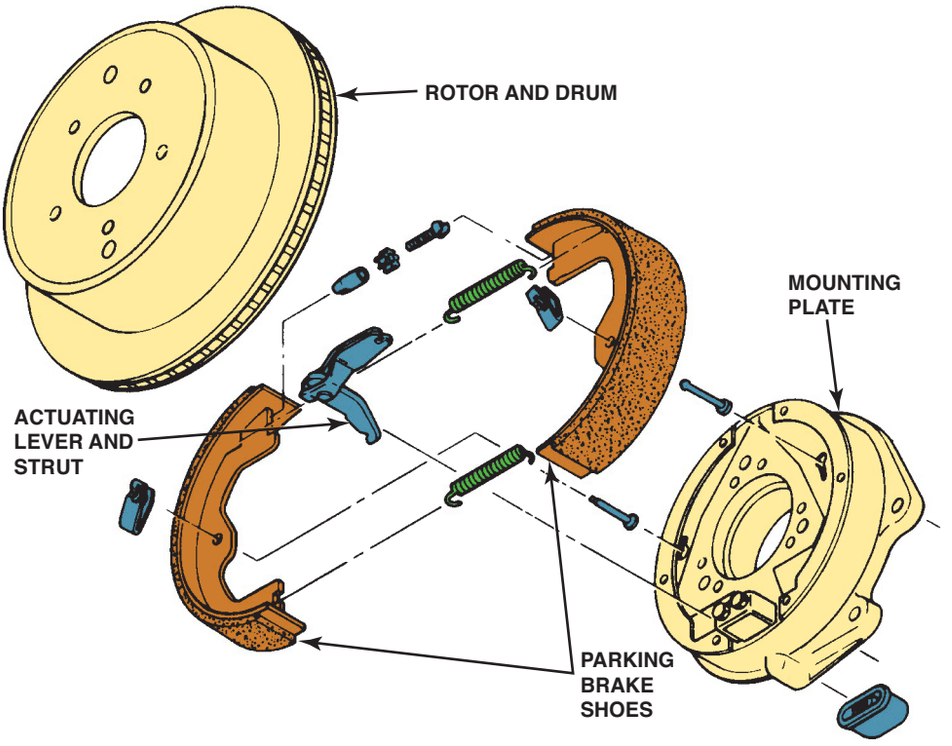

FIGURE 103–17 A typical rear disc brake auxiliary drum brake friction assembly.

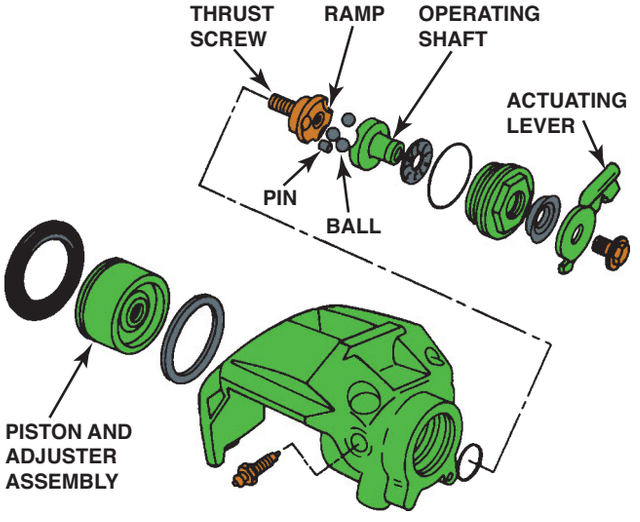

FIGURE 103–18 A Ford rear brake caliper ball and ramp-type apply mechanism.

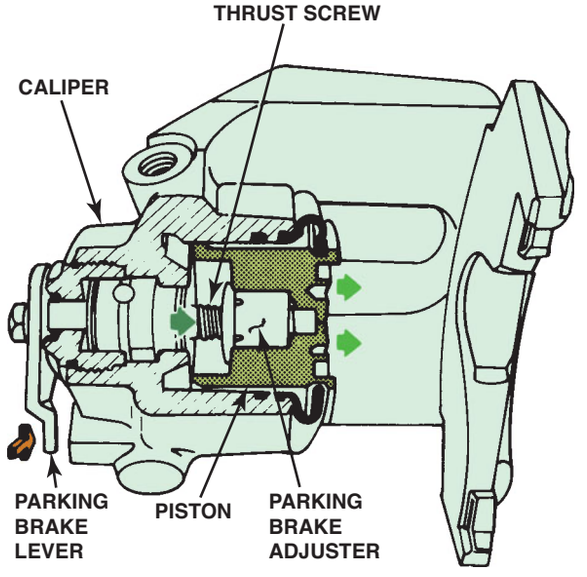

FIGURE 103–19 Operation of a ball and ramp-type rear disc brake caliper parking brake.

calipers makes them easier to mechanically actuate than multiple-piston fixed calipers. In this design, a special mechanism in the caliper applies the caliper piston mechanically. The mechanism is operated by a parking brake cable attached to a lever that protrudes from the inboard side of the caliper.

BALL AND RAMP ACTUATION The ball and ramp actuating system found in Ford rear brake calipers has three steel balls located in ramp-shaped detents between two plates. ● **SEE FIGURE 103–18.** One plate has a thrust screw attached that is threaded into an adjuster mechanism in the caliper piston. The other plate is part of the operating shaft that extends out of the caliper. The actuating lever is mounted to the end of this shaft.

As the parking brake cable moves the lever and rotates the operating shaft, the balls ride up the ramps and force the two plates apart. The operating shaft plate cannot move because it butts against the caliper body. The thrust screw plate, which is pinned to the caliper body to prevent it from rotating, is driven away from the operating shaft and toward the rotor where the thrust screw moves the caliper piston to apply the brake. ● **SEE FIGURE 103–19.**

Adjustment of the ball and ramp linkage within the caliper is automatic, and takes place during service brake application. When the caliper piston moves away from the thrust screw, an adjuster nut inside the piston rotates on the thrust screw to take up any slack created by wear. ● **SEE FIGURE 103–20.** A drive ring on the nut prevents it from rotating in the opposite direction when the parking brake is applied.

SCREW, NUT, AND CONE ACTUATION

General Motors' rear disc parking brake uses a screw, nut, and cone mechanism to apply the caliper piston. ● **SEE FIGURE 103–21.**

In this design, the actuator screw with the parking brake lever attached to it extends through the caliper body. The caliper piston contains a specially shaped nut that threads onto the actuator screw when the piston is installed in the bore. The nut butts against the backside of the cone, and is splined to the cone so that it cannot rotate unless the cone does so as well. The cone is a slip fit in the piston, and is free to rotate unless it is held tightly against a clutch surface located near the outer end of the piston bore.

When the parking brake is applied, the cable moves the lever and rotates the actuator screw. ● **SEE FIGURE 103–22.** The nut then unthreads along the screw, and jams the cone against the clutch surface of the caliper piston. This prevents the cone from rotating because the caliper piston is keyed to the brake pad, which is fixed in the caliper. Because the cone cannot rotate, movement of the nut along the actuator thread forces the cone and piston outward against the inboard pad to apply the brake.

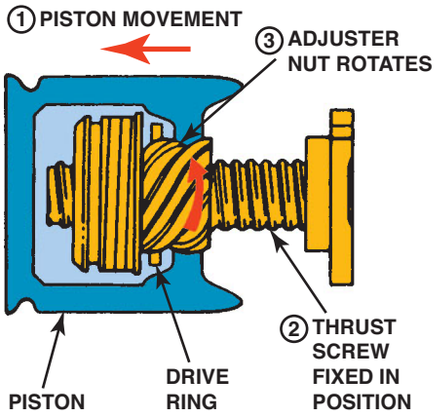

FIGURE 103–20 Automatic adjustment of a ball and ramp-type rear disc brake parking brake occurs when the service brakes are applied.

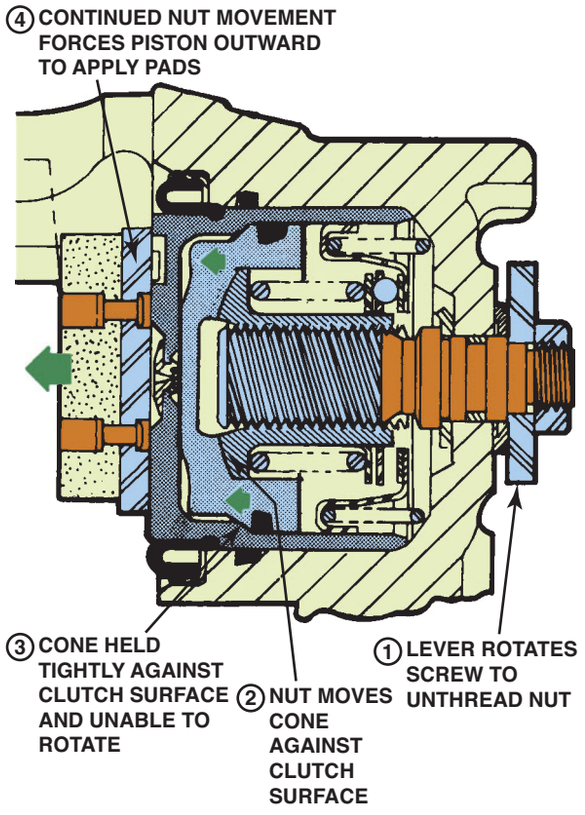

FIGURE 103–22 Parking brake application of a General Motors rear drive brake caliper.

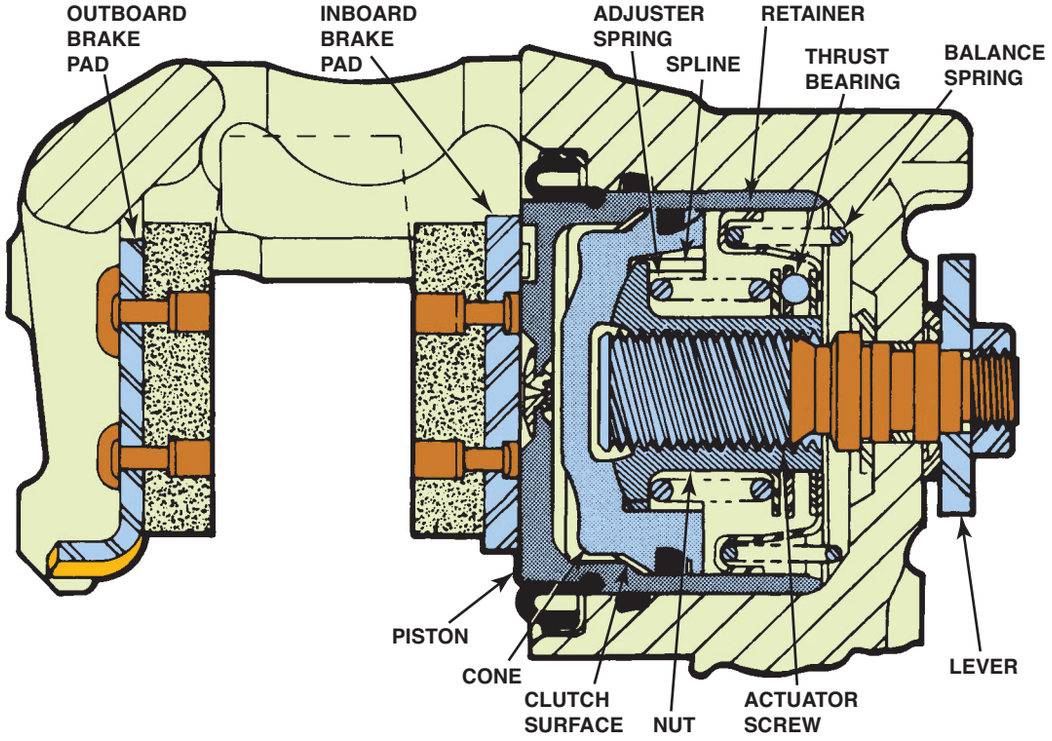

FIGURE 103–21 A typical General Motors rear disc brake with an integral parking brake. This type uses a screw, nut, and cone mechanism to apply the caliper piston.

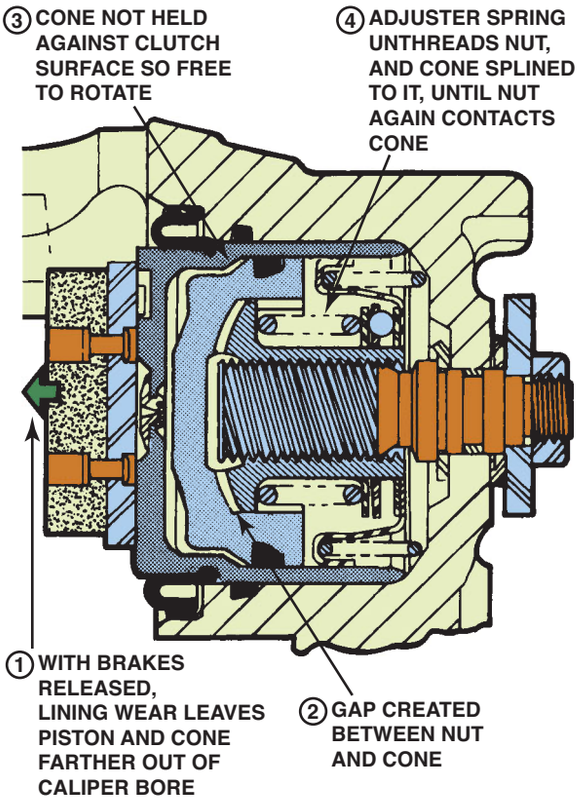

FIGURE 103–23 Automatic adjustment of a General Motors rear disc brake caliper.

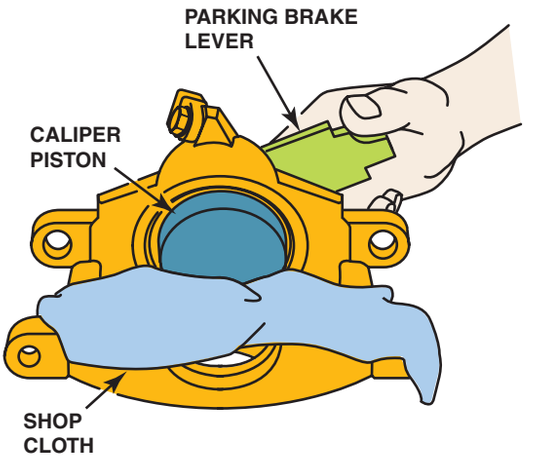

FIGURE 103–24 Removing the piston from a typical General Motors rear disc brake caliper.

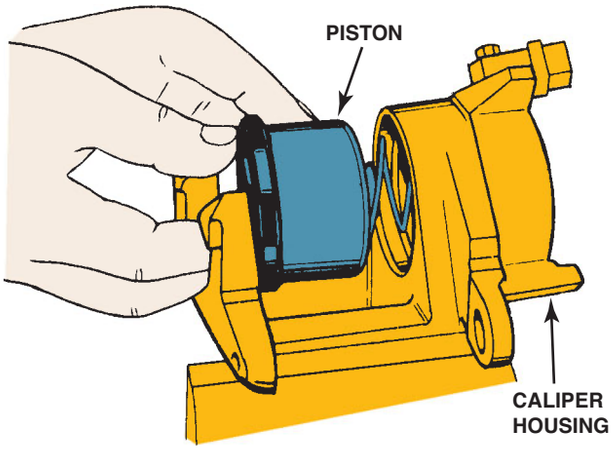

FIGURE 103–25 Installing the piston into a General Motors rear disc brake caliper.

Adjustment of the screw, nut, and cone mechanism occurs automatically during normal operation as the service brakes are released. ● **SEE FIGURE 103–23.** When the service brakes are applied, the cone and piston move outward in the bore under hydraulic pressure. The nut, however, remains fixed because the actuator screw does not rotate. As long as there is brake application pressure, the cone is held tightly against the clutch surface of the piston, which prevents the cone, and the nut splined to it, from rotating.

The result of the above actions is that a gap develops between the outer end of the nut and the backside of the cone when the brakes are applied. If sufficient brake lining wear has occurred, a gap remains after seal deflection retracts the piston and cone when the brakes are released. Once the brakes are released, the cone is no longer held against the clutch surface, and becomes free to rotate in the piston. At this point, the adjuster spring, which exerts strong axial pressure on the nut, causes the nut and cone to unthread along the actuator screw and take up any clearance between the cone and piston.

The balance spring between the piston and the caliper bore has two purposes.

1. It prevents excessive piston retraction when the brakes are released.
2. It counterbalances the pressure of the adjuster spring.

Note that the outer end of the nut is in constant contact with the cone whenever the service brakes are not applied. If the automatic adjusting system fails, the tension of the adjuster spring against the thrust bearing at the back of the piston will retract the cone and piston from the rotor until the cone does contact the nut, resulting in a low brake pedal.

REAR DISC BRAKE SERVICE

Most rear disc brake calipers are replaced as an assembly if a fault is found. The calipers should also be replaced in pairs to provide equal braking force during operation.

Always follow the instructions in service information regarding precautions and brake bleeding procedures to follow when replacing rear disc brake caliper that have integral parking park mechanisms.

Rebuilding rear disc brake calipers can be done but there are issues because of all the components that may be needed as well the need for accurate fit for them to work properly. Always follow the instructions in service information when rebuilding a rear disc brake caliper assembly. ● **SEE FIGURES 103–24 THROUGH 103–31.**

PARKING BRAKE CABLE ADJUSTMENT

Most manufacturers specify a minimum of 3 or 4, and a maximum of 8 to 10, clicks when applying the parking brake. Check service information for the vehicle being serviced for the exact specifications and

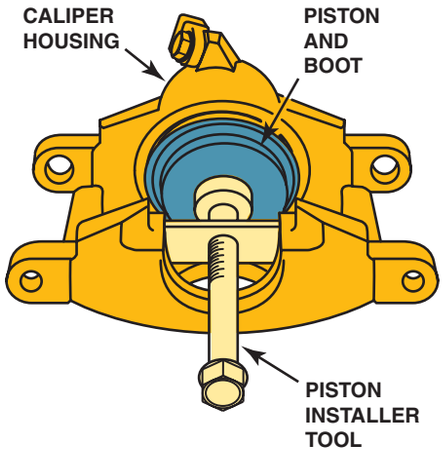

FIGURE 103–26 A piston installation tool is often needed to complete the installation of the piston in a General Motors rear disc brake.

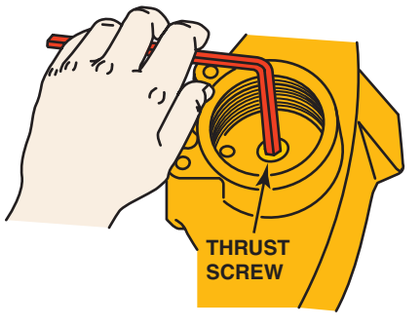

FIGURE 103–29 Unscrew the thrust screw from the piston with an Allen (hex) wrench. After removing the thrust screw, push the piston out of the caliper bore.

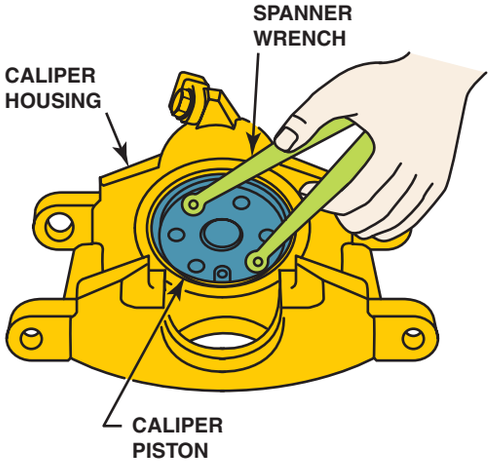

FIGURE 103–27 A spanner wrench (or needle-nose pliers) can be used to rotate the caliper piston prior to installing the disc brake pads. A notch on the piston must line up with a tab on the back of the brake pad to keep the piston from rotating when the parking brake is applied.

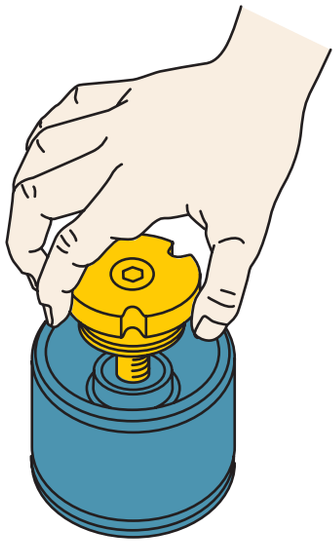

FIGURE 103–30 To test the piston adjuster, thread the thrust screw into the piston. Hold the piston and pull the thrust screw outward 1/4 in. (6 mm). The adjuster nut should not turn when the thrust screw retracts. Replace the piston assembly if not functioning correctly.

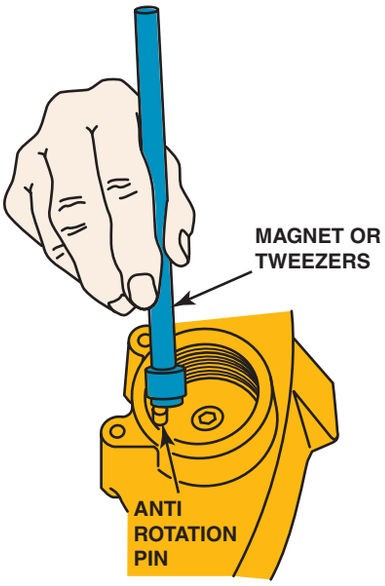

FIGURE 103–28 After removing the parking brake lever and thrust bearing, remove the antirotation pin.

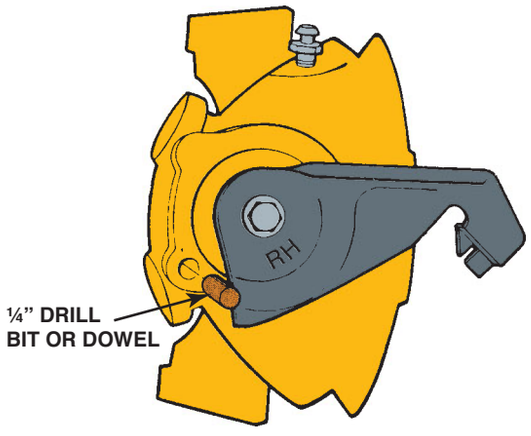

FIGURE 103–31 To adjust the parking brake cable on a Ford vehicle equipped with rear disc brakes, start by loosening the cable adjustment until the cables to the calipers are slack. Tighten until the caliper lever moves. Position a 1/4-in. drill bit or dowel into the caliper alignment hole. Adjustment is correct if the parking brake lever does not hit the 1/4-in. dowel.

TECH TIP

The Parking Brake "Click" Test

When diagnosing any brake problem, apply the parking brake and count the "clicks." This method works for both hand- and foot-operated parking brakes. Most vehicle manufacturers specify a maximum of 10 clicks. If the parking brake travel exceeds this amount, the rear brakes may be worn or out of adjustment.

CAUTION: Do not adjust the parking brake cable until the rear brakes have been thoroughly inspected and adjusted.

If the rear brake lining is usable, check for the proper operation of the self-adjustment mechanism. If the rear brakes are out of adjustment, the service brake pedal will also be low. This 10-click test is a fast and easy way to determine if the problem is due to rear brakes.

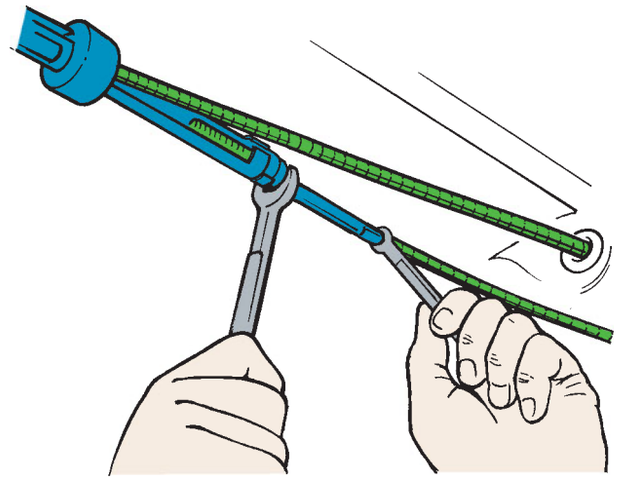

FIGURE 103–32 After checking that the rear brakes are okay and properly adjusted, the parking brake cable can be adjusted. Always follow the manufacturer's recommended procedure.

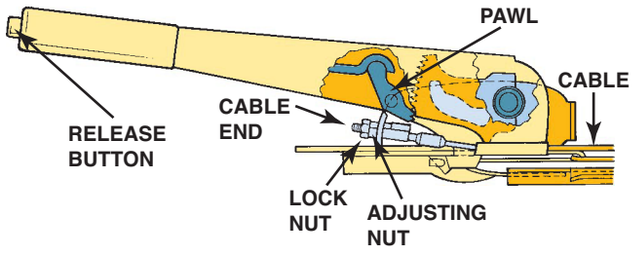

FIGURE 103–33 Many hand-operated parking brakes are adjusted inside the vehicle.

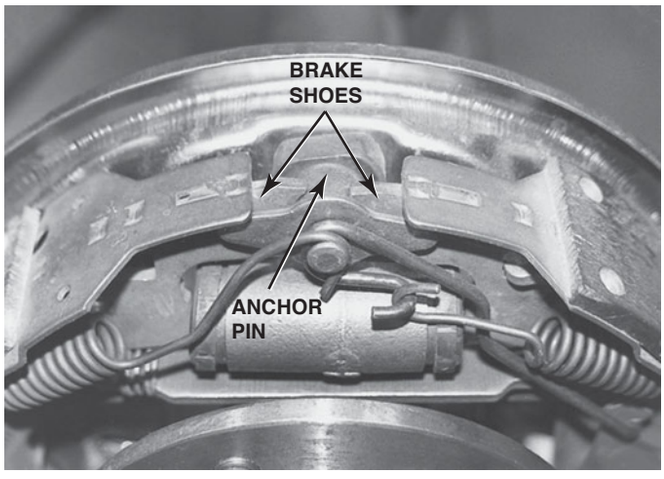

FIGURE 103–34 Always check that both brake shoes contact the anchor pin.

adjustment procedures. Most vehicle manufacturers specify that the rear brakes be inspected and adjusted correctly before attempting to adjust the parking brake cable. Always follow the manufacturer's recommended procedure exactly.

Below is a general procedure for parking brake adjustment.

1. Make certain that the rear service brakes are adjusted correctly and the lining is serviceable.
2. With the drums installed, apply the parking brake 3 or 4 clicks. There should be a slight drag on both rear wheels.
3. Adjust the cable at the equalizer (equalizes one cable's force to both rear brakes) if necessary until there is a slight drag on both rear brakes. ● **SEE FIGURES 103–32 AND 103–33.**
4. Release the parking brake. Both rear brakes should be free and not dragging. Repair or replace rusted cables or readjust as necessary to ensure that the brakes are not dragging.

NOTE: The rear parking brake adjustment should always be checked whenever replacing the rear brake linings. It may be necessary to loosen the parking brake cable adjustment to allow clearance to get the drum over the new linings. This could happen because someone may have adjusted the parking brake cable during the life of the rear linings. ● **SEE FIGURE 103–34.**

With new thicker linings, the parking brake adjustment can keep the brake shoes pushed outward toward the drum.

To prevent possible parking brake cable adjustment problems when installing new rear brakes, always observe the following:

1. Both brake shoes should make contact with the anchor pin at the top. If not, check the parking brake cable for improper adjustment or improper installation of the brake shoes.
2. Feel the tension of the parking brake cable underneath the vehicle. It should be slightly loose (with the parking brake "off").
3. Lubricate the parking brake cable to ensure that water or ice will not cause rust or freezing of the cable. This is necessary because even though the parking brake lever is released inside the vehicle, a stuck parking brake cable could cause the linings to remain out against the drums.
4. If the parking brake needs to be adjusted (will not hold on a hill or requires excessive lever movement), always check and adjust the rear brake adjustment before adjusting the parking brake cable. ● **SEE FIGURE 103–35.**

   NOTE: Some vehicles are equipped with an automatic adjusting parking brake lever/cable. Simply cycling the parking brake on/off/on three times is often all that is required to adjust the parking brake cable.
5. Replace any stuck, corroded, or broken parking brake cable.

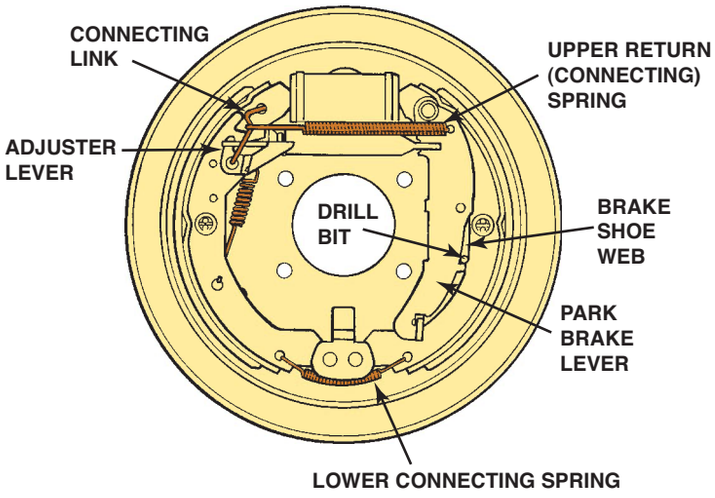

FIGURE 103–35 A 1/8-in. (3-mm) drill bit is placed through an access hole in the backing plate to adjust this General Motors leading-trailing rear parking brake. Adjust the parking brake cable until the drill can just fit between the shoe web and the parking brake lever.

FIGURE 103–37 An electric parking brake button on the center console of a Jaguar.

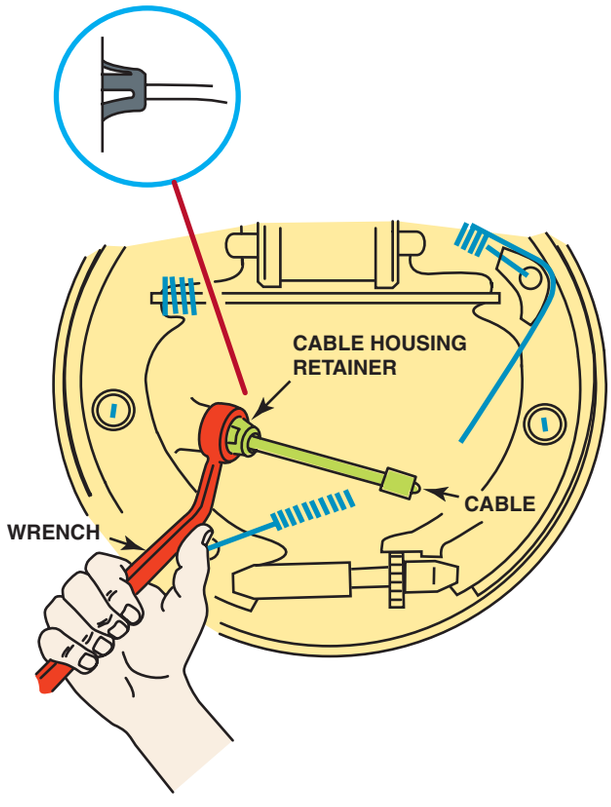

FIGURE 103–36 Many parking brake cables can be removed easily from the backing plate using a 1/2-in. (13-mm) box-end wrench. The wrench fits over the retainer finger on the end of the parking brake cable.

TECH TIP

The Hose Clamp or Wrench Trick

It is often difficult to remove a parking brake cable from the backing plate due to the design of the retainer. The many fingers used to hold the cable to the backing plate can be squeezed all at once if a hose clamp is used to compress the fingers. A wrench as shown in ● **FIGURE 103–36** can also be used.

ELECTRIC PARKING BRAKE

Electric parking brake (EPB) systems are available using two different designs including:

1. A cable-pulling type that uses an electric motor to pull the parking brake cable rather than a mechanical handle or foot pedal.
2. A more advanced unit uses a computer-controlled motor attached to the brake caliper to activate it.

Some vehicles already use an electric parking brake (EPB) that can be activated when the vehicle stops and then goes off as soon as the gas pedal is pressed, preventing the vehicle from moving while stopped. ● **SEE FIGURE 103–37.**

REVIEW QUESTIONS

1. Describe how a typical parking brake functions on a vehicle equipped with rear drum brakes.
2. Describe how a typical parking brake functions on a vehicle equipped with an integral rear disc brake system.
3. Explain how to adjust a parking brake cable properly.

CHAPTER QUIZ

1. Technician A says that the parking brake cable should be adjusted at each wheel. Technician B says that the parking brake cable adjustment is usually done after adjusting the rear brakes. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. Technician A says that the parking brake hand lever can turn on the red brake warning lamp. Technician B says that a foot-operated parking brake can turn on the red brake warning lamp. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Technician A says that if the parking brake cable is adjusted too tight, the rear brakes may drag and overheat. Technician B says that the parking brake is adjusted properly if the cable is tight when in the released position. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. On most drum brake systems, the parking brake lever and strut transfer the pulling force of the parking brake cable against the _____.
   a. Primary shoe
   b. Secondary shoe
5. On most vehicles, the antirattle spring (strut spring) should be installed on the parking brake strut toward the _____ of the vehicle.
   a. Front
   b. Rear
6. In a typical integral rear disc brake caliper, the parking brake cable moves the _____.
   a. Caliper
   b. Actuator screw
   c. Auxiliary piston
   d. Rotor
7. The rear brakes should be inspected, and adjusted if necessary, if the parking brake requires more than _____.
   a. 5 clicks
   b. 10 clicks
   c. 15 clicks
   d. 20 clicks
8. A rear drum brake is being inspected. The primary shoe is not contacting the anchor pin at the top. Technician A says that this is normal. Technician B says that the parking brake cable may be adjusted too tight or is stuck. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
9. Technician A says that a hose clamp can be used to compress the retainer fingers of a parking brake cable in order to remove it from the backing plate. Technician B says a box-end wrench can be used instead of a hose clamp. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. Technician A says that an electric parking brake (EPB) uses an electric motor to pull on the parking brake cable. Technician B says that some electric parking brake systems use a computer-controlled motor attached to the caliper. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 104

MACHINING BRAKE DRUMS AND ROTORS

OBJECTIVES: **After studying Chapter 104, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "E" (Miscellaneous Systems Diagnosis and Repair). • Discuss the construction of brake drums and rotors. • Explain the formation of hard spots in drums and rotors. • Describe how to measure and inspect drums and rotors before machining. • Discuss how surface finish is measured and its importance to satisfactory brake service. • Demonstrate how to machine a brake drum and rotor correctly.

KEY TERMS: Bellmouth 1160 • Composite rotors 1164 • Convection 1158 • Discs (disks) 1164 • Eccentric distortion 1160 • Elastic limit 1160 • Hard spots 1159 • Heat checking 1159 • Hot spots 1159 • Lateral runout (LRO) 1166 • Microinches (μ in.) 1168 • Out-of-round 1160 • Parallelism 1167 • Ra 1168 • Scoring 1158 • Scratch cut 1162 • Self-aligning spacer (SAS) 1162 • Tinnerman nuts 1161 • Thickness variation (TV) 1167 • Total indicator runout (T.I.R.) 1166

BRAKE DRUMS

CAST-IRON DRUMS Brake drums are constructed of cast iron where the lining contacts the drum, with mild steel centers. The drum is drilled for the lug studs. Cast iron contains approximately 3% carbon, which makes the drum hard, yet brittle. For this reason it is recommended that any pounding needed to remove drums be done on the center mild steel portion, which, due to its material characteristics, can take this force without damage. This 3% carbon content of the cast iron also acts as a lubricant, which prevents noise during braking. Also, the rubbing surface can be machined without the need of a coolant (as would be required if constructed of mild steel). Because of these properties, cast iron is used on the friction surface of all drums. ● **SEE FIGURE 104–1.**

ALUMINUM DRUMS Even aluminum brake drums use cast iron for the friction surface area. Besides saving weight, aluminum brake drums transfer heat to the surrounding air faster than cast iron or steel.

Brake drums and rotors are the major energy-absorbing parts of the braking system. Friction between the friction material and the drum or rotor creates heat. This heat is absorbed by the drum or rotor and travels from the friction surface to the remainder of the drum or rotor by heat **convection.** As energy continues to be absorbed, the drum or rotor increases in temperature. Airflow across the drum or rotor helps to dissipate the heat and keep the temperature rise under control. ● **SEE FIGURE 104–2.**

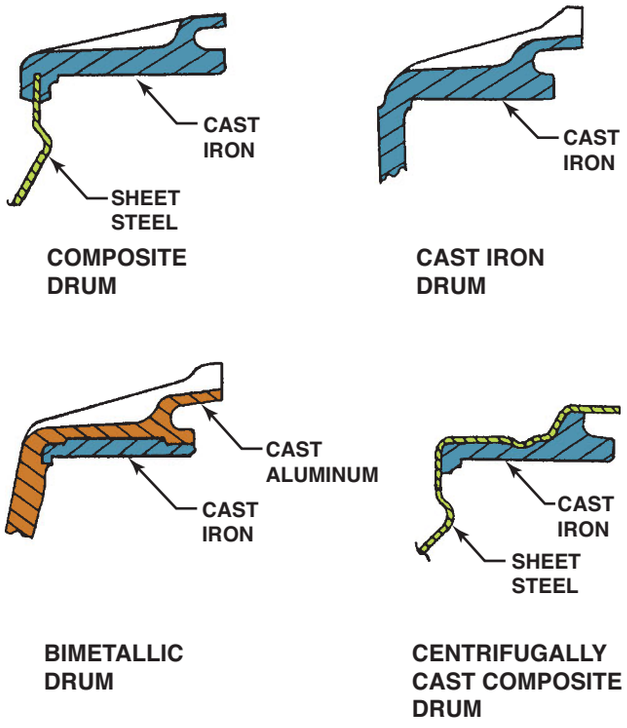

FIGURE 104–1 Types of brake drums. Regardless of the design, all types use cast iron as a friction surface.

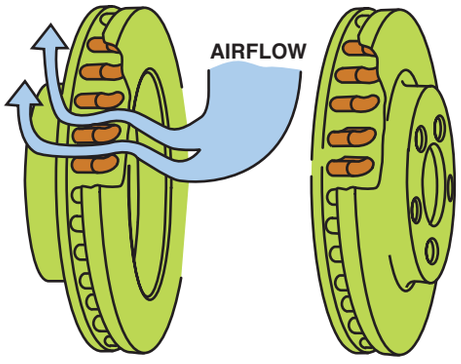

FIGURE 104–2 The airflow through cooling vents helps brakes from overheating.

BRAKE DRUM AND ROTOR DAMAGE

Besides wear, drums and rotors often experience damage to their friction surfaces. Because drum and rotor damage is caused by extremes of operation, it is most commonly found on front brakes, which experience more severe use than rear brakes.

SCORING **Scoring** is an extreme form of drum and rotor wear consisting of scratches, deep grooves, and a generally rough finish on the friction surface. ● **SEE FIGURE 104–3.**

There are a number of causes for scoring including:

1. The most common is brake linings that have worn to the point where a rivet, lining table, or pad backing plate contacts the drum or rotor.
2. Certain friction materials are more likely to score drums and rotors than others, and glazed linings that have hardened from exposure to extreme heat can also cause scoring.
3. Drum brakes are more likely to become scored than disc brakes because their closed construction holds dirt, sand, and abrasive dust inside the friction assembly. This allows the contaminants to be scrubbed repeatedly between the linings and drum.
4. Severe drum scoring often results when metal parts of the friction assembly fatigue, break loose, and are trapped between the linings and drum.

A scored drum or rotor will cause very rapid lining wear, often accompanied by a growling or grinding noise, particularly if there is metal-to-metal contact between the shoe and drum or pad and

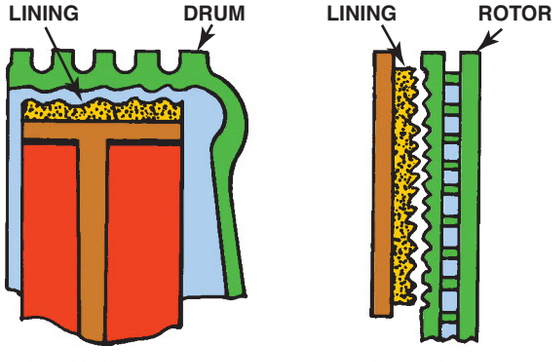

FIGURE 104–3 Scored drums and rotors often result in metal-to-metal contact.

rotor. Scoring can be machined out of a drum or rotor so long as the amount of metal removed is within the allowable limits.

CRACKING Cracks in a brake drum or rotor are caused by the stress of severe braking or an impact during an accident. ● **SEE FIGURE 104–4.** Generally, drums and rotors that have been previously

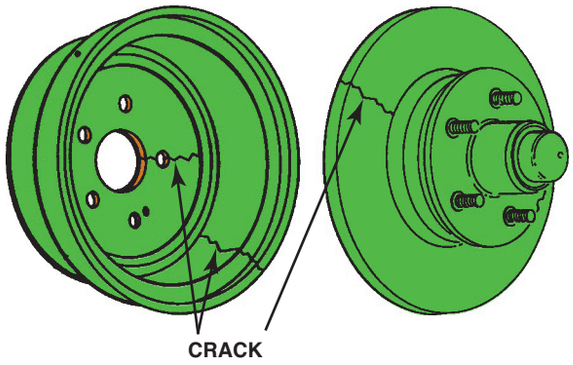

FIGURE 104–4 Cracked drums or rotors must be replaced.

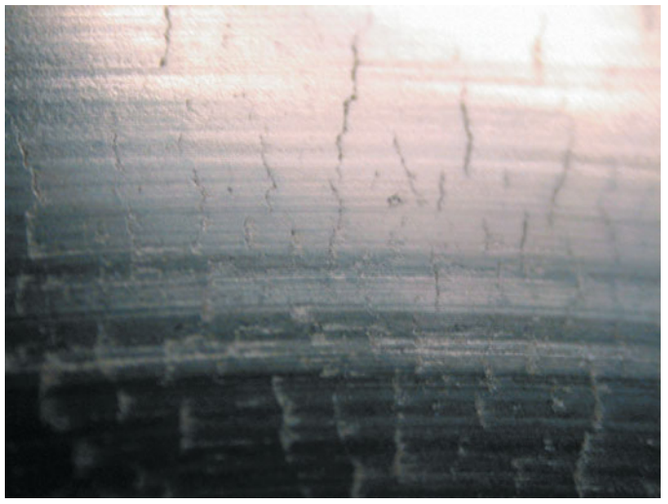

FIGURE 104–5 A heat-checked surface of a disc brake rotor.

TECH TIP

The Tap Test

Using a steel hammer, lightly tap a brake drum or rotor. It should ring if it is not cracked. If a dull thud is heard, the drum or rotor is likely cracked and should be replaced.

machined are more susceptible to cracking than new parts. Cracks can appear anywhere on a drum or rotor, although on drums they are most often found near the bolt circle on the web, or at the open edge of the friction surface. Rotors generally crack first at the edge of their friction surfaces.

HEAT CHECKING A lesser form of drum and rotor cracking is called **heat checking,** which consists of many small, interlaced cracks on the friction surface. ● **SEE FIGURE 104–5.** These cracks typically penetrate only a few thousandths of an inch into the metal and seldom pass through the structure of the drum or rotor. Heat checking is usually caused by a driver who leaves one foot on the brake pedal while applying the accelerator with the other. Heat checking can also be caused by repeated heavy braking or numerous panic stops made in rapid succession.

Light heat checking can often be machined away. In more severe cases the drum or rotor must be replaced.

HARD AND HOT SPOTS Earlier it was stated that cast-iron drums and rotors are durable because the friction, heat, and pressure of braking cause a tough "skin" to form on their friction surfaces.

FIGURE 104–6 These dark hard spots are created by heat that actually changes the metallurgy of the cast-iron drum. Most experts recommend replacement of any brake drum that has these hard spots.

However, if brake temperatures become too great, localized impurities in the metal can be burned away, altering the structure of the metal and causing **hard spots,** also called **hot spots,** to appear. Hard spots are roughly circular, bluish gold, glassy-appearing areas on the friction surface. ● **SEE FIGURE 104–6.**

Hard spots create a number of problems including the following:

- They are harder than surrounding areas of the friction surface, and do not wear at the same rate. Once the spots begin to stand out from the rest of the friction surface, they cause rapid brake lining wear.
- The friction coefficient of hard spots is less than that of surrounding areas so braking power is reduced or becomes uneven. This can cause the brakes to chatter, or result in a hard or pulsating brake pedal.
- A drum or rotor is more likely to crack in the area of hard spots than elsewhere.

Most vehicle manufacturers recommend that the drum or rotor should be replaced if hard spots are found.

BRAKE DRUM DISTORTION

To ensure smooth brake application without pedal pulsation or other problems, brake drum friction surfaces must remain a fixed position in relation to the shoes. In some cases, a position variation of less than a thousandth of an inch will create braking problems. Distortion puts the drum friction surfaces out of proper alignment with the shoes.

DRUM DISTORTION The friction surface of a brake drum in perfect condition is parallel to the axis of the axle, and rotates in a precise circle centered on the axle or hub. All brake drums suffer from distortion during brake operation, but they usually return to their original shape once the brakes are released. When the friction surface does not return to its proper shape, is no longer parallel to the axle, or does not rotate in a precise circle around the axle, the drum is distorted.

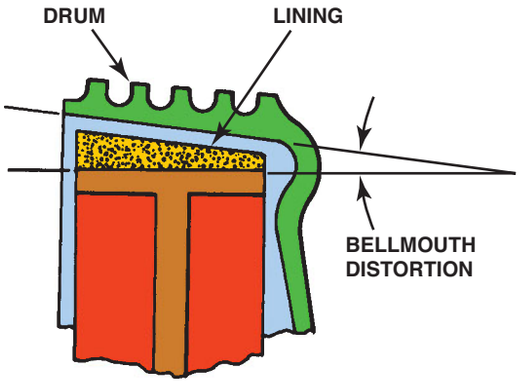

FIGURE 104–7 Bellmouth brake drum distortion.

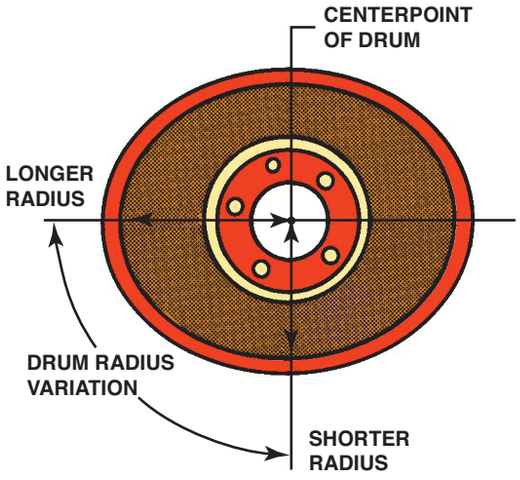

FIGURE 104–8 Out-of-round brake drum distortion.

BELLMOUTH DRUMS When an open edge of a brake drum friction surface has a larger diameter than the closed edge, the drum is suffering from **bellmouth** distortion. ● **SEE FIGURE 104–7.** Bellmouth distortion is caused by poor drum rigidity combined with high heat and brake application force.

Bellmouth distortion occurs when a drum suffers mechanical fade and its open edge, unsupported by the drum web, expands more than its closed edge. When the brakes are applied harder to compensate for the fade, the shoes distort the open edge of the drum so far outward that the **elastic limit** of its metal is exceeded. Once this happens, the drum will not return to its original shape after it cools. Repeated occurrences of this process eventually cause the drum to take on a bellmouth shape.

Bellmouth distortion is especially common on wide drums and commonly occurs when a drum has had too much metal machined from it. If new shoes are installed in a bellmouthed drum, brake fade and unusual lining wear will result.

OUT-OF-ROUND DRUMS Uneven heat distribution can sometimes cause **out-of-round** distortion in which the drum radius varies when measured at different points around its circumference. ● **SEE FIGURE 104–8.** Out-of-round distortion can take place when a vehicle drives through a puddle after a series of hard stops and cold water splashed on the brakes causes rapid and uneven cooling of the drums. It can also result if the parking brake is firmly applied after a series of hard stops before the drums have had a chance to cool. In this case, the shoes extend out against the heat-expanded drum and prevent it from contracting to its original circular shape as it cools. Instead, the extended shoes force the drum into an out-of-round shape.

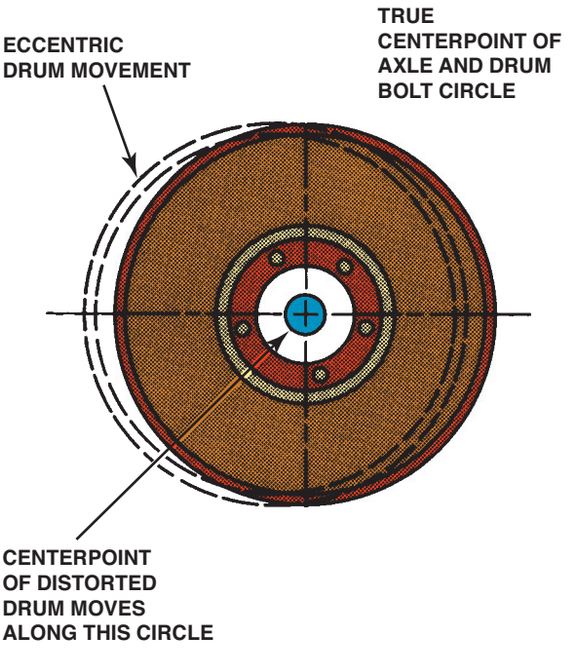

FIGURE 104–9 Eccentric brake drum distortion.

TECH TIP

Storing Drums and Rotors

A common cause of distortion in new brake drums and rotors is improper storage. Drums and rotors should always be stored lying flat; they should never be stood on edge. Distortion of new drums and rotors is common, so they should be routinely checked before installation.

TECH TIP

The Parking Brake Trick

Whenever attempting to diagnose a brake pedal pulsation, drive to a deserted area or parking lot and try stopping the vehicle using the parking brake. If a vibration occurs, the problem is due to a fault with the rear brakes. If a vibration does not occur except when using the service brakes, the problem is most likely due to a fault with the front brakes.

The most common symptom of an out-of-round drum is a pulsating brake pedal when the brakes are applied at all speeds. Out-of-round drums can also cause a vibration or brake chatter at speeds above approximately 40 mph (60 km/h). In more extreme cases, an out-of-round drum can result in erratic braking action, and possibly cause the brakes to grab with every revolution of the wheel.

ECCENTRIC DRUMS **Eccentric distortion** exists when the geometric center of the circle described by the brake drum friction surface is other than the center of the axle or the bolt circle of the drum web. ● **SEE FIGURE 104–9.** This type of distortion causes the drum to rotate with a camlike motion. An eccentric drum will result in a pulsating brake pedal similar to that caused by an out-of-round drum.

Eccentric distortion is often caused by overtightened or unevenly tightened lug nuts or bolts. Not only will this cause an

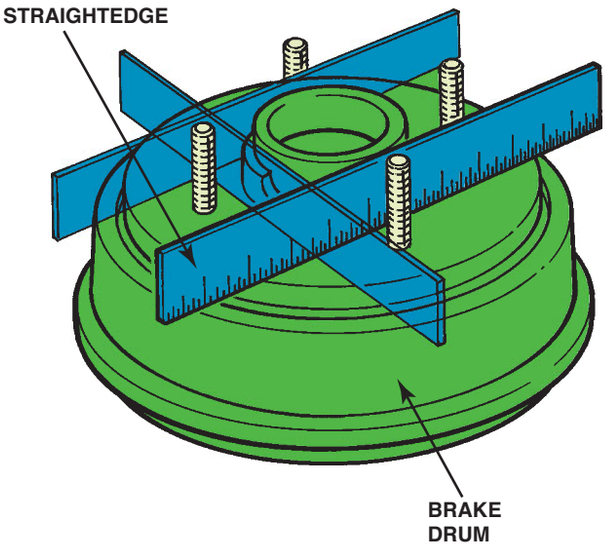

FIGURE 104–10 A straightedge can be used to check for brake drum warpage.

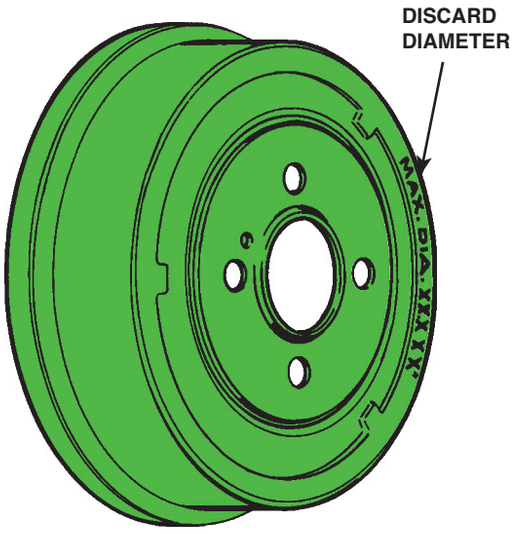

FIGURE 104–11 Discard diameter and maximum diameter are brake drum machining and wear limits.

immediate problem, but it can lead to additional problems later. If a vehicle is driven for an extended time with an eccentric drum, the linings may slowly wear the friction surface "round" again. However, as soon as tension on the lug nuts or bolts is released, the drum will relax back to its original shape creating an out-of-round condition that was not apparent before the wheel was removed.

REMOVING DRUMS

TINNERMAN NUTS Metal clips called **tinnerman nuts** are installed at the factory to keep the brake drums from falling off during vehicle assembly. These clips can be removed and do not need to be reinstalled since the wheel lug nuts hold onto the brake drum.

DRUM REMOVAL TIPS Brake drums are often hard to remove. To help remove brake drums try some of the following tips:

- Use penetrating oil around the hub to help loosen the rust that often forms in this area making drum removal difficult.
- Use a brake adjusting tool ("spoon") to loosen the brake adjuster to move the brake shoes further away from the drum.
- Use a mallet or hammer to tap the brake drum to jar it loose from the hub being careful to avoid exerting to much force that it could damage or warp the drum.

BRAKE DRUM INSPECTION The first inspection step after removing a brake drum is to check it for warpage using a straightedge, as shown in ● **FIGURE 104–10.**

A warped drum is often a source of vibration. A brake drum that is out-of-round can cause a brake pedal pulsation during braking.

"MACHINE TO" VERSUS "DISCARD"

Brake drums can usually be machined a maximum of 0.060 in. (1.5 mm) oversize (for example, a 9.500-in. drum could wear or be machined to a maximum inside diameter of 9.560 in.) unless otherwise stamped on the drum. Most brake experts recommend that both drums on the same axle be within 0.010 in. (0.25 mm) of each other. *The maximum specified inside diameter (ID) means the maximum wear inside diameter.* ● **SEE FIGURE 104–11.**

Always leave at least 0.015 in. (0.4 mm) after machining (resurfacing) for wear. Many manufacturers recommend that 0.030 in. (0.8 mm) be left for wear.

TECH TIP

Mark It to Be Sure

Most experts recommend that brake rotors, as well as drums and wheels, be marked before removing them for service. Many disc brake rotors are directional and will function correctly only if replaced in the original location. A quick-and-easy method is to use correction fluid. This alcohol-based liquid comes in small bottles with a small brush inside, making it easy to mark rotors with an "L" for left and an "R" for right. Correction fluid (also called "white-out" or "liquid paper") can also be used to make marks on wheel studs, wheels, and brake drums to help ensure reinstallation in the same location.

REASONS FOR EQUAL DRUM INSIDE DIAMETER There are several reasons why the service technician should check and make sure that both brake drums on the same axle are close to the same inside diameter (ID).

- **Reason 1.** Since heat is generated by braking, if there is less material (larger ID), the drum will tend to expand more rapidly than a drum with more material (smaller ID).
- **Reason 2.** If one drum expands more than the drum on the other side of the vehicle, unequal braking forces result.
- **Reason 3.** The drum that is larger in ID will expand away from the brake linings more than the other side.

  For example:

Left Drum	Right Drum
9.500 in.	9.560 in.

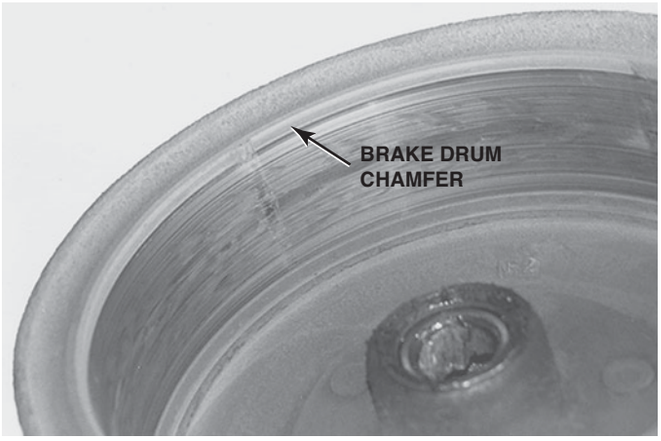

FIGURE 104–12 Most brake drums have a chamfer around the edge. If the chamfer is no longer visible, the drum is usually worn (or machined) to its maximum allowable ID.

TECH TIP

Brake Drum Chamfer

Look at the chamfer on the outer edge of most brake drums. When the chamfer is no longer visible, the brake drum is usually at or past its maximum ID. ● **SEE FIGURE 104–12.** Although this chamfer is not an accurate gauge of the ID of the brake drum, it still is a helpful indicator to the technician.

In this example, when the drums get hot (heavy braking), the vehicle will tend to pull to the left.

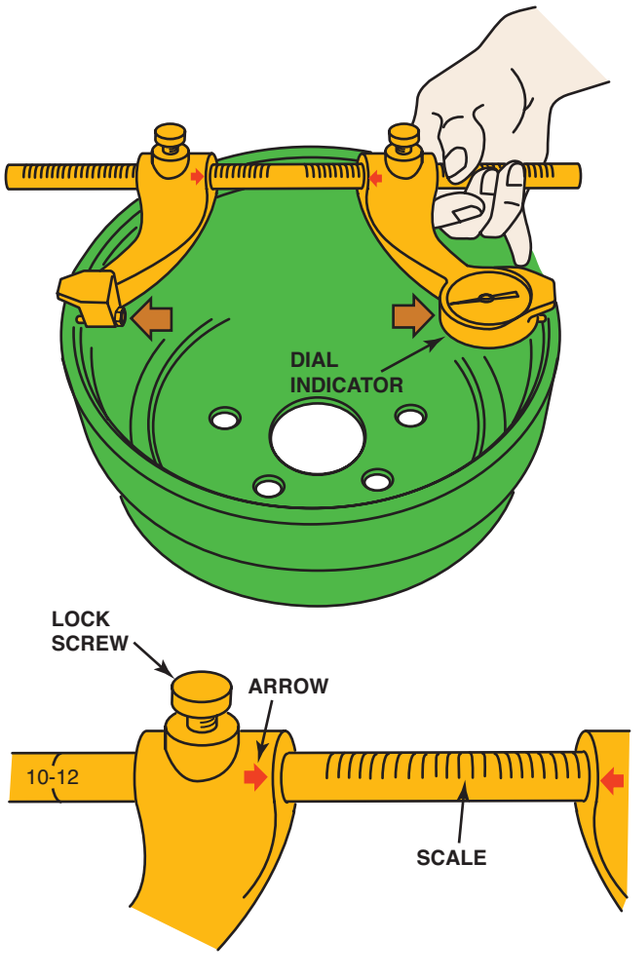

FIGURE 104–13 Typical needle-dial brake drum micrometer. The left movable arm is set to the approximate drum diameter and the right arm to the more exact drum diameter. The dial indicator (gauge) reads in thousandths of an inch.

MACHINING BRAKE DRUMS

MEASURING A DRUM Before measuring a brake drum, be sure it is not cracked by tapping it with a steel hammer. The brake drum should ring like a bell. If the brake drum makes a dull thud sound, discard the drum. Brake drums are usually measured using a micrometer especially designed for brake drums. ● **SEE FIGURE 104–13.**

Compare the micrometer reading to the discard diameter. Both drums should be measured whenever they are removed for any brake service or inspection.

BRAKE LATHE A brake lathe is a machine on which the brake drum or rotor is mounted on a spindle and rotates it in the same relationship as it does on the vehicle. A sharp carbide tool bit is then moved across the friction surface which removes metal, thus removing scratches, and scoring. It is critical that the drum and/or rotor be mounted on the spindle exactly in the same center line as it rotates on the vehicle. Various machine adapters, cones and collets are used to hold the brake drum or rotor. Always follow the operating instructions for the brake lathe being used.

MACHINING A DRUM PROCEDURE Always start any machining operation by making certain that the brake drum is clean and that excess grease is removed from the hub. If the drum has a hub with bearings, check the outer bearing races (cups) for wear and replace as necessary before placing the drum on the brake lathe. Also, carefully inspect and clean the lathe spindle shaft and cones before use. Use a **self-aligning spacer (SAS)** to be assured of even force being applied to the drum by the spindle nut. Always follow the instructions for the lathe you are using.

Hubless drums use a hole in the center of the brake drum for centering. Always check that the center hole is clean and free of burrs or nicks. Typical drum brake machining steps include the following:

STEP 1 Mount the drum on the lathe and install the silencer band as shown in ● **FIGURES 104–14 AND 104–15.**

STEP 2 Turn the drum by hand before turning on the lathe to be sure everything is properly mounted. Advance the tool bit manually until it just contacts the drum. This is called a **scratch cut.** ● **SEE FIGURE 104–16.**

STEP 3 Stop the lathe and back off the tool bit. Loosen the arbor nut, rotate the drum one-half turn (180°) on the arbor, and retighten the arbor nut. ● **SEE FIGURE 104–17.**

Turn the lathe on and make a second scratch cut.

a. If the scratch cuts are side-by-side, the lathe is okay and machining can begin.

b. If the scratch cuts are opposite, remove the drum and check for nicks, burrs, or chips on the mounting surfaces.

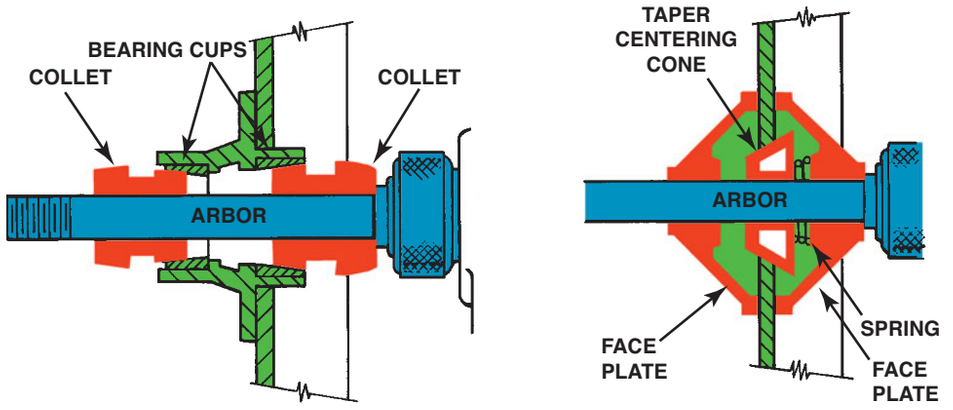

FIGURE 104–14 (a) A rotor or brake drum with a bearing hub should be installed on a brake lathe using the appropriate size collet that fit the bearing cups (races). (b) A hubless rotor or brake drum requires a spring and a tapered centering cone. A faceplate should be used on both sides of the rotor or drum to provide support. Always follow the operating instructions for the specified setup for the brake lathe being used.

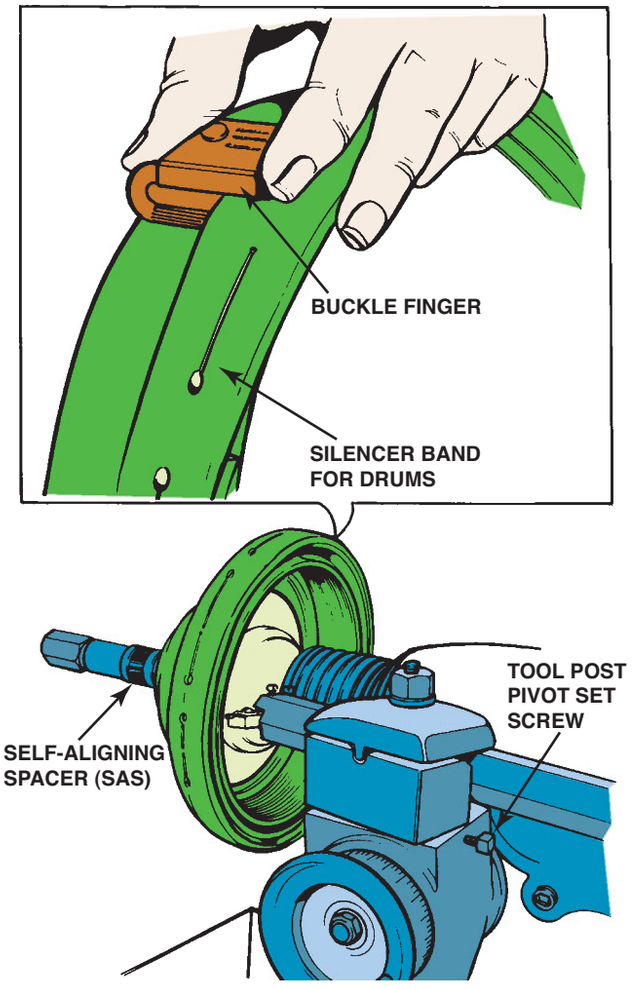

FIGURE 104–15 A self-aligning spacer (SAS) should always be used between the drum or rotor and the spindle retaining nut to help ensure an even clamping force and to prevent the adapters and cone from getting into a bind. A silence band should always be installed to prevent turning-tool chatter and to ensure a smooth surface finish. (*Courtesy of Ammco Tools, Inc.*)

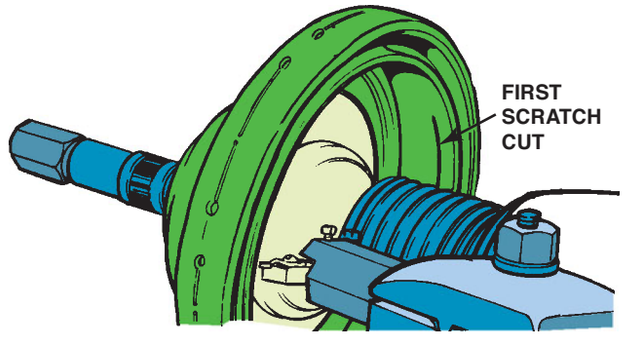

FIGURE 104–16 After installing a brake drum on the lathe, turn the cutting tool outward until the tool just touches the drum. This is called a scratch cut. (*Courtesy of Ammco Tools, Inc.*)

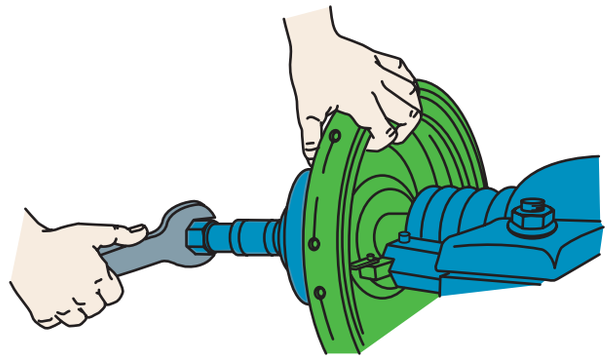

FIGURE 104–17 After making a scratch cut, loosen the retaining nut, rotate the drum on the lathe, and make another scratch cut. If both cuts are in the same location, the drum is installed correctly on the lathe and drum machining can begin. (*Courtesy of Ammco Tools, Inc.*)

STEP 4 Start the lathe and set the depth of the cut. ● **SEE FIGURES 104–18 AND 104–19.**

The maximum rough cut depends on the lathe type. The minimum cut is usually specified as no less than 0.002 in. (0.05 mm). A shallower cut usually causes the tool bit to slide over the surface of the metal rather than cut into the metal.

● **SEE FIGURE 104–20** for an example of a drum machined without properly positioning the antichatter (vibration) strap.

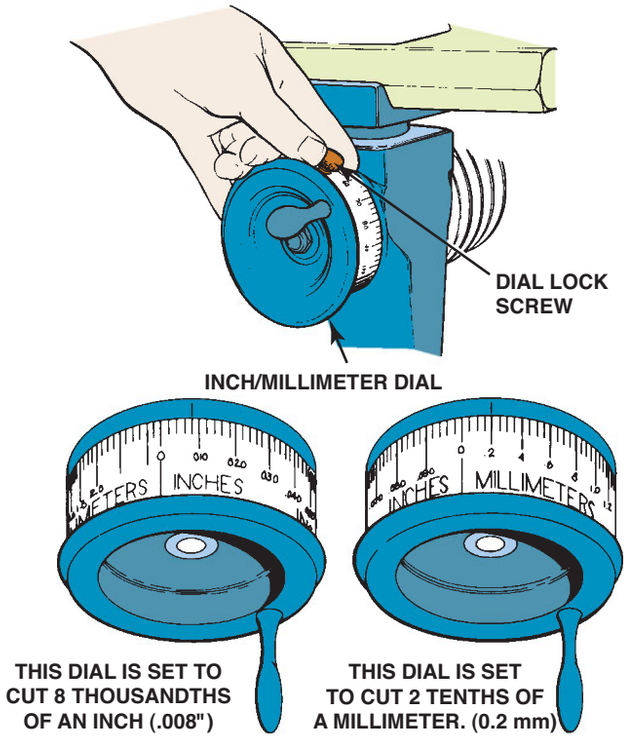

FIGURE 104–18 Set the depth of the cut indicator to zero just as the turning tool touches the drum. (*Courtesy of Ammco Tools, Inc.*)

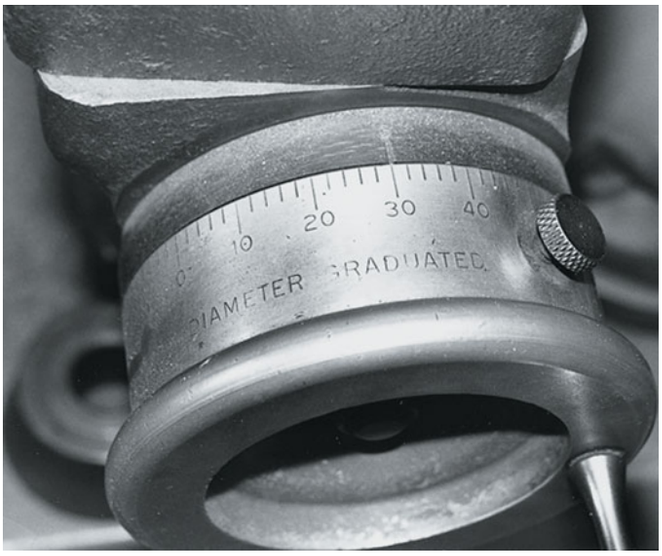

FIGURE 104–19 This lathe has a dial that is "diameter graduated". This means that a reading of 0.030 in. indicates a 0.015 in. cut that increases the inside diameter of the brake drum by 0.030 in.

DISC BRAKE ROTORS

Disc brake rotors use cast gray iron at the area that contacts the friction pad. Rotors, also called **discs** or **disks,** have mass (weight) that absorbs heat. The heavier the rotor, the more heat can be absorbed. Vehicle downsizing has resulted in the use of thinner- and lighter-weight rotors. As the weight of the rotor decreases, the less heat the rotor can "store" or absorb, resulting in the rotor getting hotter. As the rotor gets hotter, the rotor expands and "grows" larger where it is the hottest. If the rotor is allowed to cool gradually, the rotor simply returns to its original shape. If, however, the rotor is exposed to water, it may cool rapidly, causing the rotor to distort.

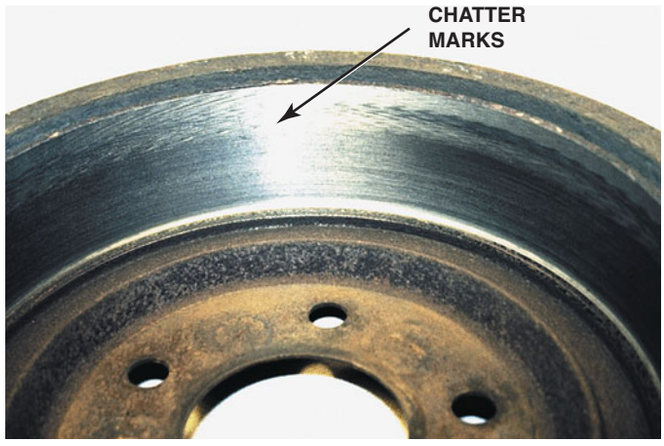

FIGURE 104–20 Notice the chatter marks at the edge of the friction-area surface of the brake drum. These marks were caused by vibration of the drum because the technician failed to wrap the dampening strap (silencer band) over the friction-surface portion of the brake drum.

FIGURE 104–21 This excessively worn (thin) rotor was removed from the vehicle in this condition. It is amazing that the vehicle was able to stop with such a thin rotor.

STYLES OR ROTORS

Rotors are made in several styles, including the following:

1. **Solid.** These are used on the rear of many vehicles equipped with rear disc brakes and on the front of some small and midsize vehicles. Solid rotors are usually used on the rear where only 20% to 40% of the braking occurs. Solid rotors are much thinner than vented rotors. ● **SEE FIGURE 104–21** for an example of an excessively worn solid rotor.
2. **Vented.** These are used on the front of most vehicles. The internal vanes allow air to circulate between the two friction surfaces of the rotor. Rotors can either be straight vane design, as shown in ● **FIGURE 104–22**, or directional vane design, as shown in ● **FIGURE 104–23.**

COMPOSITE ROTORS

Composite rotors use a steel center section with a cast iron wear surface. These composite rotors are lighter in weight than conventional cast-iron rotors. ● **SEE FIGURE 104–24.**

FIGURE 104–22 Severely worn vented disc brake rotor. The braking surface has been entirely worn away exposing the cooling fins. The owner brought the vehicle to a repair shop because of a "little noise in the front." Notice the straight vane design.

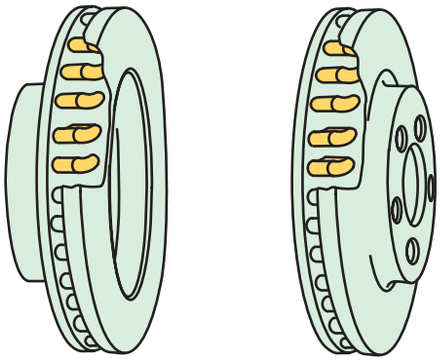

FIGURE 104–23 Directional vane vented disc brake rotors. Note that the fins angle toward the rear of the vehicle. It is important that this type of rotor be reinstalled on the correct side of the vehicle.

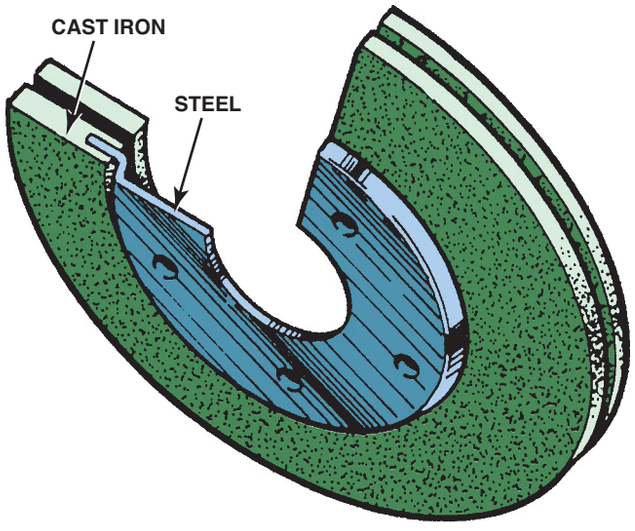

FIGURE 104–24 Typical composite rotor that uses cast iron friction surfaces and a steel center section.

The light weight of composite rotors makes them popular with vehicle manufacturers. However, technicians should be aware that full-contact adapters that simulate the actual wheel being bolted to the rotor must be used when machining composite rotors. If composite rotors are machined incorrectly, they must usually be replaced.

FIGURE 104–25 This Porsche is equipped with high-performance brakes including cross-drilled brake rotors.

FREQUENTLY ASKED QUESTION

What Does "Cross-Drilled" and "Slotted" Mean?

The expression "cross-drilled" and "slotted" refers to two separate processes. The first procedure involves drilling rows of holes through the friction surfaces of the rotor. The second procedure refers to milling a series of specially machined grooves from the center of the disc toward the edge. When the friction surfaces of a rotor are smooth and flat, there is no means of escape for the gases and dust, which build up between pad and rotor. This is not a huge problem in normal driving, but is an important consideration in street performance applications.

The drill holes (which are sometimes called "gas relief openings") provide an exit route for the dust and gas. The holes are also commonly labeled "cooling holes" because of the improvements they make in this area. Better cooling means less fade during repeated heavy brake application. They also help dissipate water when driving in poor weather. ● **SEE FIGURE 104–25.**

Slotting increases the bite of the pads and is even more effective than cross-drilling in combating the problem known as "out-gassing." This is when, at very high braking temperatures, the bonding agents used in some brake pads produce a gas. Under extreme conditions, this gas can create a gas cushion between pad and rotor, giving a driver a normal pedal feel but reducing the amount of friction being generated. The slots pump away gas and restore full contact. The "micro-shaving" effect of the slots also serves to deglaze the pads and this is why the edges of the slots are not chamfered or "radiused." It also tends to even out the wear across the brake pad faces, increasing the effective contact area.

ALUMINUM METAL MATRIX COMPOSITE ROTORS

Some disc brake rotors are manufactured from an aluminum metal matrix composite alloy reinforced with 20% silicon carbide particulate. Aluminum composites combine the light weight and thermal conductivity of aluminum with the stiffness and wear resistance of a ceramic to create a disc brake rotor with excellent heat dissipation and service life.

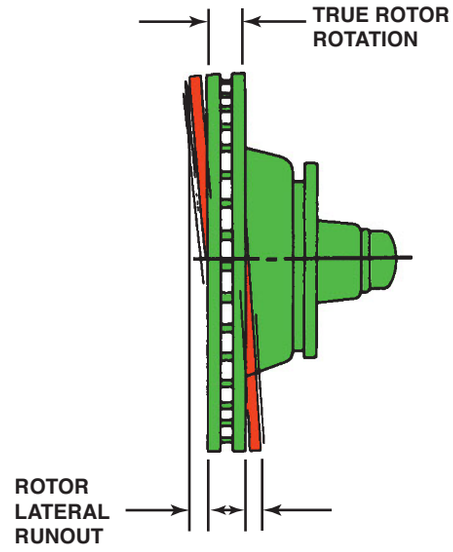

FIGURE 104–26 Brake rotor lateral-runout distortion.

These rotors can be distinguished from conventional cast-iron rotors in several ways. At first glance the rotors are silver gray with a dark gray or black transfer layer (from the brake pad) on the rubbing surface. Unlike cast iron, these rotors will show no signs of rust and are nonmagnetic. When removed from the vehicle, the aluminum composite rotors can be further distinguished by their light weight, usually under 6 lb (2.7 kg) versus over 12 lb (5.4 kg) for cast-iron rotors on the typical passenger vehicle.

Servicing these rotors is slightly different from cast-iron rotors. The dark transfer layer on the rubbing surface does not harm rotor performance and should not be removed unless the rotor needs to be machined due to being warped. Carbide tools can be used to machine a single set of aluminum composite rotors. If a shop receives these rotors on a regular basis, a polycrystalline diamond (PCD)-tipped tool is a good investment. Although more expensive initially, the PCD tool can last 100 times longer than a carbide tool.

DISC BRAKE ROTOR DISTORTION

CAUSES OF ROTOR DISTORTION The friction surfaces of a rotor in perfect condition are perpendicular to the axle centerline, and have no side-to-side movement. Unlike brake drums, rotors do not suffer distortion as a routine part of brake operation. However, distortion can occur during braking if there is a problem with the friction assembly, such as a frozen caliper piston that creates unequal application force on the two sides of the rotor.

Friction surface distortion is much more significant in a disc brake rotor than in a brake drum because the design of the friction assembly magnifies the effect of any wear. The hydraulic principles dictate that small movements of the large pistons in the brake calipers are converted into large movements of the small pistons in the master cylinder. Even very small amounts of distortion in a disc brake rotor can cause large amounts of pedal pulsation.

ROTOR LATERAL RUNOUT **Lateral runout,** often abbreviated **LRO or T.I.R.** for **total indicator runout,** is side-to-side wobble of the rotor as it rotates on the spindle. ● **SEE FIGURE 104–26.**

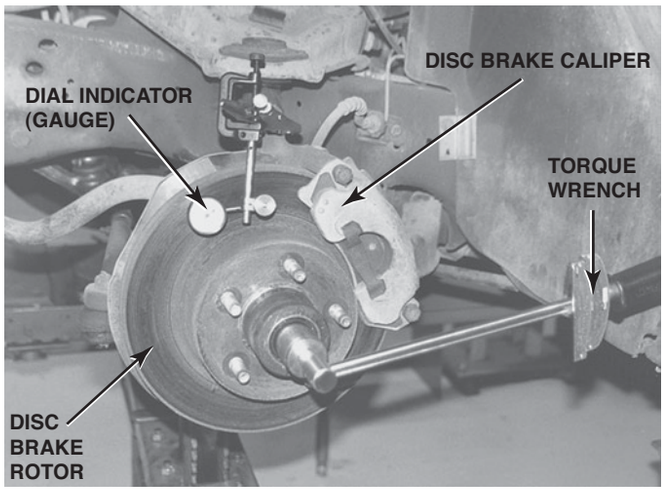

FIGURE 104–27 Before measuring lateral runout with a dial indicator (gauge), remove any wheel bearing end play by tightening the spindle nut to 10 to 20 ft-lb with a torque wrench. This step helps prevent an inaccurate reading. If the vehicle is to be returned to service, be sure to loosen the spindle nut and retighten to specifications (usually, finger tight) to restore proper bearing clearance.

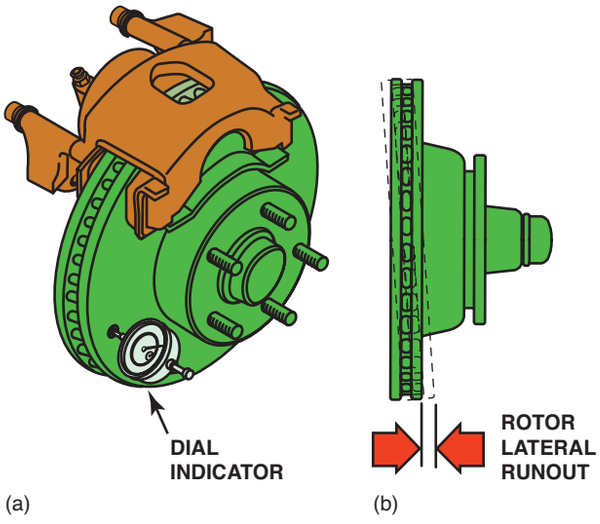

FIGURE 104–28 (a) Rotate the disc brake rotor one complete revolution while observing the dial indicator (gauge). (b) Most vehicle manufacturers specify a maximum runout of about 0.003 in. (0.08 mm).

A small amount of runout provides caliper piston knockback that reduces drag when the brakes are not applied. However, if the amount of runout is too great, excessive brake pedal travel and front-end vibration, felt in the steering wheel, will result. In cases of severe runout, a pulsating brake pedal may also be present.

Lateral runout can be caused by several factors. Overtightened or unevenly tightened lug nuts or bolts are a common source of runout on newer vehicles with downsized brake rotors. Extreme heat or rapid temperature variations also cause runout. Inaccurate machining at the factory or in the field is also a common cause of this distortion. Most maximum values range between 0.002 and 0.005 in. (0.05 and 0.13 mm). Always check service information for the exact specifications for the vehicle being serviced. ● **SEE FIGURES 104–27 AND 104–28.**

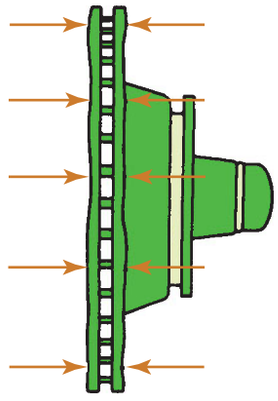

FIGURE 104–29 Brake rotor lack-of-parallelism distortion.

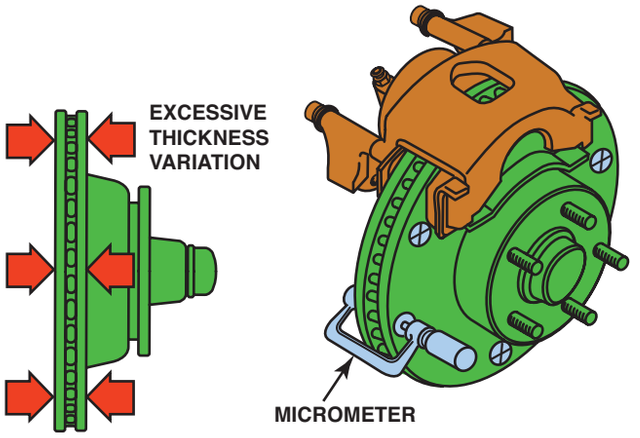

FIGURE 104–30 (a) Disc brake rotor thickness variation (parallelism). (b) The rotor should be measured with a micrometer at four or more equally spaced locations around the rotor.

ROTOR LACK OF PARALLELISM

Lack of **parallelism,** also called **thickness variation (TV),** is a variation in the thickness of the rotor when it is measured at several places around its circumference. ● **SEE FIGURE 104–29.**

A rotor with friction surfaces that are not parallel is the most common disc brake cause of a pulsating brake pedal. A lack of rotor parallelism will cause a pedal pulsation when the brakes are applied at all speeds, and can also cause front-end vibration during braking. ● **SEE FIGURE 104–30.**

Lack of parallelism can be caused by a soft spot in the rotor casting that wears more rapidly than surrounding areas, but the most common cause is rust buildup on the rotor when the vehicle is not driven for an extended period. The part of the friction surface protected by the brake pads does not rust as much as the rest of the rotor, and because the rusted areas wear faster, this results in a thickness variation when the vehicle is driven again.

Because parallelism variation is much more likely to cause a problem than lateral runout, the maximum amount allowed is much smaller than for runout. Most manufacturers specify that the two friction surfaces of a rotor must be parallel within half a thousandth of an inch, 0.0005 in. (0.013 mm), or less.

TECH TIP

Braking Vibration Could Be Due to the Tires

A vibrating condition (roughness) during braking is usually caused by disc brake rotor thickness variation or an out-of-round brake drum. Both conditions should be investigated. However, the tires and/or road conditions can also cause the same vibrations.

Tests performed by vehicle and tire-manufacturing engineers have shown that tires, and tires alone, could be the cause. If no other problem can be isolated, install a different brand of tire on the vehicle and retest. The cause of the tire vibration seems to be due to distortion or movement of the tire tread. A different brand of tires would have a different tread rubber compound, carcass body ply angles, or other factor that can contribute to a vibration during braking.

TECH TIP

Think of a Human Hair

Measurements and specifications do not seem to mean much unless you can visualize the size compared to something with which you are familiar. The diameter of a human hair is from 0.002 to 0.004 in. (2 to 4 thousandths of an inch).

The maximum lateral runout of a rotor is usually within this same dimension. The reason a dial indicator has to be used to measure runout, and a micrometer to measure parallelism, is that the dimensions involved are less than the diameter of a human hair. ● **SEE FIGURE 104–31.**

DISC BRAKE ROTOR THICKNESS

Most rotors have a minimum thickness cast or stamped into the rotor. This thickness is minimum wear thickness. At least 0.015 in. (0.4 mm) must remain after machining to allow for wear. Some vehicle manufacturers, such as General Motors, specify that 0.030 in. [0.8 mm] be left for wear. ● **SEE FIGURE 104–32.**

Whenever machining (resurfacing) a rotor, an equal amount of material must be removed from each side.

WHEN THE ROTORS SHOULD BE MACHINED

According to brake design engineers, a worn rotor has a very smooth friction surface that is ideal for replacement (new) disc brake pads. Often when the rotors are machined, the surface finish is not as

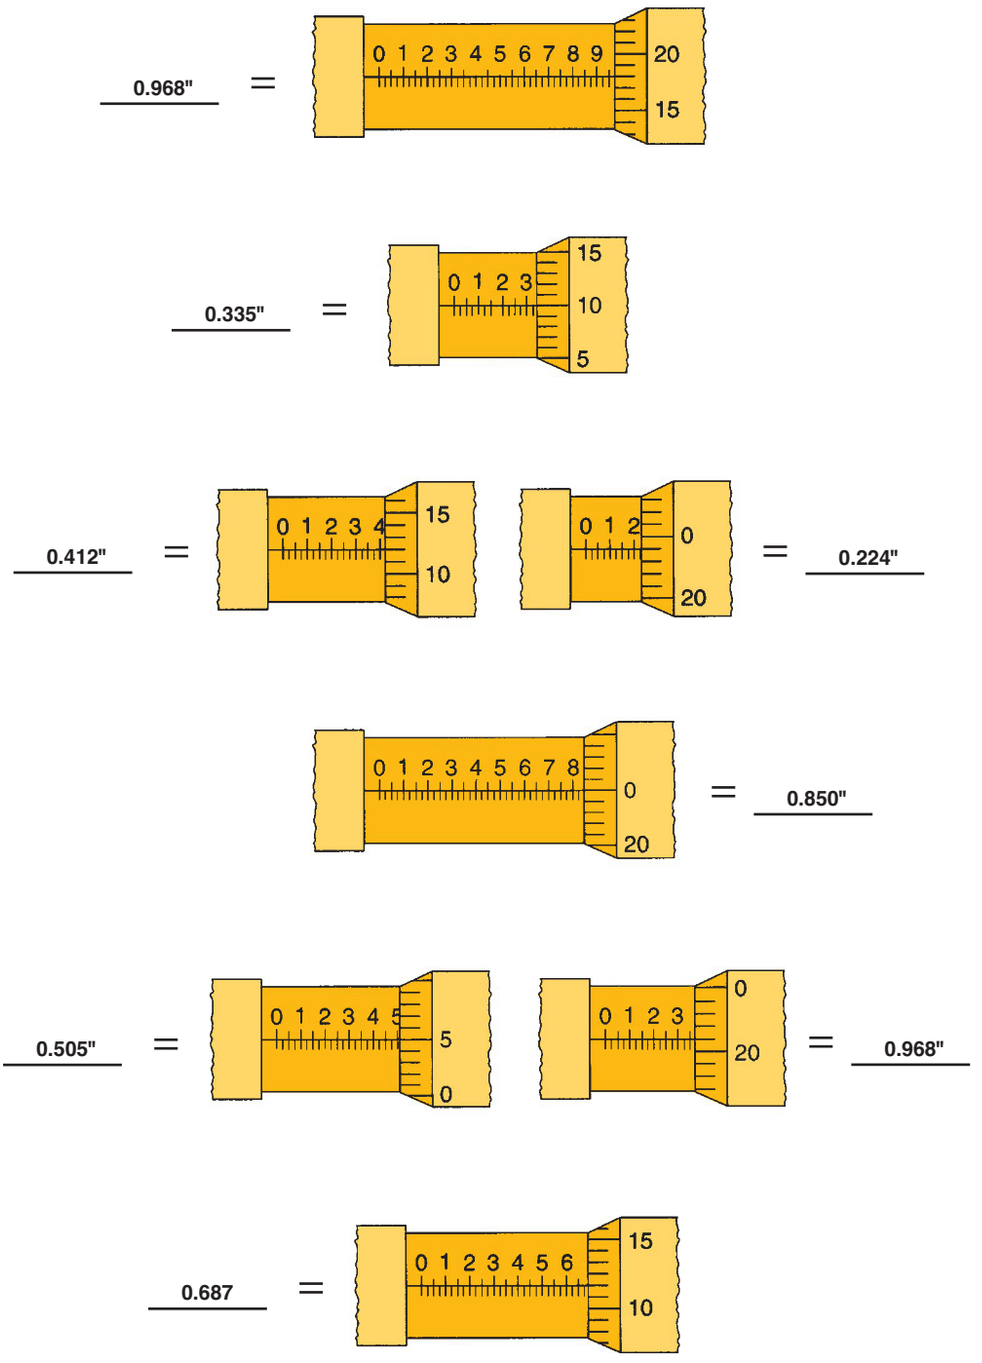

FIGURE 104–31 Sample micrometer readings. Each larger line on the barrel between the numbers represents 0.025″. The number on the thimble is then added to the number showing and the number of lines times 0.025″.

smooth as specified. Therefore, a rotor should be machined only if one of the following conditions exists:

1. Deep grooves deeper than 0.060 in. (1.5 mm). This is the approximate thickness of a nickel! ● **SEE FIGURE 104–33.**
2. Thickness variation exceeding specifications and a brake pedal pulsation complaint.
3. Heavy rust that has corroded the friction surface of the rotor. ● **SEE FIGURES 104–34 AND 104–35.**

Therefore, if there is no complaint of a pulsating brake pedal during braking and the rotor is not deeply grooved or rusted, it should not be machined. New disc brake pads perform best against a smooth surface, and a used disc brake rotor is often smoother than a new rotor.

ROTOR FINISH

The smoothness of the rotor is called rotor finish or surface finish. Surface finish is measured in units called **microinches,** abbreviated **µin.,** where the symbol in front of "in." is the Greek lowercase letter µ (mu). One microinch equals 0.000001 in. (0.025 micrometer [µm]). The finish classification of microinch means the distance between the highest peaks and the deepest valley. The usual method of expressing surface finish is the arithmetic average roughness height, abbreviated **Ra,** which is the average of all peaks and valleys from the mean (average) line. This surface finish is measured using a machine with a diamond stylus, as shown in ● **FIGURE 104–36.**

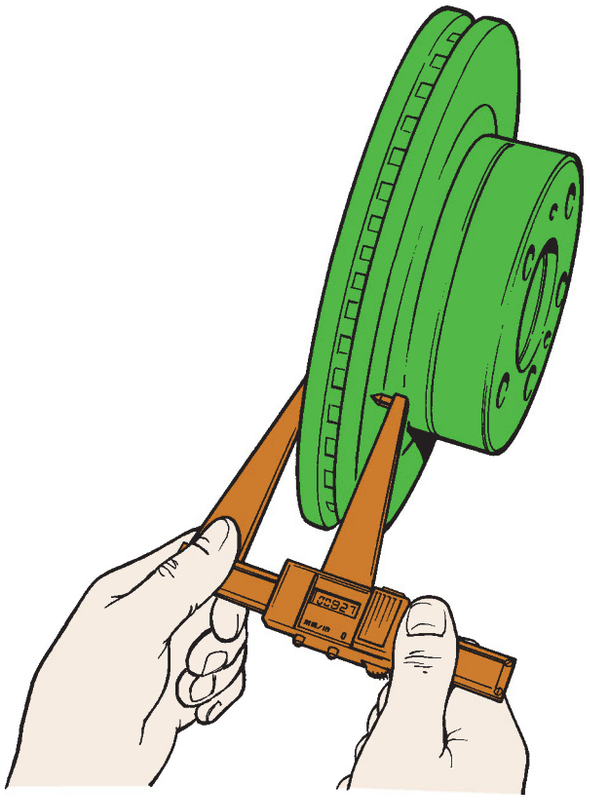

FIGURE 104–32 A digital readout rotor micrometer is an accurate tool to use when measuring a rotor. Both fractional inches and metric millimeters are generally available.

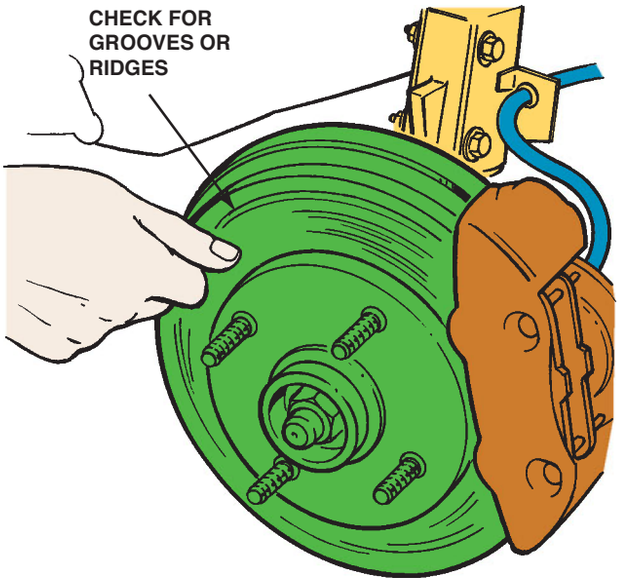

FIGURE 104–33 If a fingernail catches on a groove in the rotor, the rotor should be machined.

FIGURE 104–34 This rusted rotor should be machined.

FIGURE 104–35 Rotors that have deep rust pockets usually cannot be machined.

TECH TIP

The Ballpoint Pen Test

A smooth friction surface on a drum or rotor is necessary for proper brake operation. To quickly determine if the friction surface of a brake drum or rotor is not smooth enough, draw a ballpoint pen across the surface. If the surface is smooth enough, a solid ink line will be observed. If the line drawn by the pen is not solid, then the surface is not smooth enough.

Another classification of surface finish that is becoming obsolete is the *root mean square (RMS).* The RMS method gives a slightly higher number and can be obtained by multiplying Ra × 1.11 = RMS.

Often, a machined rotor will not be as smooth as a new rotor, resulting in a hard-stopping complaint after new brakes have been installed. A rough rotor has less surface area touching the new brake pads, resulting in a hard brake pedal and reduced braking effectiveness. Most new rotors have a surface finish of 45 to 60 µin. Ra.

- The higher the Ra of a rotor, the rougher the surface finish.
- The lower the Ra number, the smoother the surface finish

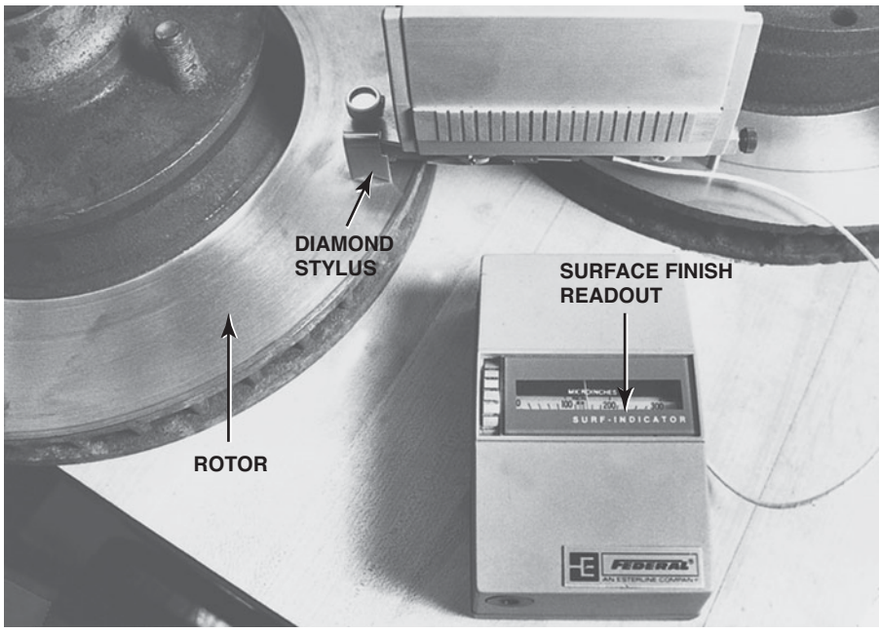

FIGURE 104–36 Electronic surface finish machine. The reading shows about 140 µin. This is much too rough for use but is typical for a rough cut surface.

MACHINING A DISC BRAKE ROTOR

Before machining a rotor, be sure that it can be machined by comparing the minimum thickness specification and the measured thickness of the rotor. Many lathes are capable of removing a large amount of material in one pass, thereby reducing the time necessary to refinish a rotor. These lathes usually use a positive rake tool bit angle. ● **SEE FIGURE 104–37.**

Other lathes that use six-sided reversible tool bits usually use a negative rake tool bit angle. Ammco is an example of a negative rake lathe, whereas Perfect-Hofmann and Accu-turn are examples of positive rake lathes.

CAUTION: Some original equipment and replacement disc brake rotors are close to the minimum allowable thickness when new. Often, these rotors cannot be safely machined at all!

Following is an example of the steps necessary to machine a disc brake rotor. Always follow the instructions for the equipment you are using.

STEP 1 Mount the disc brake rotor to the spindle of the lathe using the cones and adapters recommended. ● **SEE FIGURES 104–38 AND 104–39.**

STEP 2 Install a rotor damper and position the cutting tools close to the rotor surface as shown in ● **FIGURE 104–40.**

NOTE: Failure to install the damper causes vibrations to occur during machining that create a rough surface finish.

STEP 3 Make a scratch cut on the rotor face, as shown in ● **FIGURE 104–41.**

STEP 4 To check that the rotor is mounted correctly, loosen the retaining nut, turn the rotor one-half turn (180°), and retighten the nut. Make another scratch cut.

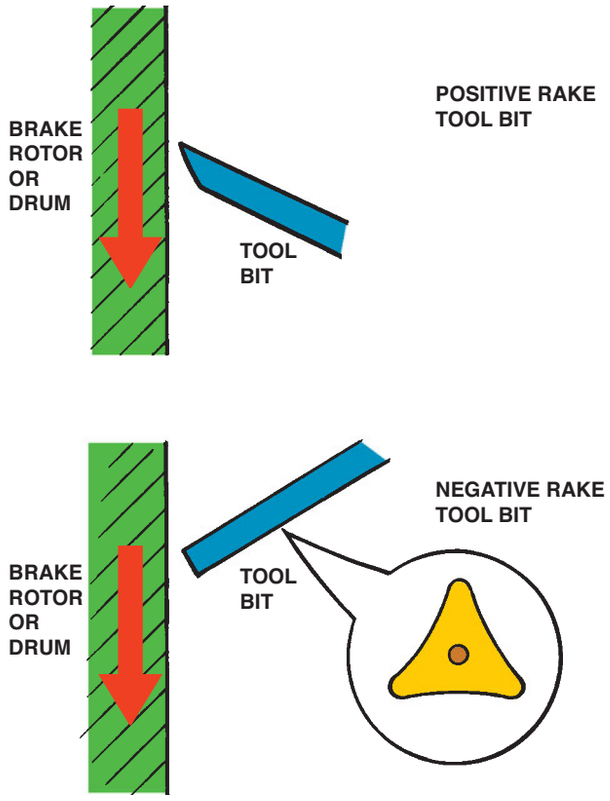

FIGURE 104–37 Most positive rake brake lathes can cut any depth in one pass, thereby saving time. A typical negative rake lathe uses a three-sided turning tool that can be flipped over, thereby giving six cutting edges.

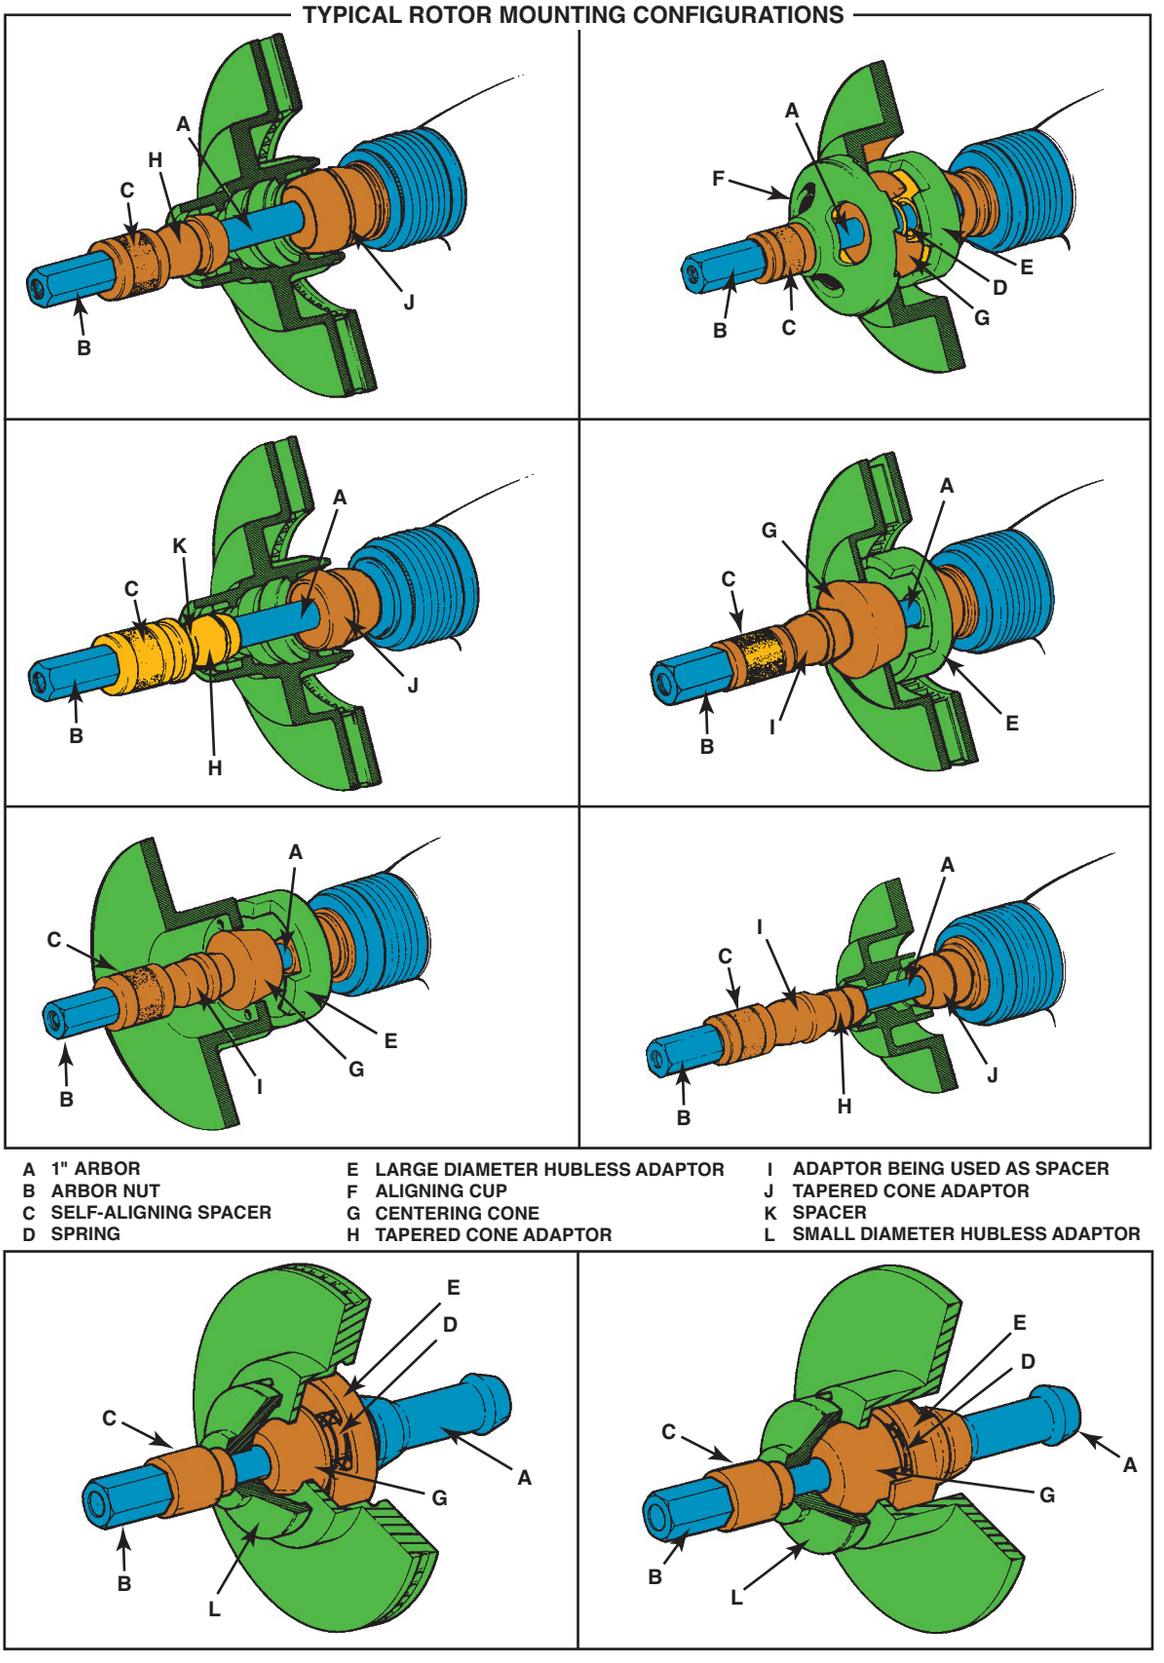
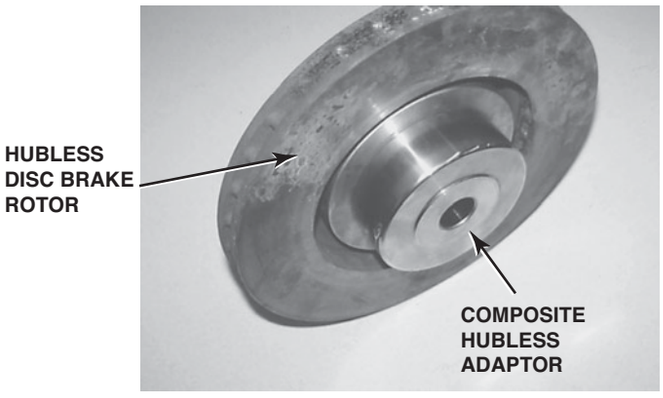
a. The second scratch cut should be side-by-side with the first scratch cut if the rotor is properly installed, as shown in ● **FIGURE 104–42.**

b. If the second scratch cut is on the opposite side (180°) from the first scratch cut, the rotor may not be installed on the lathe correctly.





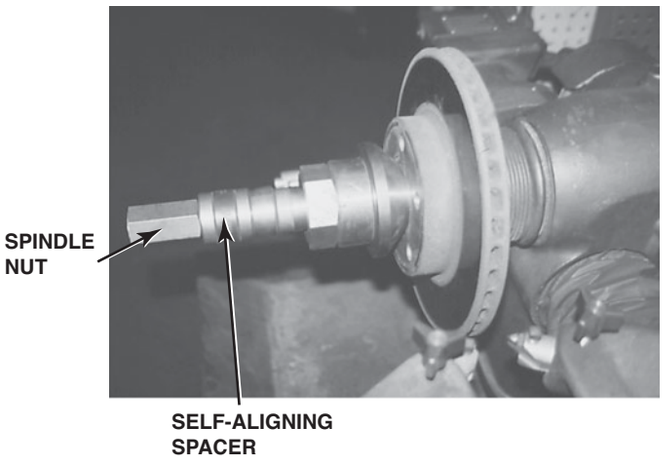


FIGURE 104–38 Recommended adapters and location for machining hubbed and hubless rotors. (*Courtesy of Ammco Tools, Inc.*)

NOTE: The runout as measured with a dial indicator on the brake lathe should be the same as the runout measured on the vehicle. If the runout is not the same, the rotor is not installed on the brake lathe correctly.

STEP 5 After proper installation of the disc brake rotor on the brake lathe, proceed with machining the rotors. For best results do not machine any more material from the rotor than is absolutely necessary. Always follow the recommendations and guidelines as specified by the vehicle manufacturer.

(a)

(b)

FIGURE 104–39 (a) Composite adapter fitted to a rotor. (b) Composite rotor properly mounted on a lathe.

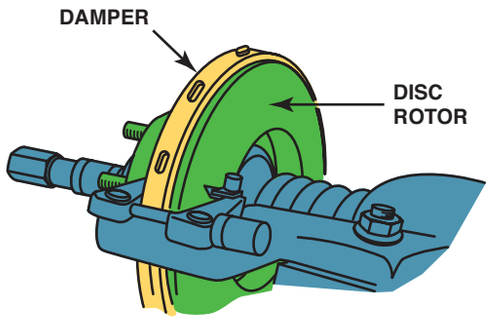

FIGURE 104–40 A damper is necessary to reduce cutting-tool vibrations that can cause a rough surface finish.

ROUGH CUT A rough cut on a lathe involves cutting 0.005 in. per side with a feed of 0.008 in. per revolution and 150 RPM spindle speed. This usually results in a very coarse surface finish of about 150 µin. Ra.

FINISH CUT A finish cut means removing 0.002 in. per side with a feed of 0.002 in. per revolution and 150 RPM spindle speed. Although this cut usually looks smooth, the surface finish is about 90 to 100 µin. Ra. Even a typical finish cut is still not nearly as smooth as a new rotor.

NOTE: Measure the thickness of the rotor after the finish cut and compare with manufacturers' specifications. Be sure to allow for wear. ● SEE CHART 104–1 for a metric/fractional measurement chart.

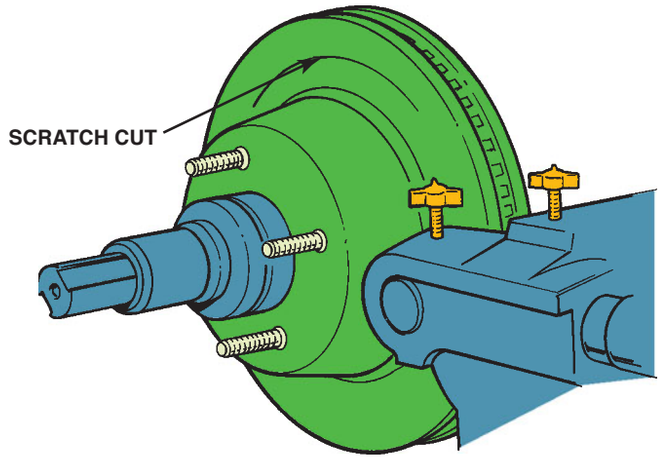

FIGURE 104–41 After installing the rotor on the brake lathe, turn the cutting tool in just enough to make a scratch cut.

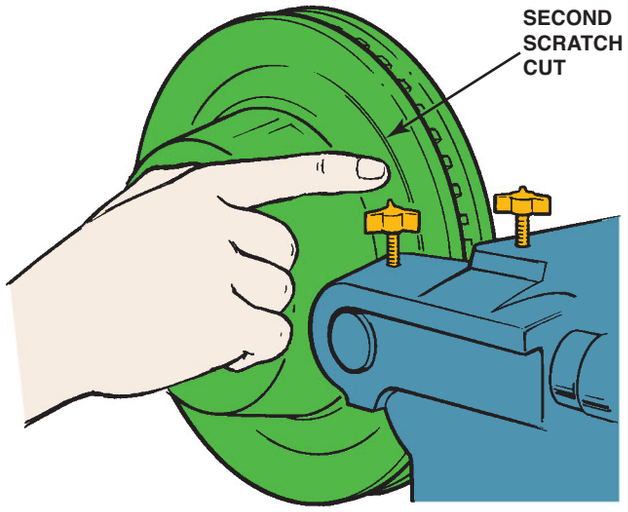

FIGURE 104–42 After making a scratch cut, loosen the retaining nut and rotate the rotor on the spindle of the lathe one-half turn. Tighten the nut and make a second scratch cut. The second scratch cut should be side-by-side with the first scratch if the rotor is installed correctly on the brake lathe.

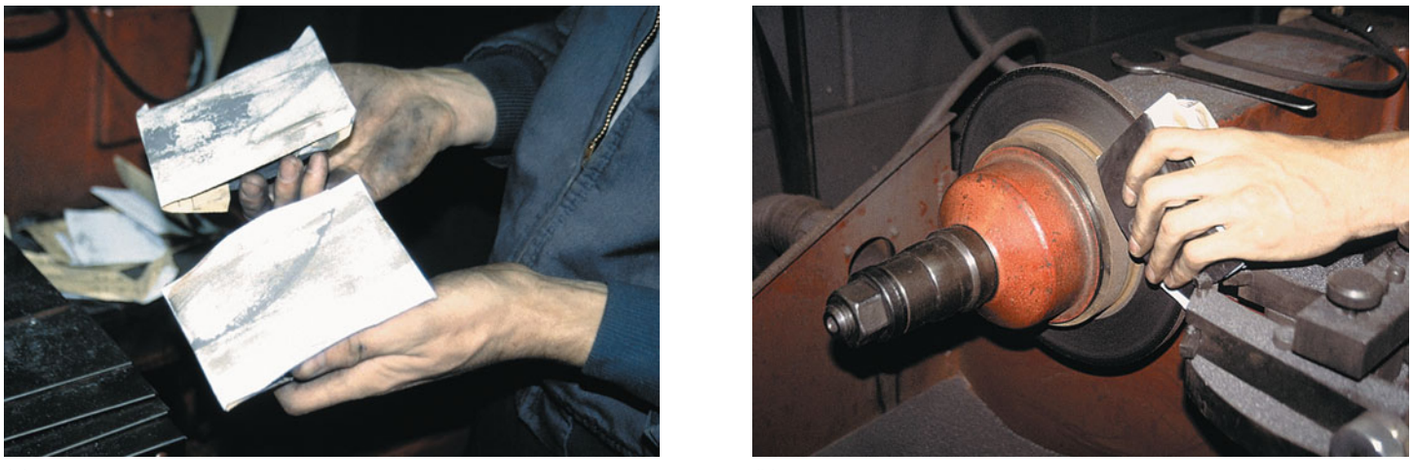
NONDIRECTIONAL FINISH Most vehicle and brake component manufacturers recommend a nondirectional finish to help prevent the grooves machined into the rotor from acting like record grooves that can force the pads to move outward while the rotor rotates.

CAUTION: Some nondirectional finish tools such as those that use Scotch Brite (a registered trademark) plastic pads often do not make the rotor as smooth as new, even though the finish has been swirled.



SURFACE FINISHING THE ROTOR The goal of any brake repair or service should be to restore the braking effectiveness to match new vehicle brakes. This means that the rotor finish should be as smooth or smoother than a new rotor for maximum brake pad contact. Research conducted at Delphi has shown that like-new rotor finish can easily be accomplished by using a block and sandpaper. After completing the finish cut, place 150-grit aluminum-oxide sandpaper on a block and apply steady pressure against the rotor surface for 60 seconds on each side of the rotor. ● **SEE FIGURES 104–43 AND 104–44.**

The aluminum oxide is hard enough to remove the highest ridges left by the lathe cutting tool. This results in a surface finish

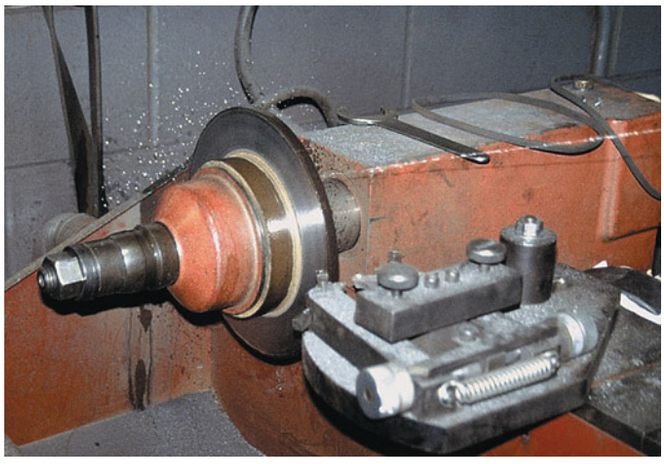
CHART 104–1

Metric/fractional chart.



(a) (b)

FIGURE 104–43 (a) This technician uses two sanding blocks each equipped with 150-grit aluminum-oxide sandpaper. (b) With the lathe turned on, the technician presses the two sanding blocks against the surface of the rotor after the rotor has been machined, to achieve a smooth microinch surface finish.

(a)

(b)

FIGURE 104–44 (a) After machining and sanding the rotor, it should be cleaned. In this case brake cleaner from an air pressurized spray can is used. (b) With the lathe turning, the technician stands back away from the rotor and sprays both sides of the rotor to clean it of any remaining grit from the sanding process. This last step ensures a clean, smooth surface for the disc brake pads and a quality brake repair. Sanding each side of the rotor surface for one minute using a sanding block and 150-grit aluminum-oxide sandpaper after a finish cut gives the rotor the proper smoothness and finish.

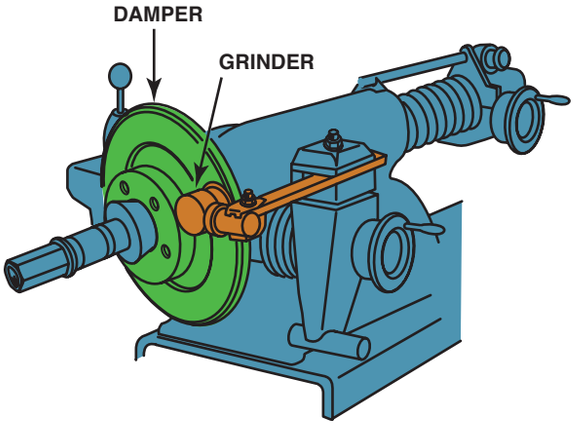


FIGURE 104–45 A grinder with sandpaper can be used to give a smooth nondirectional surface finish to the disc brake rotor.

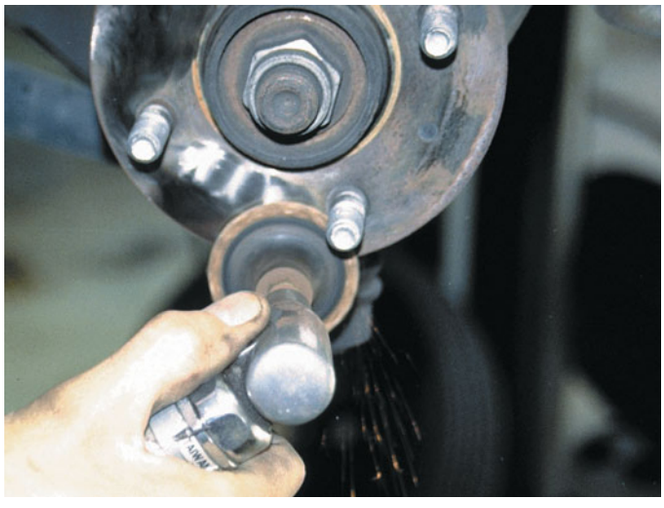

FIGURE 104–47 Rust should always be cleaned from both the rotor and the hub whenever the rotors are machined or replaced. An air-powered die grinder with a sanding disc makes quick work of cleaning this hub.

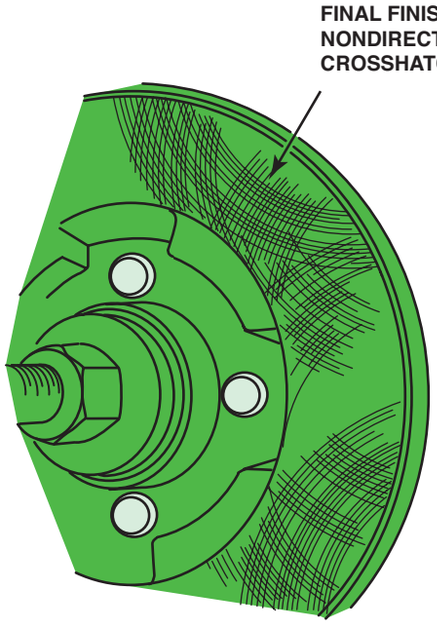

FIGURE 104–46 The correct final surface finish should be smooth and nondirectional.

ranging from 20 to 80 µin. and usually less than 40 µin., which is smoother than a new rotor. ● **SEE FIGURE 104–45.**

NOTE: Many commercial rotor-finish products may also give as smooth a surface finish. ● **SEE FIGURES 104–46.**

Always compare rotor finish to the rotor finish of a new rotor. Microinch finish is often hard to distinguish unless you have a new rotor with which to compare.

BRAKE HUB CLEANING Before installing the disc brake rotor on the vehicle be sure that bearing hub surface is clean and rust free. Using an air-powered die grinder equipped with a sanding disc works well. ● **SEE FIGURE 104–47**

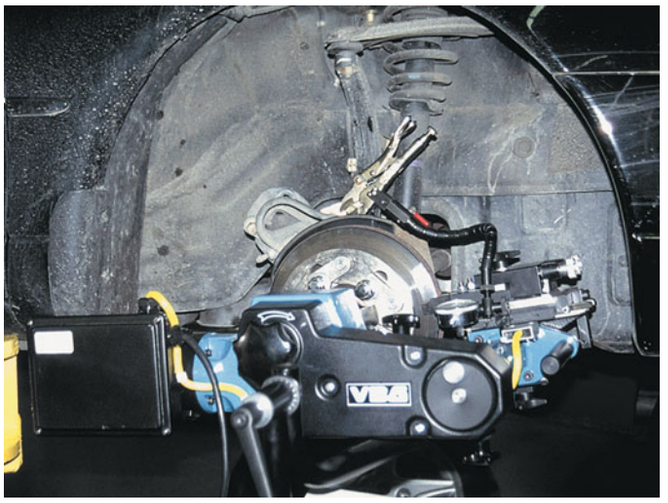

FIGURE 104–48 A typical hub-mount on-the-vehicle lathe. This particular lathe oscillates while machining the rotor, thereby providing a smooth and nondirectional finish at the same time.

FIGURE 104–49 A wheel stud was replaced on the rotor hub assembly when it was discovered to be stripped.

TECH TIP

Turn or Machine?

When asked about what was done to their vehicle, a common response of customers is "They rotated my rotors." Many customers do not understand the terms that are commonly used in the vehicle service industry. Try to use terms that are technically correct and avoid slang when talking to customers. For example, the expression *machined the rotors* indicates an operation, whereas the expression *turned the rotors* may be misinterpreted by some customers as simply meaning using your hand and moving (rotating) the rotor. *Resurfacing, refinishing,* and *reconditioning* are other terms that could be used to describe a drum or rotor machining operation.

TECH TIP

Always Check the Wheel Studs

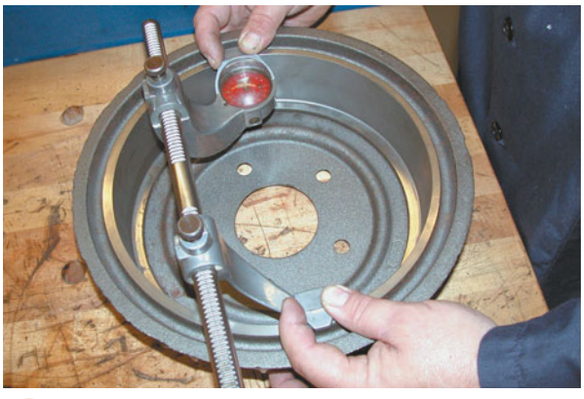
Before installing the wheel after brake service, check the condition of the wheel studs and lug nuts. Check for stripped threads, rust, or cracks. If necessary, replace the stud. Most studs are replaced by driving them out using a large hammer and then using washers and a lug nut to draw the serrated shoulder of the lug stud into the rotor stud hole. ● **SEE FIGURE 104–49.** Best to always use a torque wrench when installing lug nuts to ensure proper and even torque on all lug nuts. This helps to prevent rotor distortion, which can lead to vibration in the steering and/or pedal pulsation during braking.

ON-THE-VEHICLE ROTOR MACHINING

Many vehicle manufacturers recommend on-the-vehicle machining for rotors if the disc brake rotor must be machined due to deep scoring or pulsating brake pedal complaint. This is especially true of composite rotors or for vehicles such as many Honda vehicles that require major disassembly to remove the rotors.

Caliper-mount, on-the-vehicle lathes require that the disc brake caliper be removed. The cutter attaches to the steering knuckle or caliper support in the same location as the caliper. ● **SEE FIGURE 104–48.** Hub-mount, on-the-vehicle lathes attach to the hub using the lug nuts of the vehicle. To achieve a proper cut, the hub mount must be calibrated for any runout caused by the hub bearings and the outside surface face of the rotor.

NOTE: All on-the-vehicle lathes require that the wheel be removed. For best results, always use a torque wrench when tightening lug nuts or lathe adapters. Unequal torque on the bolts causes stress and distortion that can cause warped rotors and a pulsating brake pedal.



DRUM MACHINING

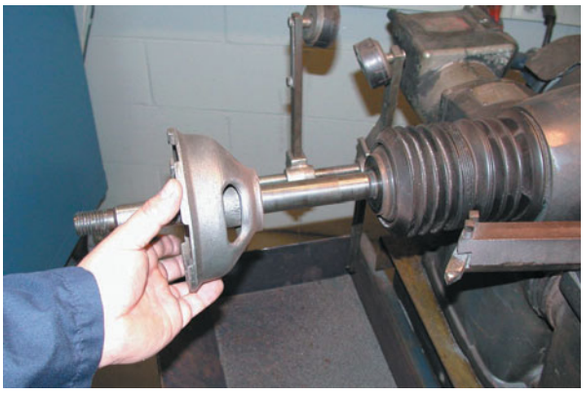
1 Before starting to machine a brake drum, check the drum for any obvious damage such as heat cracks or hard spots.

2 Lightly tap the drum. It should ring like a bell. If a dull thud is heard, the drum may be cracked and should be discarded.

3 Use a drum micrometer to measure the inside diameter of the drum and compare this measurement to specifications to be sure that the drum can be safely machined.

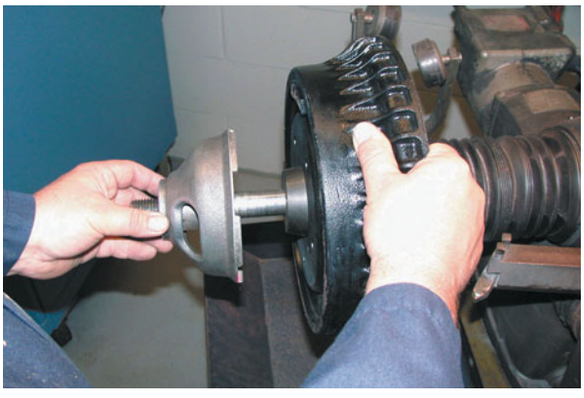
4 Most brake drums have the maximum inside diameter cast into the drum as shown. Allow 0.030 inch for wear after the machining has been performed.

5 Thoroughly clean the outside and inside of the drum.



6 Be sure the center hole in the drum is clean and free from any burrs that could prevent the drum from being properly centered on the shaft of the brake lathe.

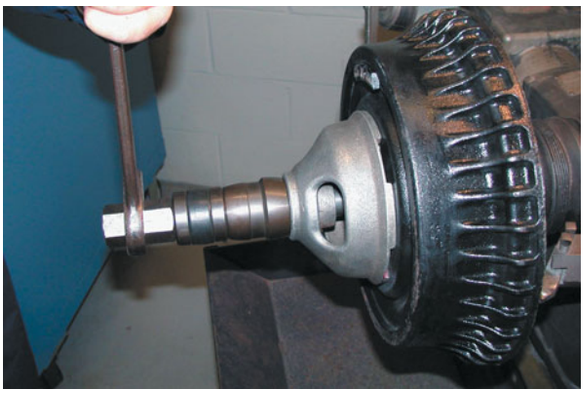
7 A typical brake lathe used to machine drums.



8 Locate a tapered, centering cone that best fits inside the hole of the brake drum.

9 Slide the large face plate over the shaft of the brake lathe.

10 Slide the tapered centering cone onto the shaft with the spring between the face plate and the centering cone.

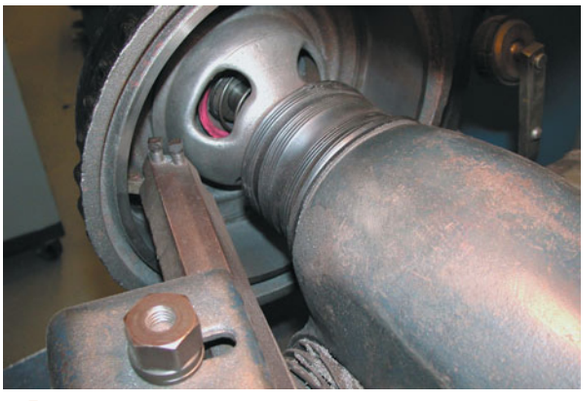


11 Slide the other face plate onto the shaft.

12 Install a bearing collet used as a spacer, then the self-aligning spacer (SAS) and left-hand-thread spindle nut.

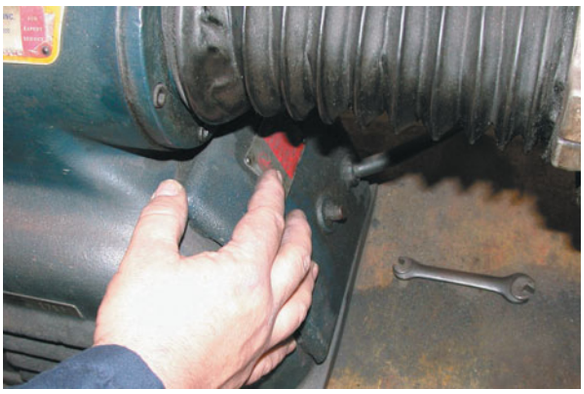
CONTINUED ▶

13 Tighten the spindle nut.

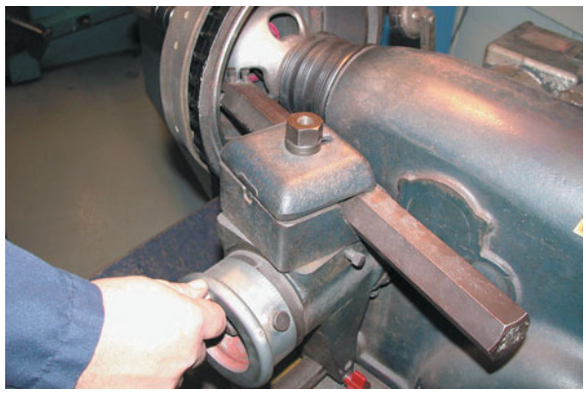


14 Loosen the turning bar retainer.

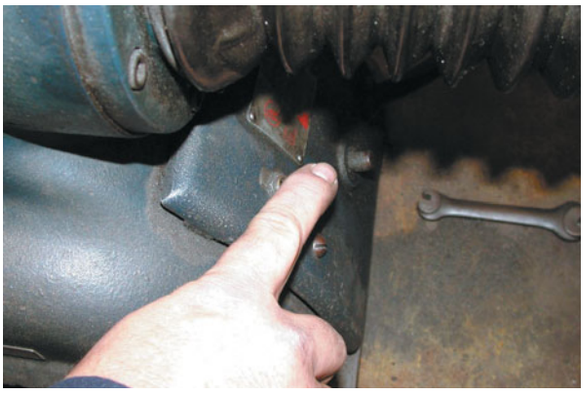
15 Carefully check the cutting bits and either rotate the bit to a new cutting point or replace it with a new part as necessary.



16 Turn the spindle control knob until the spindle is as short as possible (i.e., the drum as close to the machine as possible) to help reduce vibration as much as possible.

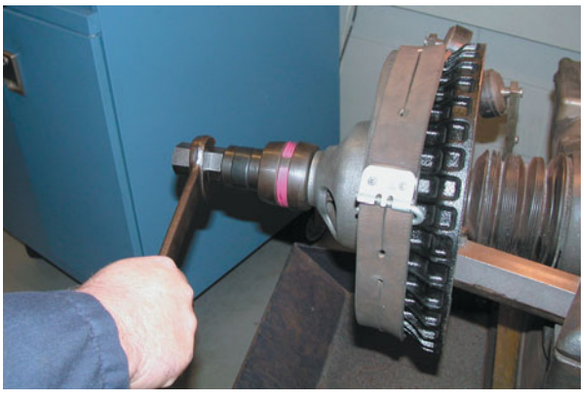


17 Position the cutting bar so that the cutting bit is located at the back surface of the drum.

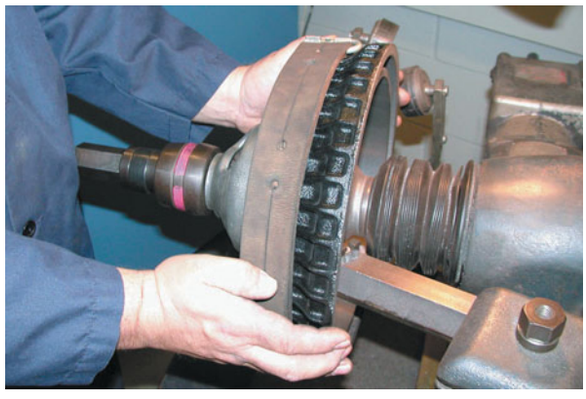


18 Install the silencer band (vibration dampener strap).

19 Be sure the tool bit and clothing are away from the drum and turn the brake lathe on.

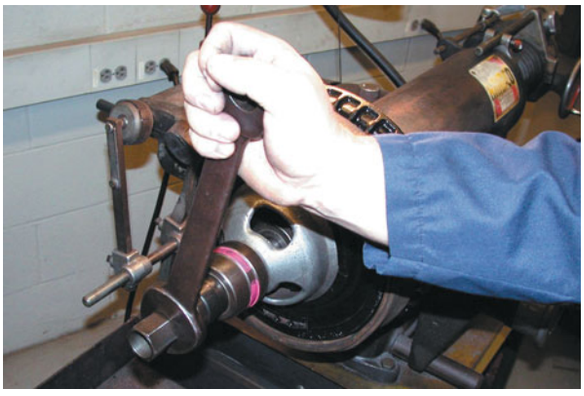


20 Center the bit in the center of the brake surface of the drum and rotate the control knob that moves the bit into contact with the drum friction surface. This should produce a light scratch cut.

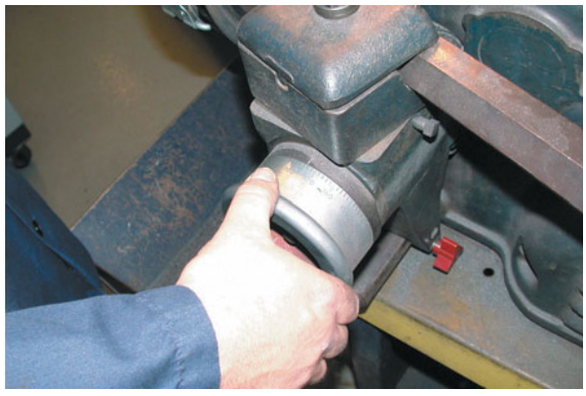


21 Turn the lathe off.

22 Observe the scratch cut.

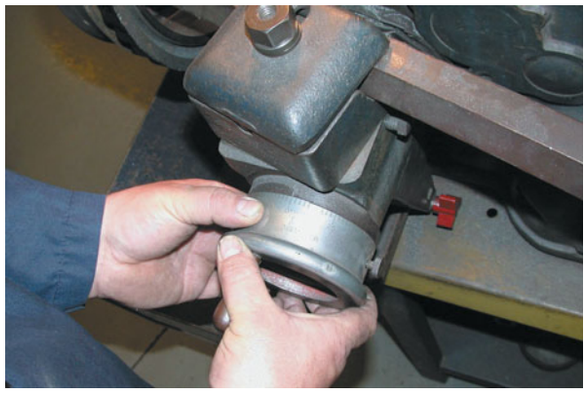


23 Loosen the spindle nut.



24 Rotate the drum 180° (one-half turn) on the spindle.

CONTINUED ▶



25 Tighten the spindle nut.

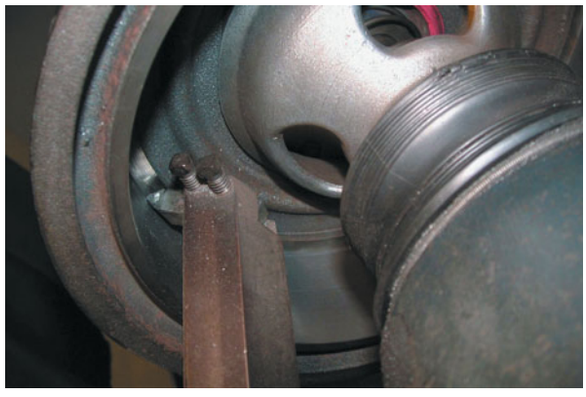
26 Turn the lathe on, rotate the control knob, and run the cutter into the drum for another scratch cut.

27 Observe the scratch cut. If the second scratch cut is in the same place as the first scratch cut or extends all the way around the drum, the drum is correctly mounted on the lathe.

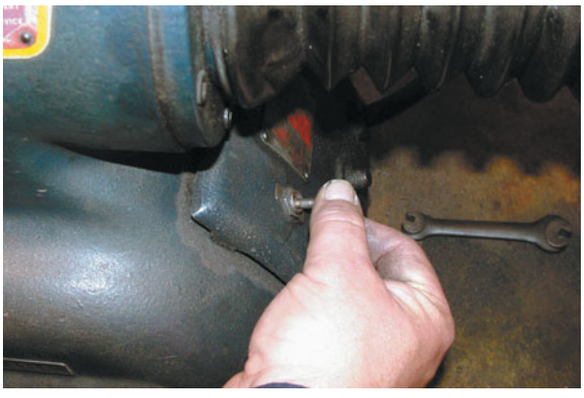
28 Adjust the depth gauge to zero when the cutter just touches the drum.

29 Run the cutter all the way to the back surface of the drum.

30 Adjust the depth of the cut and lock it in position by turning the lock knob. Most vehicle manufacturers recommend a rough cut depth should be 0.005–0.010 in. and a finish cut of 0.002 in.



31 Select a fast-feed rate if performing a rough cut (0.006–0.016 in. per revolution) or 0.002 in. per revolution for a finish cut.

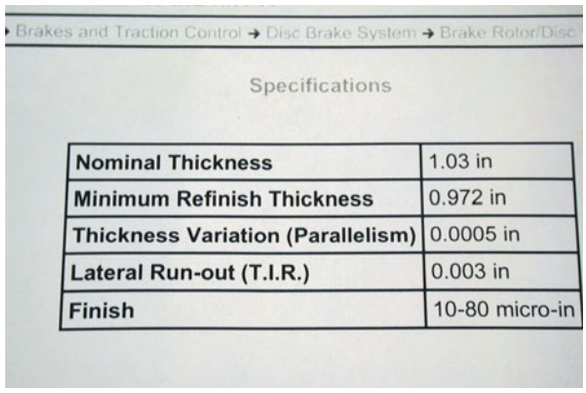


32 Turn the lock knob to keep the feed adjustment from changing.

33 Engage the automatic feed.

34 The drum will automatically move as the tool remains stationary to make the cut.

35 Turn the lathe off.



36 If additional material must be removed, proceed with the finish cut. Clean thoroughly before installing on a vehicle.

ROTOR MACHINING

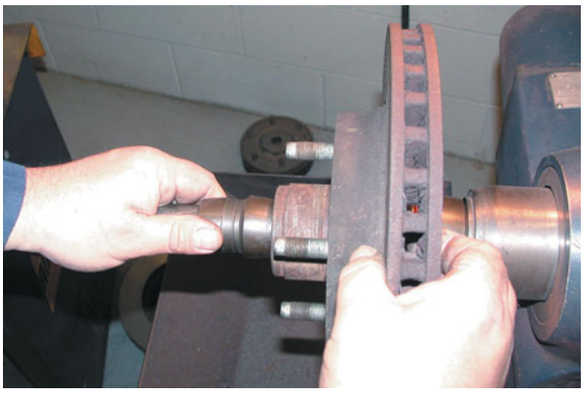
1 Before machining any rotor, use a micrometer and measure the thickness of the rotor.

2 Check the specifications for the minimum allowable thickness.

3 Visually check the rotor for evidence of heat cracks or hard spots that would require replacement (rather than machining) of the rotor.

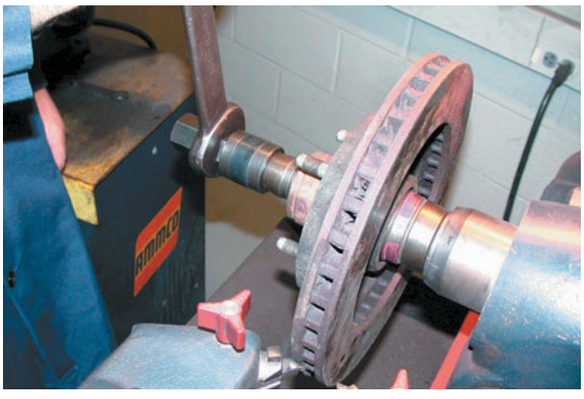
4 After removing the grease seal and bearings, remove the grease from the bearing races.

5 Clean and inspect the brake lathe spindle for damage or burrs that could affect its accuracy.



6 Select a tapered cone adapter that fits the inner bearing race.

7 Slide the cone adapter onto the brake lathe spindle.

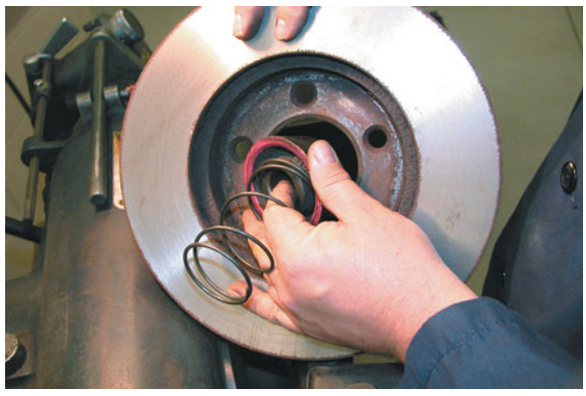


8 Select the proper size cone adapter for the smaller outer wheel bearing race.

9 Place the rotor onto the large cone adapter and then slide the small cone adapter into the outer wheel bearing race.

10 Install the self-aligning spacer (SAS) and spindle nut.

11 Tighten the spindle nut (usually left-hand threads).



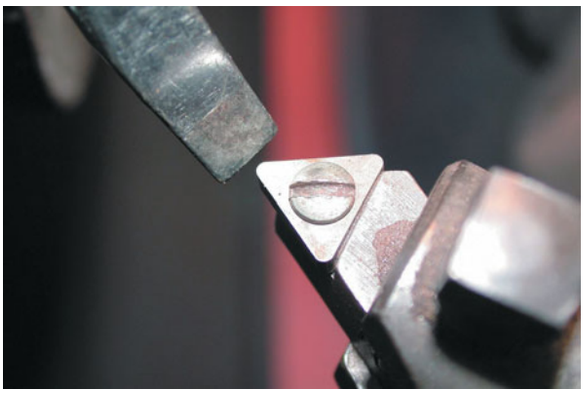
12 If a hubless rotor is being machined, be sure to thoroughly clean the inside surface.

CONTINUED ▶

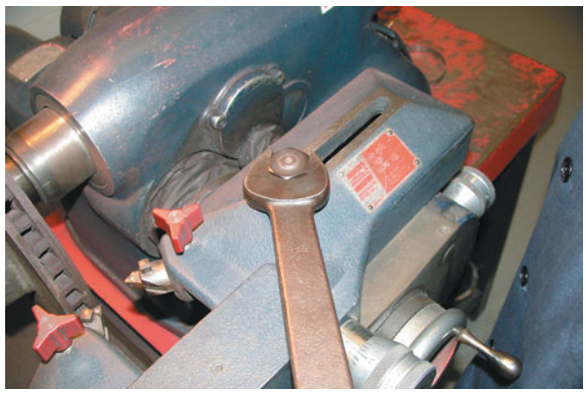
13 Also remove all rust from the other side of the hubless rotor.

14 Select the proper centering cone for the hole in the center of the hub.

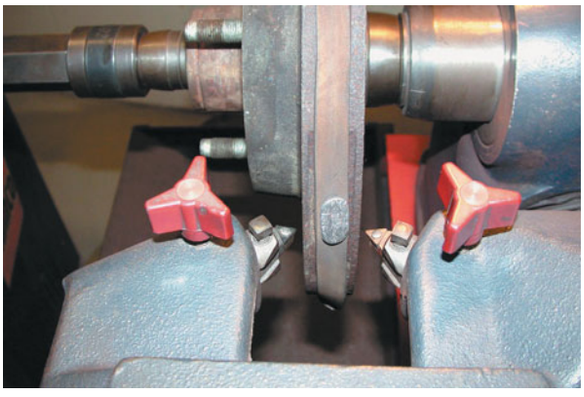
15 Select the proper size cone-shaped hubless adapter and the tapered centering cone with a spring in between.



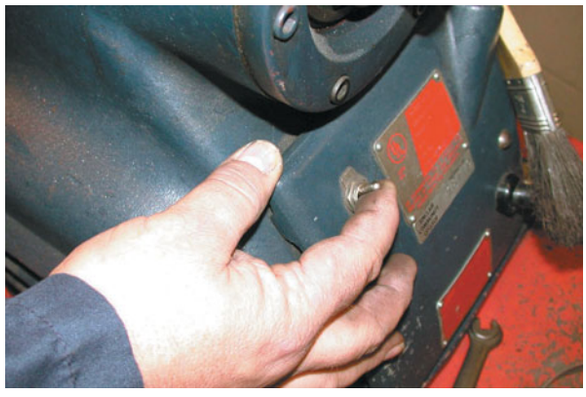
16 After sliding the rotor over the centering cone, install the matching hubless adapter.



17 Install the self-aligning spacer (SAS) and spindle nut.

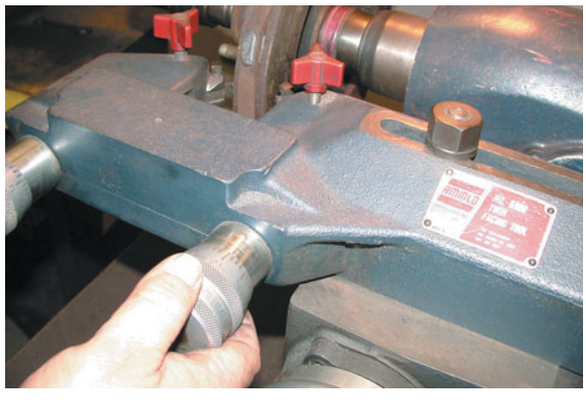


18 After the rotor has been secured to the brake lathe spindle, install the noise silencer band (dampener).



19 Carefully inspect the cutting bits and replace, if necessary.

20 Loosen the tool holder arm.



21 Adjust the twin cutter arm until the rotor is centered between the two cutting bits.

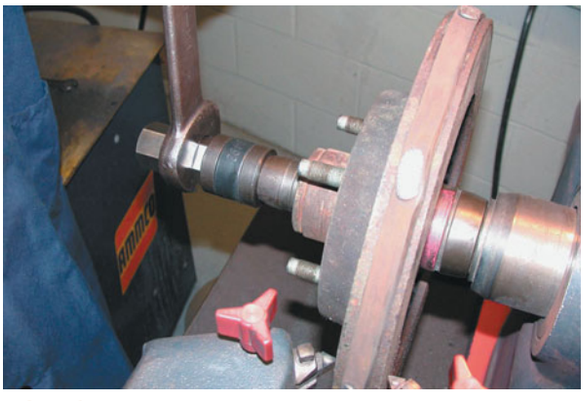
22 Turn the lathe on.

23 Move the cutter arm toward the center of the rotor, placing the cutting bits in about the center of the friction surface.

24 Turn one cutting bit into the surface of the rotor to make a scratch cut. This step checks the lathe setup for accuracy.

CONTINUED ▶

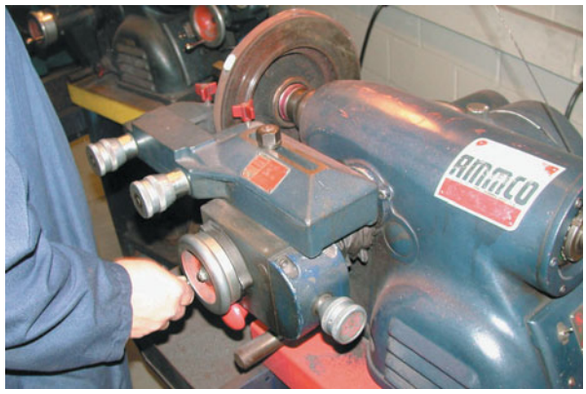
25 Turn the lathe off.



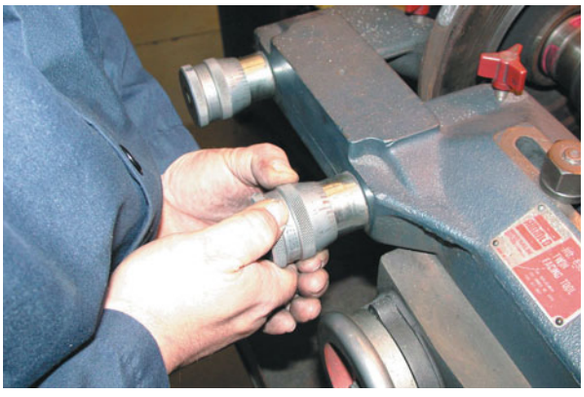
26 Observe the first scratch cut.

27 Loosen the spindle retaining nut.

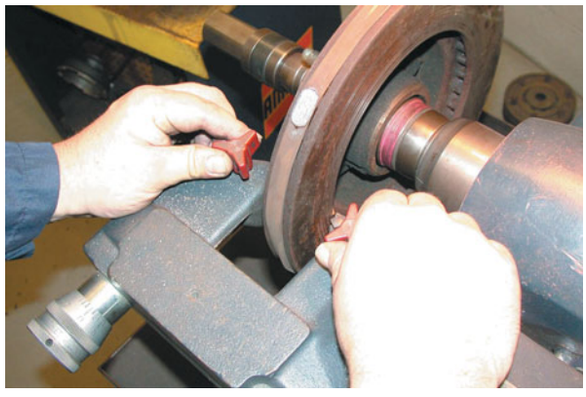
28 Rotate the rotor 180° (one-half turn) on the spindle of the brake lathe.



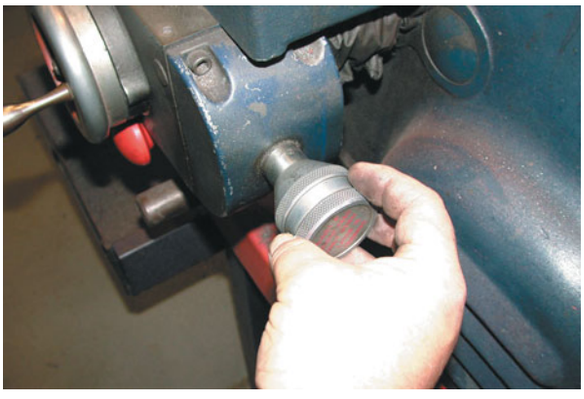
29 Tighten the spindle nut.



30 Turn the lathe back on and turn the cutting bit slightly into the rotor until a second scratch cut is made.



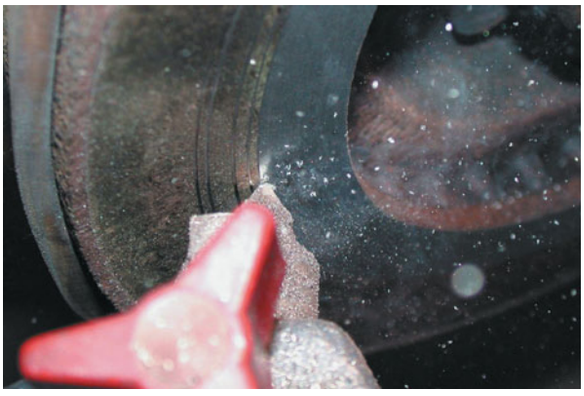
31 If the second scratch cut is in the same location as the first scratch cut or extends all around the surface of the rotor, then the rotor is properly installed on the lathe.



32 Start the machining process by moving the twin cutters to about the center of the rotor friction surface.

33 Turn the cutting bits inward until they touch the rotor and zero the depth adjustment.

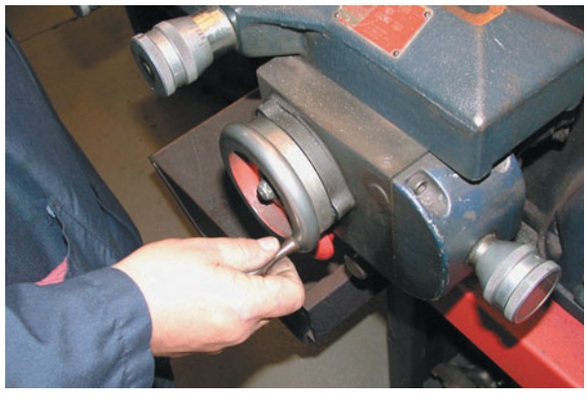
34 Adjust the twin cutters, then dial in the amount of depth (0.005–0.010 in. per side for a rough cut or 0.002 in. for a finish cut) and lock the adjustment so that vibration will not change the setting.



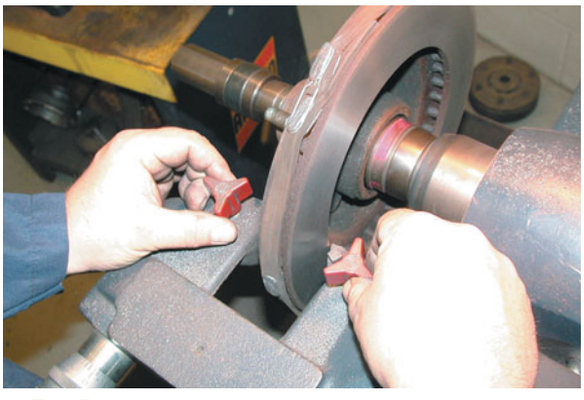
35 Turn the feed control knob until the desired feed rate is achieved for the first or rough cut (0.006–0.010 in. per revolution) or finish cut (0.002 in. per revolution).

36 Engage the automatic feed.

CONTINUED ▶



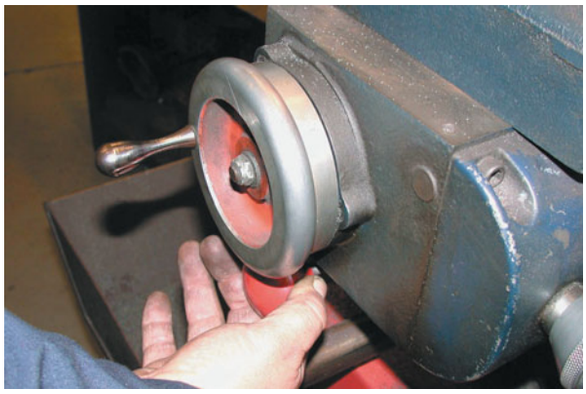
37 Observe the machining operation.



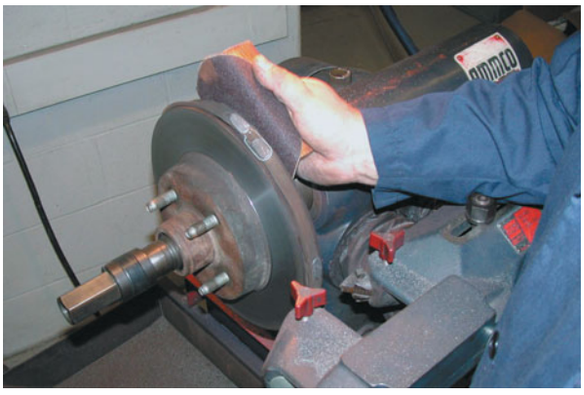
38 After the cutting bits have cleared the edge of the rotor, turn the lathe off and measure the thickness of the rotor.

39 Readjust the feed control to a slow rate (0.002 in. per revolution or less) for the finish cut.

40 Reposition the cutting bits for the finish cut.



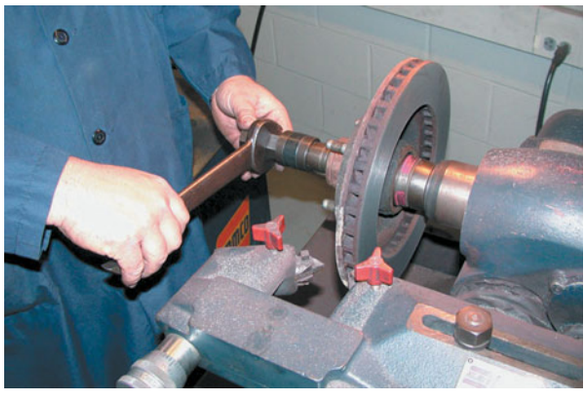
41 Loosen the adjustment locks.



42 Turn the depth of the cut for the finish cut (0.002 in. maximum).

43 Lock the adjustment.

44 Engage the automatic feed.

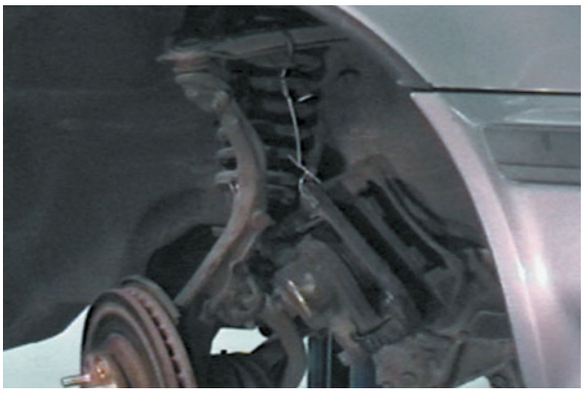


45 Use 150-grit aluminum-oxide sandpaper on a block of wood for 60 seconds per side or a grinder to give a nondirectional and smooth surface to both sides of the rotor.

46 After the sanding or grinding operation, thoroughly clean the machined surface of the rotor to remove any and all particles of grit that could affect the operation and life of the disc brake pads.

47 Remove the silencer band.

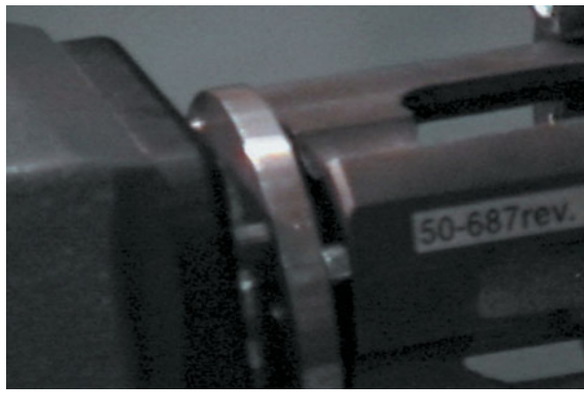
48 Loosen the spindle retaining nut and remove the rotor.



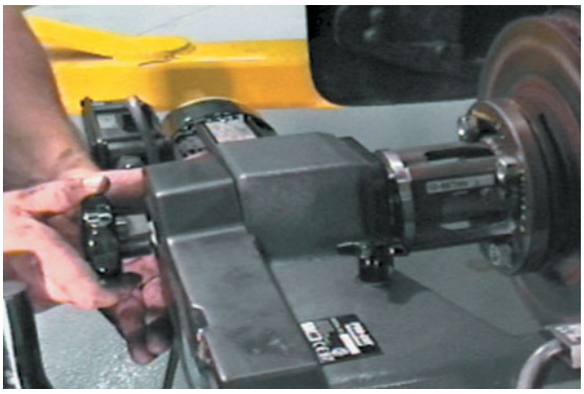
ON-THE-VEHICLE LATHE

1 Prepare to machine a disc brake rotor using an on-the-vehicle lathe by properly positioning the vehicle in the stall and hoisting the vehicle to a good working height.

2 Mark the lug nut closest to the valve stem so that the wheel can be reinstalled in the same location. Remove the wheels and place them out of the way.

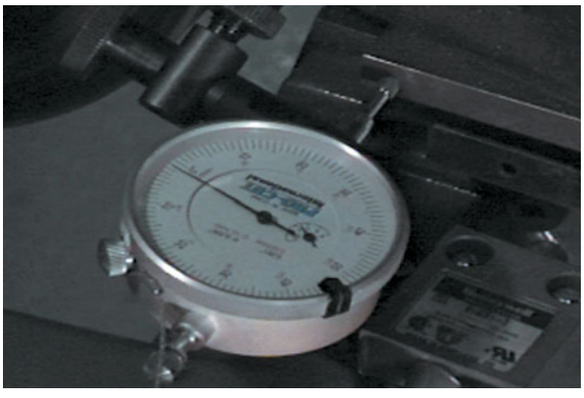


3 Remove the disc brake caliper on caliper mount type lathes and use a wire to support the caliper out of the way of the rotor.

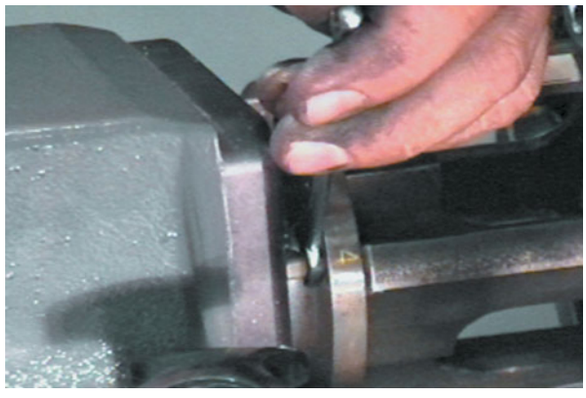


4 Measure the rotor thickness and compare it with factory specifications before machining. If a discard thickness is specified, be sure to allow an additional 0.015 in. for wear.

5 Install the hub adapter onto the hub and secure it using the wheel lug nuts. Never use an impact wrench to install the lug nuts.

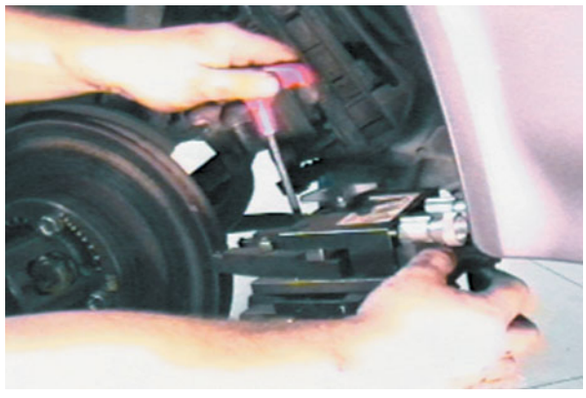


6 Engage the drive unit by aligning the hole in the drive plate with the raised button on the adapter.



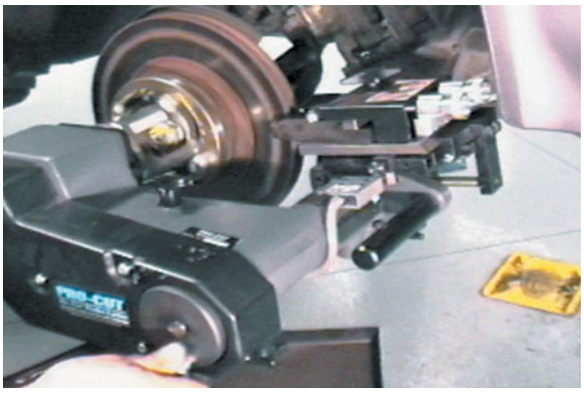
7 Use the thumb wheel to tighten the drive unit to the adapter.

8 Attach a dial indicator to a secure part on the vehicle and position the dial indicator on a flat portion of the lathe to measure the lathe runout.

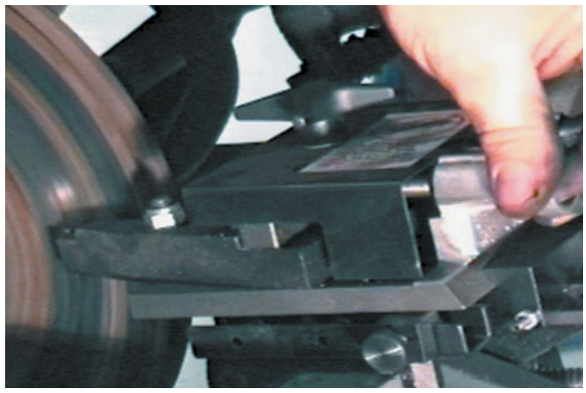


9 Rotate the wheel or turn the lathe motor on and measure the amount of runout. Newer models are self-adjusting.

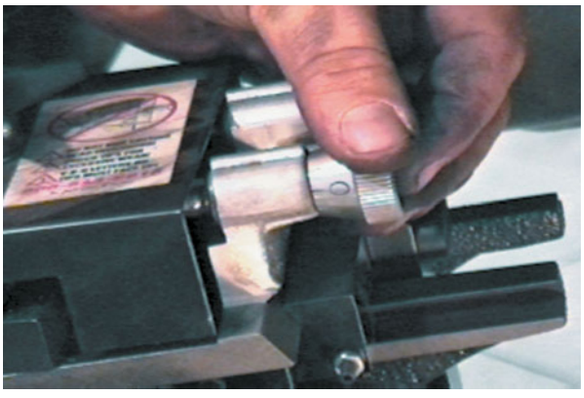
10 Use a wrench to adjust the runout using the four numbers stamped on the edge of the drive flange as a guide.



11 After the hub runout is adjusted to 0.005 in. or less, remove the dial indicator from the vehicle.



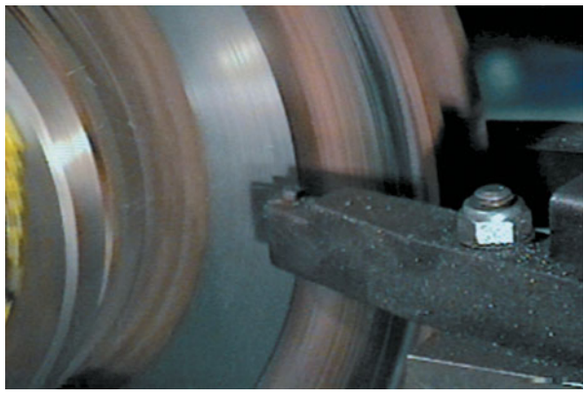
12 Using a T-handle Allen wrench, adjust the cutter arms until they are centered on the disc brake rotor.



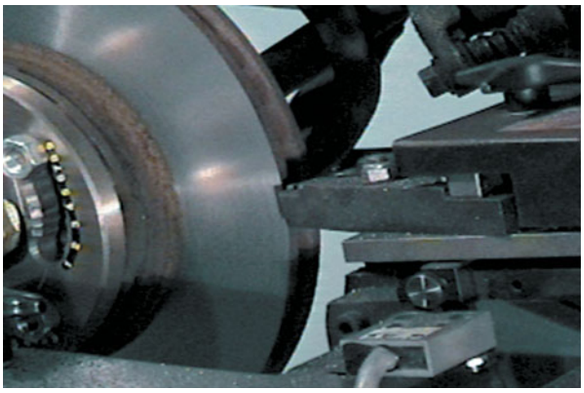
CONTINUED ▶

13 Move the cutters to the center of the rotor.

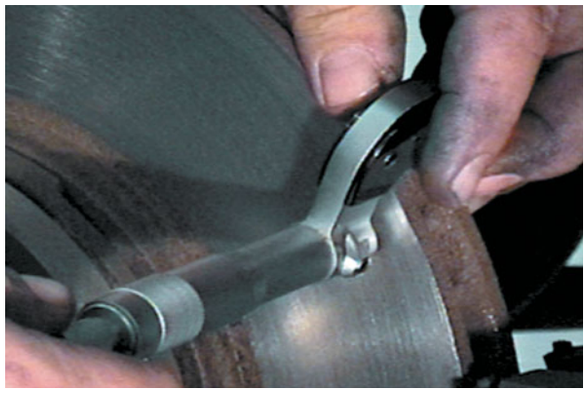
14 Adjust the cutter depth until each cutter barely touches the rotor.



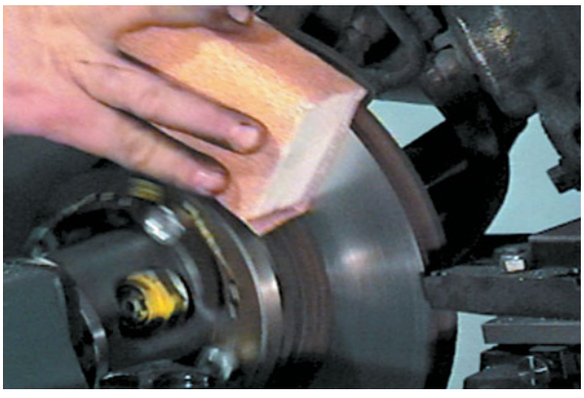
15 Position the cutters to the inside edge of the rotor surface and adjust the cutters to the desired depth of cut.



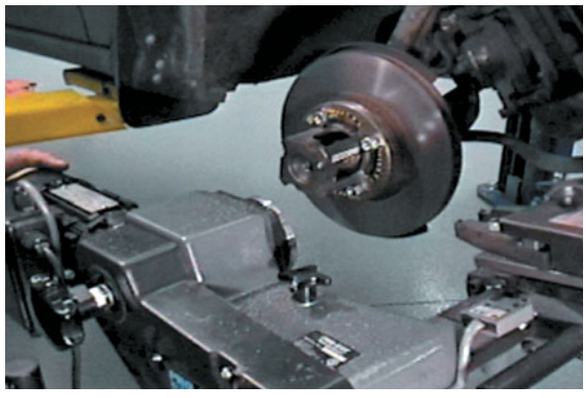
16 Adjust the automatic shut-off so the lathe will turn itself off at the end of the cut.



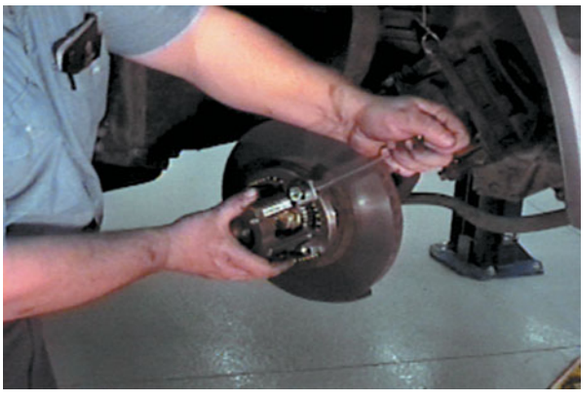
17 Turn the lathe on by depressing the start button.



18 Monitor the machining operations as the lathe automatically moves the cutters from the center toward the outside edge of the rotor.



19 After the lathe reaches the outside edge of the rotor, the drive motor should stop.



20 Measure the thickness of the rotor after machining to be certain that the rotor thickness is within service limits.

21 The technician is using 150-grit aluminum-oxide sandpaper and a wood block for 60 seconds on each side of the rotor to provide a smooth surface finish.

22 After completing the machining and resurfacing of the rotor unclamp the drive unit from the hub adapter and clean the rotor.

23 After the drive unit has been removed, remove the lug nuts holding the adapter to the rotor hub.

24 After removing the hub adapter, the caliper with new brake pads and hardware can be reinstalled.

CONTINUED ▶

25 Be sure to torque the caliper retaining bolts to factory specifications.

26 Install the wheel and wheel cover. On this vehicle, the wheel cover must be installed before the lug nuts because the lug nuts hold the wheel cover on the wheel.

27 Always use a torque wrench or a torque-limiting adapter with an air impact wrench as shown here when tightening lug nuts.

28 Be sure to clean the wheel covers of any grease or fingerprints before returning the vehicle to the customer.

29 Pump the brake pedal several times to restore proper brake pedal height. Check and add brake fluid as necessary before moving the vehicle.

30 Carefully back out of the stall and test-drive the vehicle to be assured of proper brake operation before returning the vehicle to the customer.

REVIEW QUESTIONS

1. Explain the difference between "machine to" specifications and "discard."
2. List the steps for machining a brake drum.
3. Describe how to measure a disc brake rotor for lateral runout and thickness variation.
4. List the steps for machining a disc brake rotor.
5. Describe what is necessary to achieve "like-new" disc brake rotor finish.

CHAPTER QUIZ

1. Technician A says that aluminum brake drums use cast iron friction surfaces. Technician B says that up to 0.030 in. (0.8 mm) should be left after machining a drum to allow for wear. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. Technician A says that hard spots in a brake drum should be removed using a carbide-tip machining tool. Technician B says that the drum should be replaced if hard spots are discovered. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
3. Technician A says that brake drums on the same axle should be close to the same inside diameter for best brake balance. Technician B says that a brake drum may be cracked if it rings like a bell when tapped with a light steel hammer. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. A hubless brake drum cannot be machined because it cannot be held in a lathe.
   a. True **b.** False
5. The major reason for brake pedal pulsation during braking is due to excessive rotor thickness variation.
   a. True **b.** False
6. Rotor finish is measured in _____.
   a. Millimeters **c.** Microinches
   b. Inches **d.** Centimeters
7. The lower the Ra of a rotor, the _____ the surface.
   a. Smoother **c.** Higher
   b. Rougher **d.** Lower
8. A disc brake rotor is being installed on a lathe for machining. During the setup a scratch test is performed. The scratch extended all the way around the rotor. Technician A says that the rotor should be loosened, rotated 180°, and retightened. Technician B says that the rotor is not warped. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
9. Typical maximum rotor runout specifications are _____.
   a. 0.0003 to 0.0005 in. (0.008 to 0.013 mm)
   b. 0.003 to 0.005 in. (0.08 to 0.13 mm)
   c. 0.030 to 0.050 in. (0.8 to 1.3 mm)
   d. 0.300 to 0.500 in. (8.0 to 13 mm)
10. Typical maximum rotor thickness variation (parallelism) specifications are _____.
    a. 0.0003 to 0.0005 in. (0.008 to 0.013 mm)
    b. 0.003 to 0.005 in. (0.08 to 0.13 mm)
    c. 0.030 to 0.050 in (0.8 to 1.3 mm)
    d. 0.300 to 0.500 in. (8.0 to 13 mm)

chapter 105

POWER BRAKE UNIT OPERATION, DIAGNOSIS, AND SERVICE

OBJECTIVES: **After studying Chapter 105, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "D" (Power Assist Units Diagnosis and Repair). • List the parts of a vacuum brake booster. • Describe how a vacuum brake booster operates. • Explain how to test a vacuum brake booster. • Describe how a hydraulic brake booster operates.

KEY TERMS: Atmospheric pressure 1196 • Brake assist system (BAS) 1201 • Dual-diaphragm vacuum booster 1201 • in. Hg (inches of mercury) 1196 • mm Hg (millimeters of mercury) 1196 • Power chamber 1197 • Pressure differential 1196 • Supplemental brake assist (SBA) 1203 • Tandem-diaphragm vacuum booster 1201 • Vacuum 1196

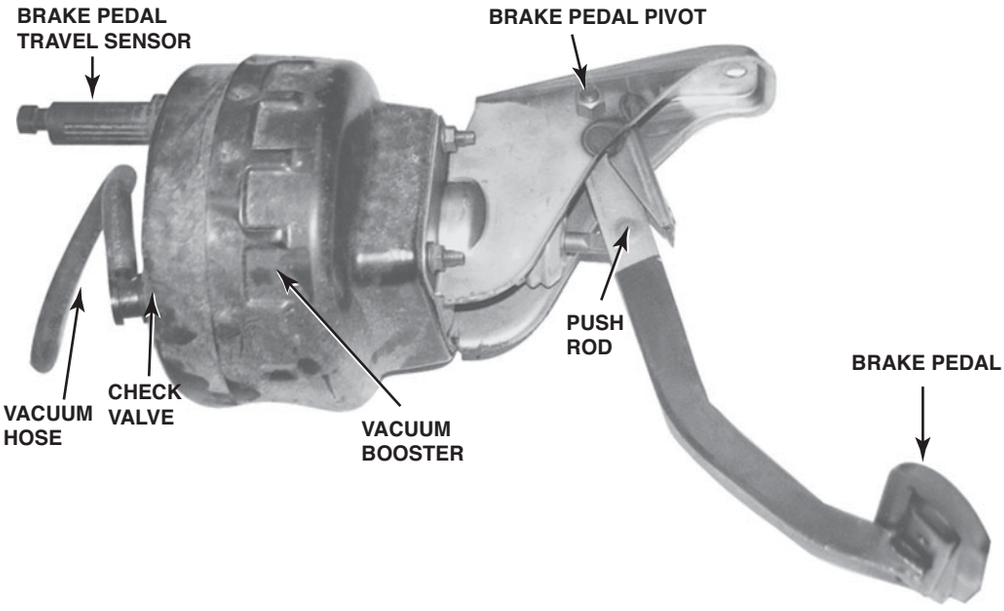


FIGURE 105–1 Typical vacuum brake booster assembly. The vacuum hose attaches to the intake manifold of the engine. The brake pedal travel sensor is an input sensor for the antilock braking system.

THE NEED FOR POWER BRAKE ASSIST

To double the stopping power of a disc brake, the driver must double the force on the brake pedal. This is the reason that most vehicles equipped with disc brakes are power assisted, even on small, lightweight vehicles. The use of semimetallic brake pads also requires greater force. The most commonly used power-assisted units are vacuum operated.

On vehicles equipped with a power brake booster, the brake pedal ratio is decreased and the master cylinder bore size is increased. The combined effect of these changes is to reduce pedal effort, while greatly increasing pedal reserve. ● **SEE FIGURE 105–1.**

Power boosters do not alter the hydraulic system and they still allow braking even if the booster fails or its power supply is cut off. All boosters have a power reserve that provides assist for at least one hard stop, and sometimes several light brake applications, even after power is lost. However, because power brake systems are designed with the added force of the booster taken into account, the amount of brake pedal pressure required to slow or stop a vehicle is much higher than in a nonboosted system once the reserve is used up. For this reason, some vehicles with power brakes have a brake pedal that is wide enough to allow two-foot braking should the booster fail. ● **SEE FIGURE 105–2.**

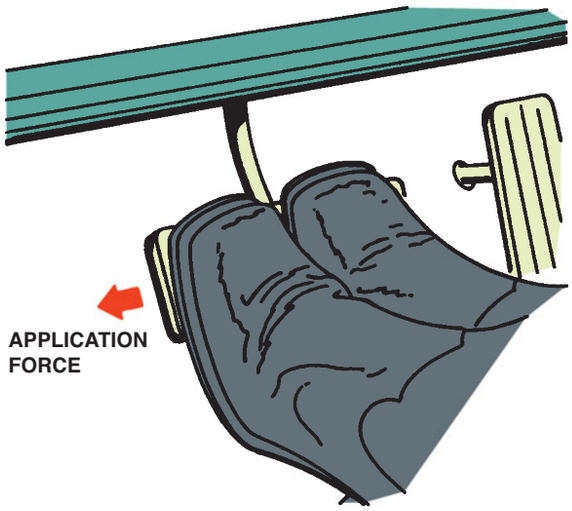

FIGURE 105–2 A wide brake pedal allows two-foot braking if power assist is lost.

PRINCIPLES OF VACUUM

Most vacuum-powered brake boosters get their vacuum supply from the engine intake manifold. An engine is essentially a big air pump because the pistons move up and down in the cylinders to pump in air and fuel, and pump out exhaust. They do this by creating differences in air pressure.

As a piston moves downward on an intake stroke with the intake valve open, it creates a larger area inside the cylinder for air to fill. This lowers the air pressure within the cylinder, and the higher-pressure air outside the engine flows in through the intake manifold in an attempt to fill the low-pressure area. Although it may seem as though the low pressure is pulling air into the engine, it is really the higher pressure outside that forces air in. The difference in pressure between two areas is called a **pressure differential.**

Because throttle valves and manifold shape restrict intake airflow, high-pressure air from outside the engine is almost never able to move into the cylinders fast enough to fill the space created. As a result, gasoline-powered internal-combustion engines normally operate with a low-pressure area, or partial vacuum, in the intake manifold. The term **vacuum** is used to refer to any pressure lower than **atmospheric pressure.** Atmospheric pressure varies with altitude, but is approximately 14.7 pounds per square inch (PSI) at sea level. ● **SEE FIGURE 105–3.**

MEASURING VACUUM Vacuum is measured in **inches of mercury (in. Hg)** or in **millimeters of mercury (mm Hg),** a figure that indicates how far a column of mercury in a tube will rise when

a vacuum is applied at one end, and atmospheric pressure at the other. Vacuum is a measurement of the pressure differential between the lower pressure inside the tube, and the higher pressure outside it.

A perfect vacuum is about 30 in. Hg (762 mm Hg). However, a perfect vacuum occurs only in space, and is never achieved in an engine's intake manifold. Manifold vacuum varies with throttle position. The lowest manifold vacuum (highest pressure) occurs when the throttle is wide open with the engine under load. The highest manifold vacuum (lowest pressure) may be as much as 24 in. Hg (610 mm Hg) when the vehicle is rolling rapidly downhill in gear with the throttle closed. Manifold vacuum at idle typically falls between 15 and 20 in. Hg (381 and 508 mm Hg), and most vacuum brake boosters are designed to operate with vacuum levels in this range.

BOOSTER VACUUM SUPPLY Vacuum boosters get their vacuum supply from the engine intake manifold. Diesel engines, however, run unthrottled (engine speed is controlled strictly by the amount of fuel injected) and have little or no intake manifold vacuum. If a vehicle with a diesel engine is equipped with a vacuum-powered brake booster, it must also be fitted with an auxiliary vacuum pump.

Some small gasoline-powered and diesel engines use a belt-driven add-on pump. ● **SEE FIGURE 105–4.**

Some vehicles use an electric vacuum pump. An electrically powered vacuum pump is turned on and off by a pressure switch on the booster. This means they operate only when needed, and thus reduce power drain on the engine. ● **SEE FIGURE 105–5.**

VACUUM BOOSTER THEORY

Vacuum boosters use the principle of pressure differential to increase brake application force. The typical vacuum booster has a **power chamber** separated into two smaller chambers by a flexible

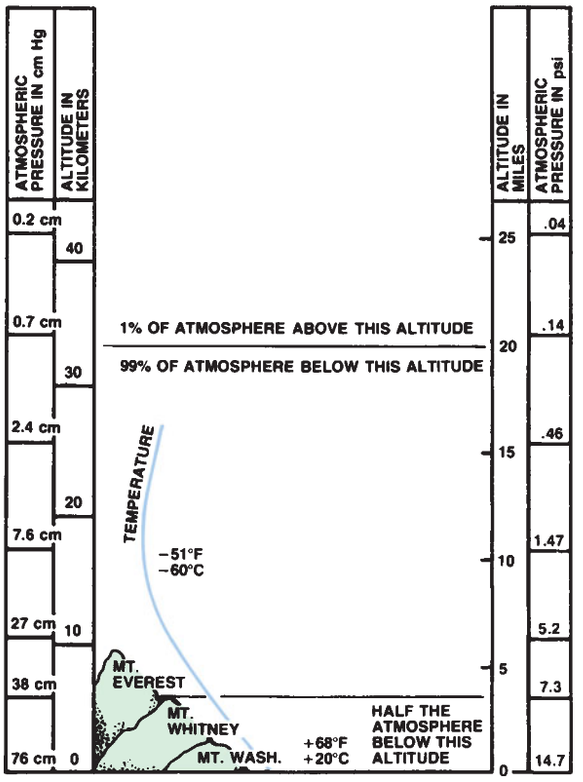

FIGURE 105–3 Atmospheric pressure varies with altitude.

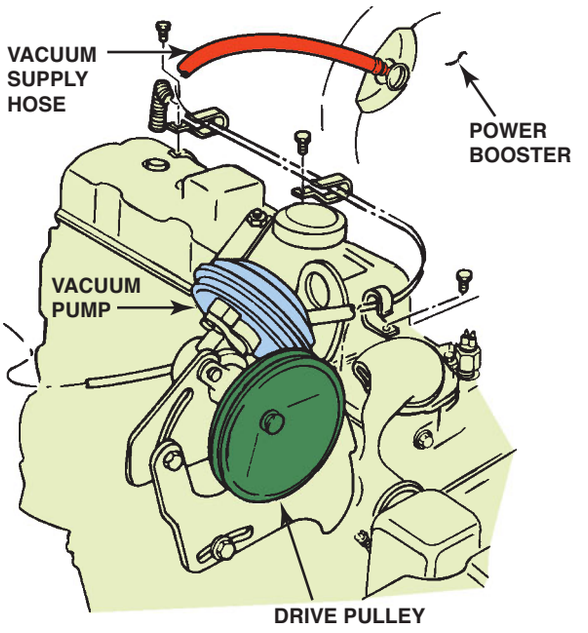

FIGURE 105–4 A belt-driven auxiliary vacuum pump.

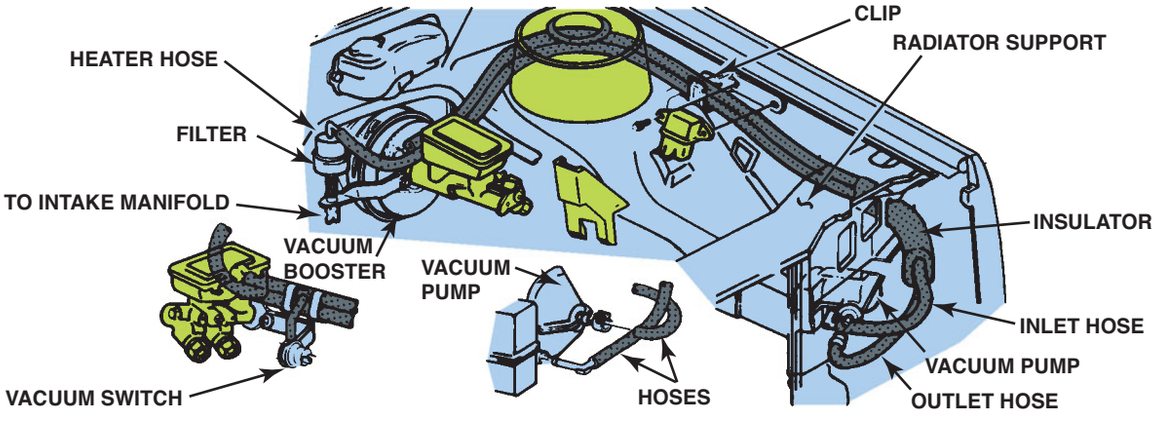

FIGURE 105–5 An electrically powered vacuum pump.

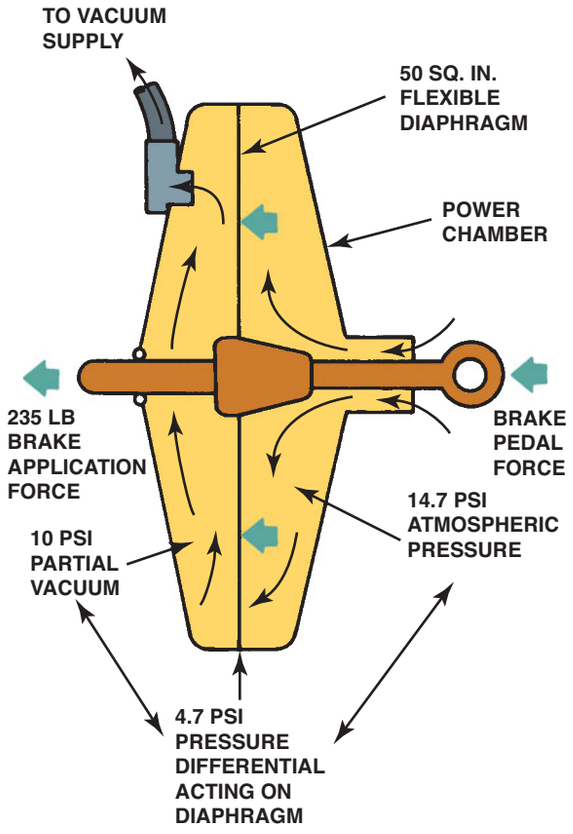

FIGURE 105–6 Vacuum brake boosters operate on the principle of pressure differential.

diaphragm. When air pressure is greater on one side of the diaphragm than the other, a pressure differential is created. In an attempt to equalize pressure in the two chambers, the higher pressure exerts a force that moves the diaphragm toward the lower-pressure area. Rods attached to the diaphragm transmit this force, plus the force the driver exerts on the brake pedal, to the master cylinder.

The amount of force created in this manner is proportional to the difference in pressure between the two sides. In other words, the greater the pressure differential, the greater the force. To calculate the force, the pressure differential is multiplied by the diaphragm surface area. For example, if a power booster diaphragm has atmospheric pressure (14.7 PSI) on one side, and a typical intake manifold vacuum of 20 in. Hg (10 PSI of absolute pressure), the pressure differential acting on the diaphragm would be as follows.

14.7 PSI − 10 PSI = 4.7 PSI

If we once again multiply this times the area of the diaphragm, the result is as follows.

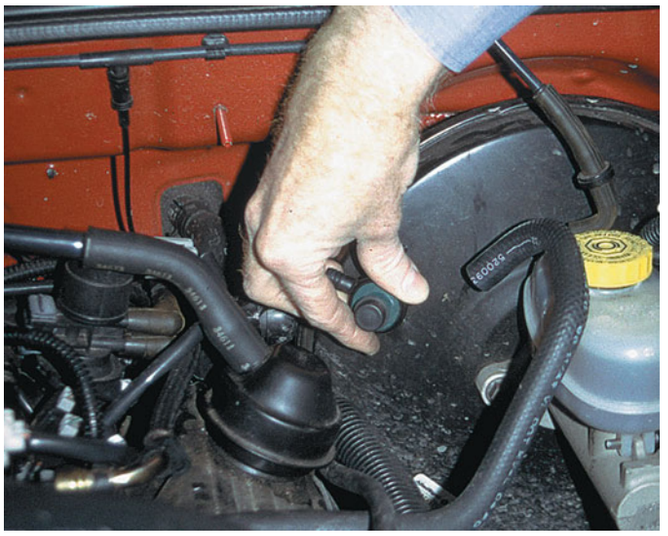
4.7 PSI × 50 sq. in. = 235 pounds of force

Vacuum booster diaphragms are sized to fit specific applications and provide the necessary application force. Most vacuum boosters are capable of providing hundreds of pounds of application force. ● **SEE FIGURE 105–6.**

CHARCOAL FILTER

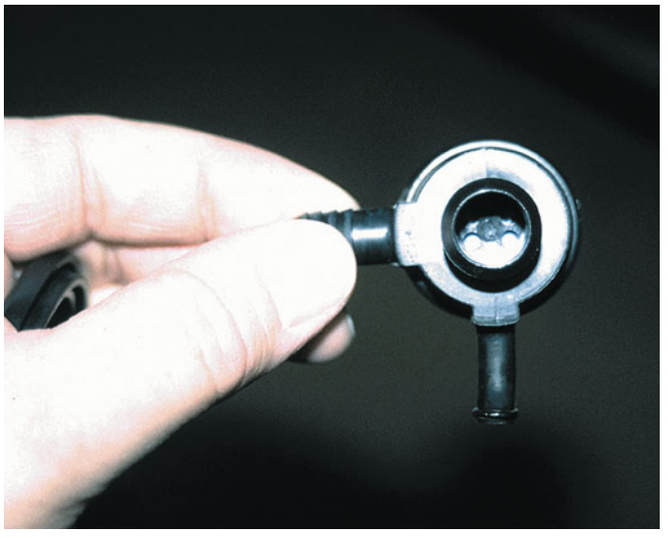
The vacuum hose leading from the engine to the power booster should run downward without any low places in the hose. If a dip or sag occurs in the vacuum hose, condensed fuel vapors and/or moisture can accumulate that can block or restrict the vacuum to the booster. Many manufacturers use a small charcoal filter in the vacuum line between the engine and booster, as shown in ● **FIGURE 105–7.**

FIGURE 105–7 The charcoal filter traps gasoline vapors that are present in the intake manifold and prevents them from getting into the vacuum chamber of the booster.



TECH TIP

Check the Vacuum, Then the Brakes



A customer complained of a very rough idle and an occasional pulsating brake pedal. The customer was certain that the engine required serious work since there were over 100,000 miles on the vehicle. During the troubleshooting procedure, a spray cleaner was used to find any vacuum (air) leaks. A large hole was found melted through a large vacuum hose next to the vacuum hose feeding the vacuum-operated power brake booster.

After repairing the vacuum leak, the vehicle was test driven again to help diagnose the cause of the pulsating brake pedal. The engine idled very smoothly after the vacuum leak was repaired and the brake pulsation was also cured. The vacuum leak resulted in lower-than-normal vacuum being applied to the vacuum booster. During braking, when engine vacuum is normally higher (deceleration), the vacuum booster would assist, then not assist when the vacuum was lost. This on-and-off supply of vacuum to the vacuum booster was noticed by the driver as a brake pulsation. Always check the vacuum at the booster whenever diagnosing any brake problems. Most vehicle manufacturers specify a minimum of 15 in. Hg of vacuum at the booster. The booster should be able to provide at least two or three stops even with no vacuum. The booster should also be checked to see if it can hold a vacuum after several hours. A good vacuum booster, for example, should be able to provide a power assist after sitting all night without starting the engine.

The charcoal filter attracts and holds gasoline vapors and keeps fumes from entering the vacuum booster. Without this filter, gasoline fumes can enter the vacuum booster, where they can deteriorate the rubber diaphragm and other rubber components of the booster.

(a)

(b)

FIGURE 105–8 (a) Many vacuum brake booster check valves are located where the vacuum hose from the engine (vacuum source) attaches to the vacuum booster. (b) This one-way valve prevents the loss of vacuum when the engine is off. The diaphragm inside allows air to flow in one direction only.

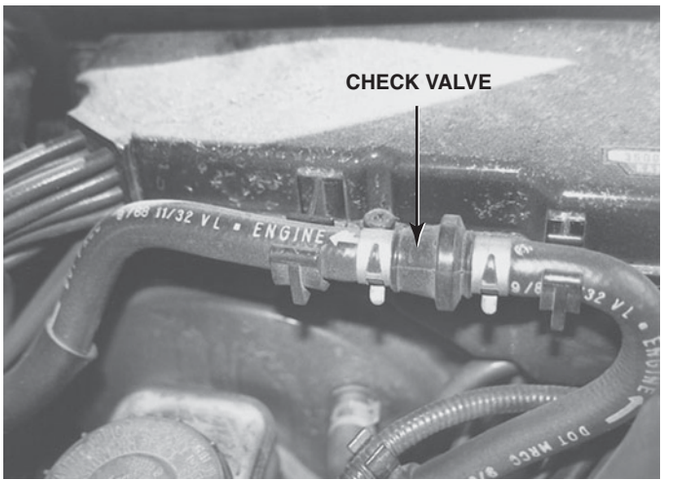


FIGURE 105–9 Not all check valves are located at the vacuum line to the booster housing connection. This vehicle uses an inline check valve located between the intake manifold of the engine and the vacuum brake booster.

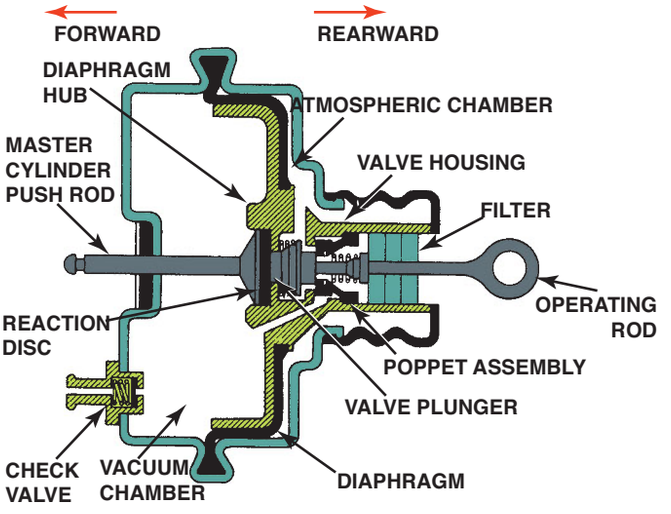

FIGURE 105–10 Cross-sectional view of a typical vacuum brake booster assembly.

VACUUM CHECK VALVE

All vacuum boosters use a one-way vacuum check valve. This valve allows air to flow in only one direction—from the booster toward the engine. This valve prevents loss of vacuum when the engine stops. Without this check valve, the vacuum stored in the vacuum booster would simply be lost through the hose and intake manifold of the engine. ● **SEE FIGURES 105–8 AND 105–9.**

CAUTION: Sometimes an engine backfire can destroy or blow the vacuum check valve out of the booster housing. If this occurs, all power assist will be lost and a much greater-than-normal force must be exerted on the brake pedal to stop the vehicle. Be sure to repair the cause of the backfire before replacing the damaged or missing check valve. Normal causes of backfire include an excessively lean air–fuel ratio or incorrect firing order or ignition timing.

VACUUM BRAKE BOOSTER OPERATION

A vacuum power-brake booster contains a rubber diaphragm(s) connected to the brake pedal at one end and to the master cylinder at the other end. When the brakes are off or released, there is equal vacuum on both sides of the diaphragm.

The vacuum power unit contains the power-piston assembly, which houses the control valve and reaction mechanism, and the power-piston return spring. The control valve is composed of the air valve (valve plunger), the floating control-valve assembly, and the pushrod. The reaction mechanism consists of a hydraulic piston reaction plate and a series of reaction levers. An air filter, air silencer, and filter retainer are assembled around the valve operating rod, filling the cavity inside the hub of the power piston. The pushrod that operates the air valve projects out of the end. ● **SEE FIGURE 105–10.**

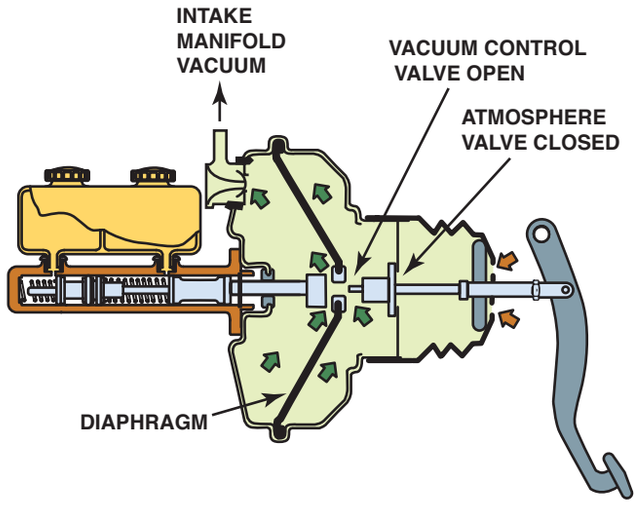

FIGURE 105–11 In the release position (brake pedal up), the vacuum is directed to both sides of the diaphragm.

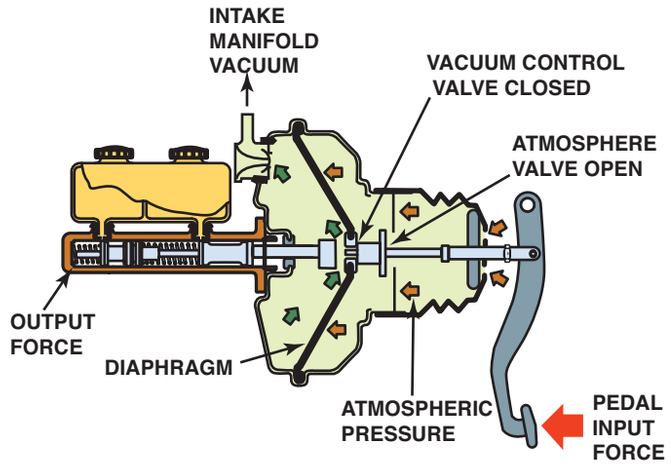

FIGURE 105–12 Simplified diagram of a vacuum brake booster in the apply position. Notice that the atmospheric valve is open and air pressure is being applied to the diaphragm.

RELEASED-POSITION OPERATION At the released position (brake pedal up), the air valve is seated on the floating control valve, which shuts off the air. The floating control valve is held away from the valve seat in the power-piston insert. Vacuum from the engine is present in the space on both sides of the power piston. Any air in the system is drawn through a small passage in the power piston, over the seat in the power-piston insert, and through a passage in the power-piston insert. There is a vacuum on both sides of the power piston, and it is held against the rear of the housing by the power-piston return spring. At rest, the hydraulic reaction plate is held against the reaction retainer. The air-valve spring holds the reaction lever against the hydraulic reaction plate and holds the air valve against its stop in the tube of the power piston. The floating control-valve assembly is held against the air-valve seat by the floating control-valve spring. ● **SEE FIGURE 105–11.**

APPLIED-POSITION OPERATION As the brake pedal is depressed, the floating control valve is moved toward its seat in the power piston, away from the rear of the booster. The smaller air valve spring causes the air valve to stretch out toward the retreating floating control valve until it bottoms out on the lip of the power piston's vacuum passage. This closes off the vacuum supply to the rear section of the housing. Since the floating control valve travels farther than the sealing end of the air valve, atmospheric air is allowed to enter between the air valve and the floating control valve pressurizing the rear section of the housing. At this point, the rear section of the housing is pressurized and the front section is under vacuum. Atmospheric pressure can then force the power piston forward.

NOTE: This movement of air into the rear chamber of the brake booster may be heard inside the vehicle as a hissing noise. The loudness of this airflow varies from vehicle to vehicle and should be considered normal.

As the power piston travels forward, the pushrod pushes against the hydraulic reaction plate in the master cylinder, pushing the master cylinder primary and secondary pistons forward. As back-pressure builds up on the end of the master cylinder piston, the floating control valve is pushed back off of its seat in the power piston, applying back-pressure to the brake pedal. The power piston return spring also generates some brake pedal force. All in all, approximately 30% of the brake load is applied back to the brake pedal. This gives the driver a feel that is proportional to the degree of brake application. ● **SEE FIGURE 105–12.**

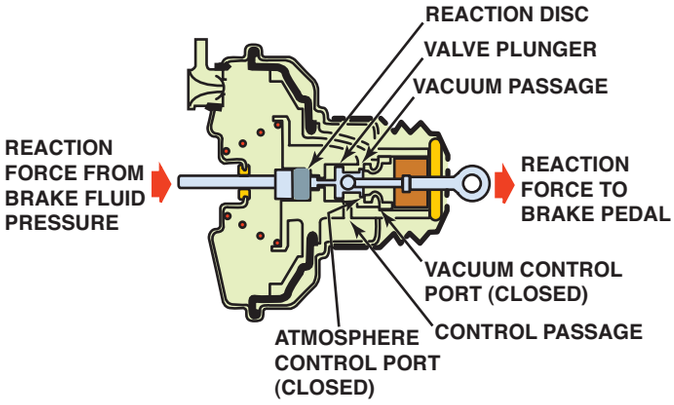

FIGURE 105–13 Cross section of a vacuum brake booster in the hold position with both vacuum and atmospheric valves closed. Note that the reaction force from the brake fluid pressure is transferred back to the driver as a reaction force to the brake pedal.

HOLD-POSITION OPERATION When the desired brake pedal force is reached and there is balance between the opposing forces of the brake pedal and the master cylinder, the power piston moves forward "around" the floating control valve and reaction disc until the air valve sealing end "catches up" with the floating control valve. At this point, the air valve is once again sealed against the floating control valve and is no longer blocking the vacuum passage in the power piston. The floating control valve is again held away from its seat. Vacuum once again is present on both sides of the diaphragm and power piston. The status of the booster is almost exactly as it was in the released state except that the positions of the power piston and subsequently the master cylinder pistons are farther forward. Brake pedal force is keeping the power piston in its position. If additional braking is required (brake pedal pushed farther), the floating control valve moves away from the air valve permitting the power of atmospheric pressure to push the power piston and master cylinder pistons forward. If the pedal is released, since vacuum is then present on both sides of the diaphragm, the power piston return spring moves the power piston to its released state. ● **SEE FIGURE 105–13.**

VACUUM-FAILURE MODE In case of vacuum source interruption, the brake operates as a standard brake as follows. As the pedal is pushed down, the operating rod forces the floating control

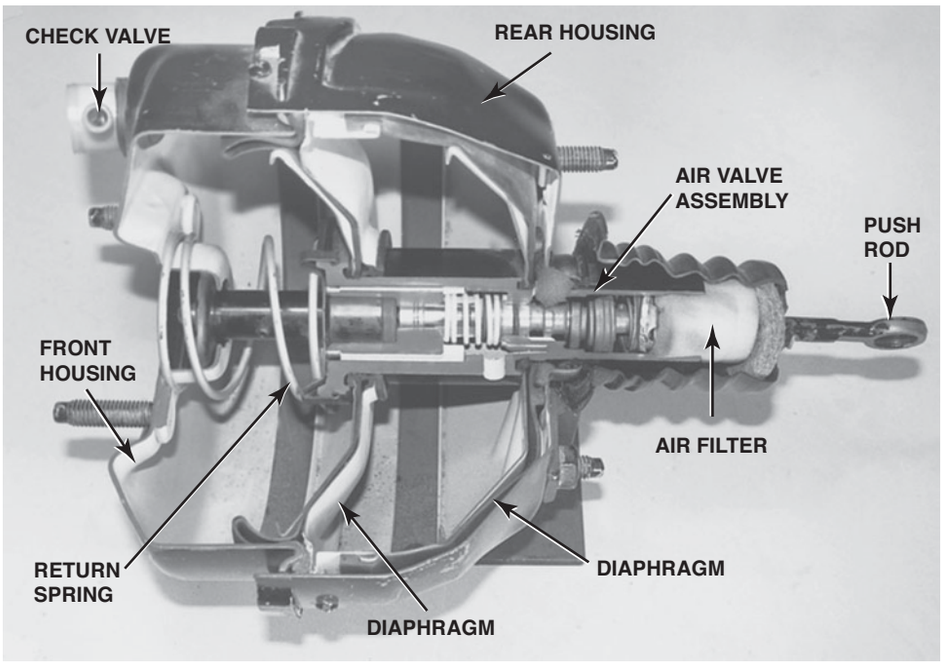

FIGURE 105–14 Cutaway showing a dual-diaphragm (tandem) vacuum brake booster.

TECH TIP

A Low, Soft Brake Pedal Is Not a Power Booster Problem

Some service technicians tend to blame the power brake booster if the vehicle has a low, soft brake pedal. A defective power brake booster causes a hard brake pedal, not a soft brake pedal. A soft or spongy brake pedal is usually caused by air being trapped somewhere in the hydraulic system.

Many times, the technician has bled the system and, therefore, thinks that the system is free of any trapped air. According to remanufacturers of master cylinders and power brake boosters, most of the returned parts under warranty are not defective. Incorrect or improper bleeding procedures account for much of the problem.

valve against the power piston and reaction disc. This force is then applied to the pushrod and subsequently the hydraulic reaction plate fastened to the master cylinder piston rod, which applies pressure in the master cylinder. For safety in the event of a stalled engine and a loss of vacuum, a power brake booster should have adequate storage of vacuum for several power-assisted stops.

DUAL- (TANDEM-) DIAPHRAGM VACUUM BOOSTERS

To provide power assist, air pressure must work against a rubber diaphragm. The larger the area of the diaphragm, the more force can be exerted. The usual method of increasing the area of the vacuum diaphragm was to increase the diameter of the vacuum booster. However, a larger vacuum booster took up too much room under the hood of many vehicles. Instead of increasing the diameter, vacuum booster manufacturers used two smaller-diameter diaphragms and placed one in front of the other. These designs increased the total area without increasing the physical diameter of the booster. This style is called a **dual-diaphragm** or **tandem-diaphragm** vacuum booster. ● **SEE FIGURE 105–14.**

BRAKE ASSIST SYSTEM

Some vehicles are equipped with a **brake assist system (BAS)** that applies the brakes with maximum force if the system detects that the driver is making a panic stop. Tests performed by brake engineers have indicated that it is normal for a person to first apply the brakes rapidly during a panic situation. However, it was also found that the driver would tend to reduce the force applied to the brake pedal. As a result, the vehicle did not brake with the maximum effort.

OPERATION The brake assist system opens an air valve on the rear part of the vacuum booster assembly. As a result, more air at atmospheric pressure can flow into the rear chamber of the vacuum booster, thereby increasing the force applied to the master cylinder. The BAS function works with the electronic stability control (ESC) system to ensure maximum braking efficiency during evasive or emergency situations.

If the speed of the brake pedal application exceeds a predetermined limit as determined by the brake pedal travel sensor, the ABS controller energizes the BAS solenoid valve. When the solenoid valve opens, additional air at atmospheric pressure enters the driver's side of the booster. The additional pressure applies the brakes faster and with more force. The BAS solenoid is deenergized when the brake pedal is released and normal braking returns. ● **SEE FIGURES 105–15 AND 105–16.**

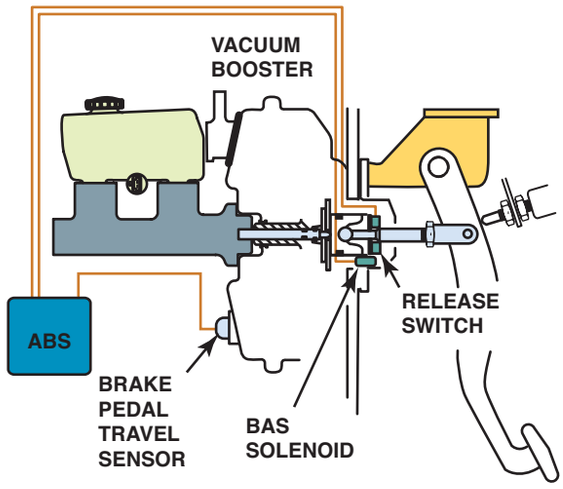

FIGURE 105–15 A typical brake assist system uses a brake pedal travel sensor and a BAS solenoid to apply the brakes during a panic condition.

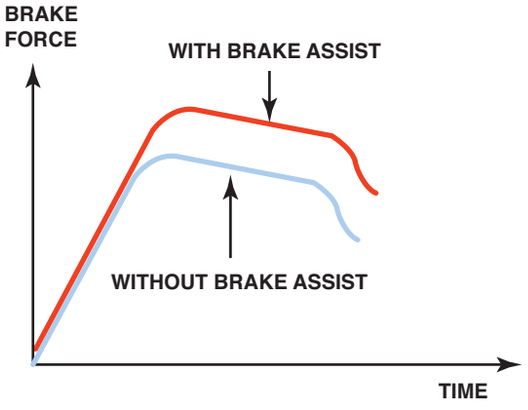

FIGURE 105–16 When the brake assist function operates, the brake force is much higher than normal.

VACUUM BOOSTER OPERATION TEST

With the engine "off," apply the brakes several times to deplete the vacuum. With your foot on the brake pedal, start the engine. The brake pedal *should* drop. If the brake pedal does *not* drop, check for proper vacuum source to the booster. There should be at least 15 in. Hg of vacuum at the booster for proper operation. If there is proper vacuum, repair or replacement of the power booster is required.

VACUUM BOOSTER LEAK TEST

To test if the vacuum booster can hold a vacuum perform the following steps:

STEP 1 Operate the engine to build up a vacuum in the booster, then turn the engine off.

STEP 2 Wait one minute.

STEP 3 Depress the brake pedal several times. There should be two or more power-assisted brake applications.

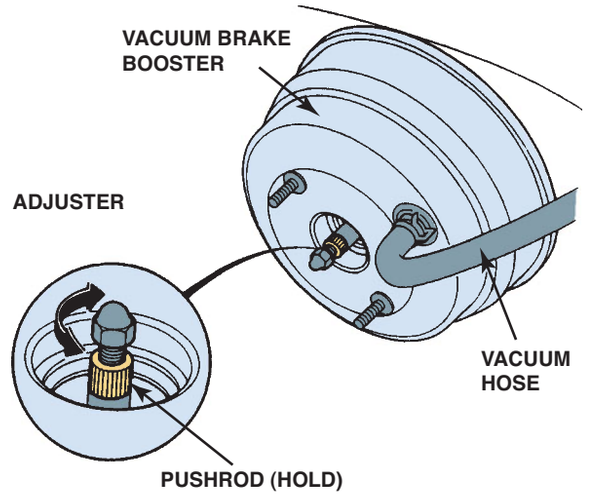

FIGURE 105–17 Typical adjustable pushrod. This adjustment is critical for the proper operation of the braking system. If the pushrod is too long, the brakes may be partially applied during driving. If the rod is too short, the brake pedal may have to be depressed farther down before the brakes start to work.

If applications are not power assisted, either the vacuum check valve or the booster is leaking. To test the check valve, remove the valve from the booster and blow through the check valve. If air passes through, the valve is defective and must be replaced. If the check valve is okay, the vacuum booster is leaking and should be repaired or replaced based on the manufacturer's recommendations.

HYDRAULIC SYSTEM LEAK TEST

An internal or external hydraulic leak can also cause a brake system problem. To test if the hydraulic system (and not the booster) is leaking, depress and release the brake pedal (service brakes) several times. This should deplete any residual power assist. On some ABS units, this may require depressing the brake pedal 20 or more times!

After depleting the power-assist unit, depress and then hold the brake pedal depressed with medium force (20 to 35 lb or 88 to 154 N). The brake pedal should *not* fall away. If the pedal falls, the hydraulic brake system is leaking. Check for external leakage at wheel cylinders, calipers, hydraulic lines, and hoses. If there is no external leak, there may be an internal leak inside the master cylinder. Repair or replace components as needed to correct the leakage.

PUSHROD CLEARANCE ADJUSTMENT

Whenever the vacuum brake booster or the master cylinder is replaced, the pushrod length should be checked. The length of the pushrod must match correctly with the master cylinder. ● **SEE FIGURE 105–17.**

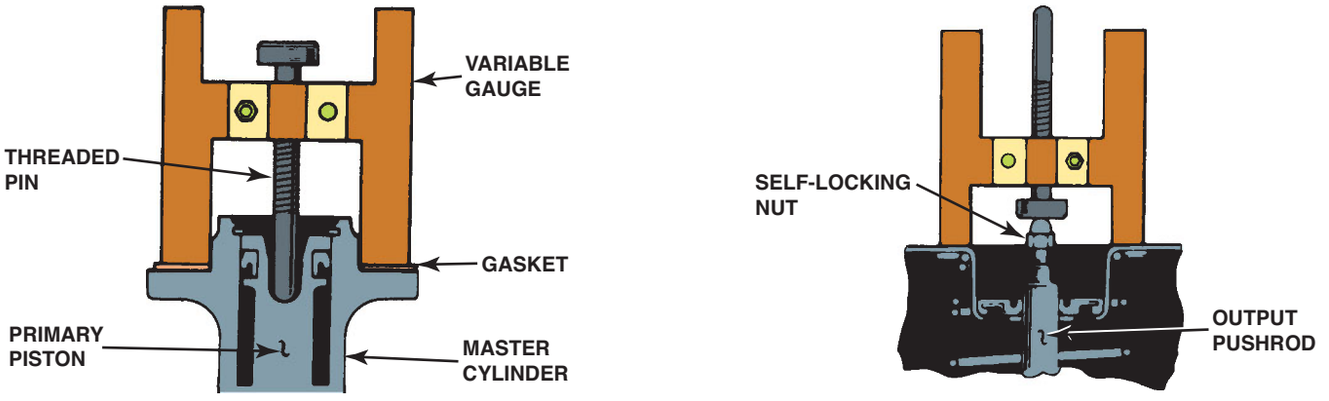

FIGURE 105–18 Typical vacuum brake booster pushrod gauging tool. (a) The tool is first placed against the mounting flange of the master cylinder and the depth of the piston determined. (b) The gauge is then turned upside down and used to gauge the pushrod length. Some vacuum brake boosters do not use adjustable pushrods. If found to be the incorrect length, a replacement pushrod of the correct length should be installed.

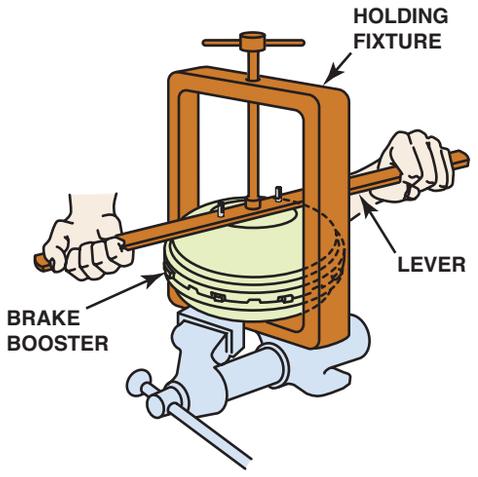

FIGURE 105–19 A holding fixture and a long tool being used to rotate the two halves of a typical vacuum brake booster.

If the pushrod is too long and the master cylinder is installed, the rod may be applying a force on the primary piston of the master cylinder even though the brake pedal is not applied. This can cause the brakes to overheat, causing the brake fluid to boil. If the brake fluid boils, a total loss of braking force can occur. Obviously, this pushrod clearance check and adjustment is very important. A gauge is often used to measure the position of the master cylinder piston, and then the other end of the gauge is used to determine the proper pushrod clearance. ● **SEE FIGURE 105–18.**

VACUUM BOOSTER DISASSEMBLY AND SERVICE

Some vehicle manufacturers recommend that the vacuum brake booster be replaced as an assembly if tested to be leaking or defective. Some vehicle manufacturers recommend that the vacuum brake booster be disassembled and overhauled if defective. A special holding fixture should be used before rotating (unlocking) the front and rear housing because the return spring is strong. ● **SEE FIGURE 105–19.**

Disassemble the vacuum brake booster according to the manufacturer's recommended procedures for the specific unit being serviced. ● **SEE FIGURE 105–20.**

A rebuilding kit is available that includes all necessary parts and the proper silicone grease. The manufacturer warns that all parts included in the kit be replaced. Always follow the manufacturer's recommendations.

? FREQUENTLY ASKED QUESTION

What Is Supplemental Brake Assist?

Supplemental brake assist, SBA, is a motor-driven vacuum pump that can supplement engine vacuum to the vacuum brake booster. This unit is used on some General Motors vehicles. When a vehicle is driven under a heavy load, engine vacuum is low. To meet the brake standards, some vehicles are equipped with the brake assist system that consists of the following components:

- A pressure sensor that is used to measure the vacuum in the vacuum booster.
- An intake manifold check valve that is used to prevent vacuum from escaping the vacuum boost.
- A motor-driven vacuum pump.

The vacuum pump motor will start and run if the pressure sensor detects the vacuum in the booster is below 7 in. Hg and will shut off after the vacuum level increases to 9 in. Hg.

HYDRO-BOOST HYDRAULIC BRAKE BOOSTER

Hydro-Boost is a hydraulically operated power-assist unit built by Bendix. The Hydro-Boost system uses the pressurized hydraulic fluid from the vehicle's power steering pump as a power source rather

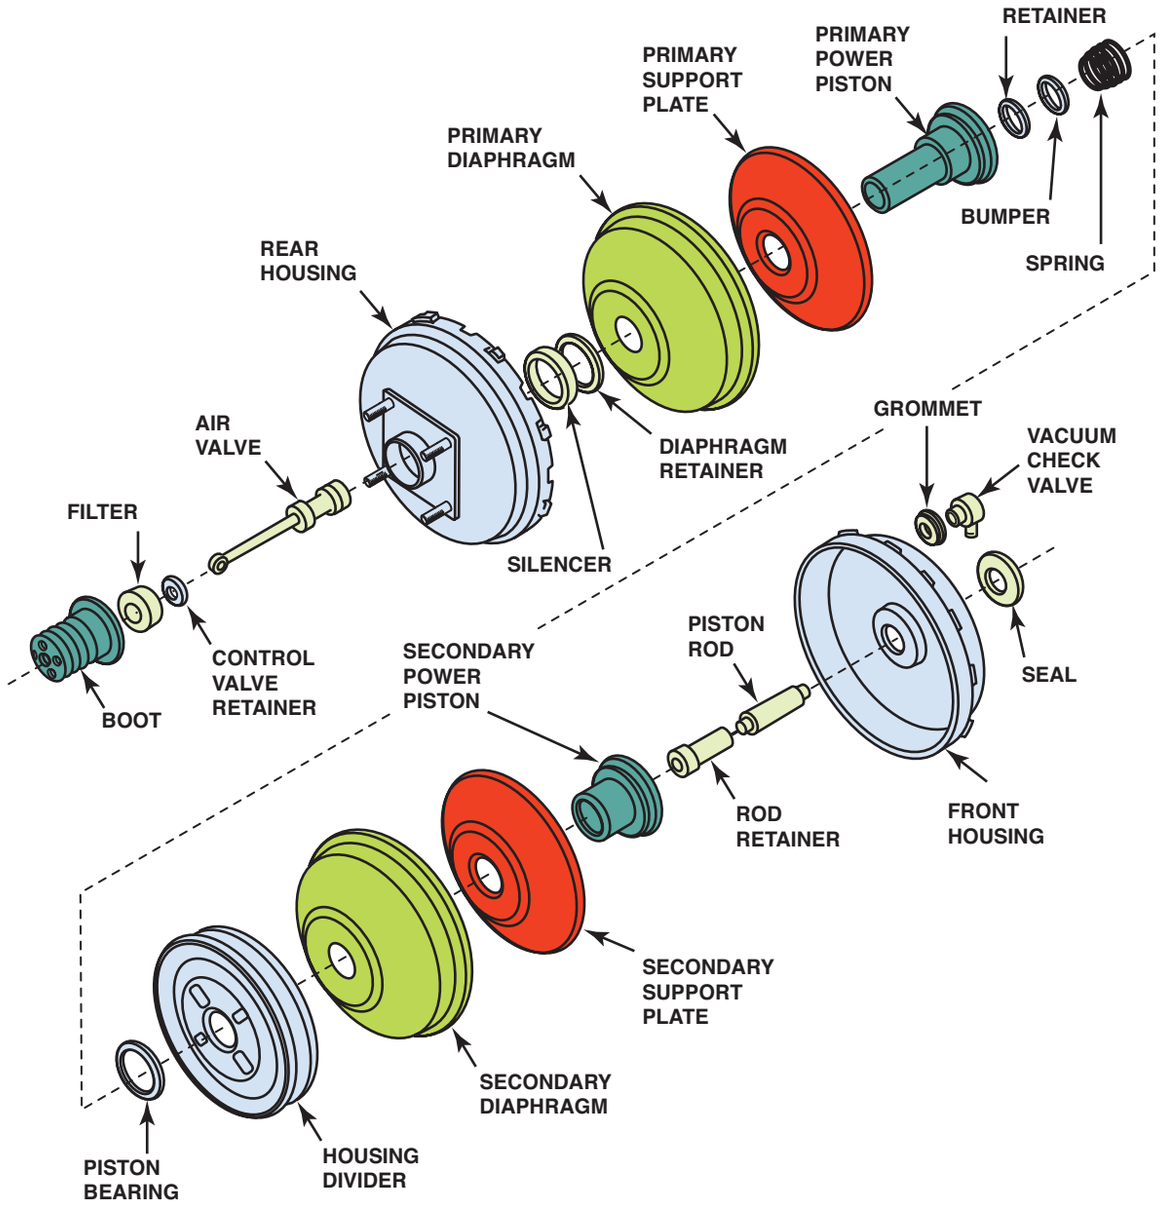

FIGURE 105–20 Exploded view of a typical dual-diaphragm vacuum brake booster assembly.

than using engine vacuum as is used with vacuum boosters. ● **SEE FIGURES 105–21 AND 105–22.**

The Hydro-Boost unit is used on vehicles that lack enough engine vacuum, such as turbocharged or diesel engine vehicles. During operation, diesel engines do not produce vacuum in the intake manifold. As a result, diesel engines must use accessory engine-driven vacuum pumps to operate vacuum accessories. Turbocharged and supercharged engines do not create engine vacuum during periods of acceleration. Even though vacuum is available when the engine is decelerating, some vehicle manufacturers elect to install a Hydro-Boost system rather than equip the vehicle with an accessory engine-driven vacuum pump.

OPERATION Fluid pressure from the power steering pump enters the unit and is directed by a spool valve. ● **SEE FIGURE 105–23.** When the brake pedal is depressed, the lever and primary valve are moved. The valve closes off the return port, causing pressure to build in the boost pressure chamber. The hydraulic pressure pushes on the

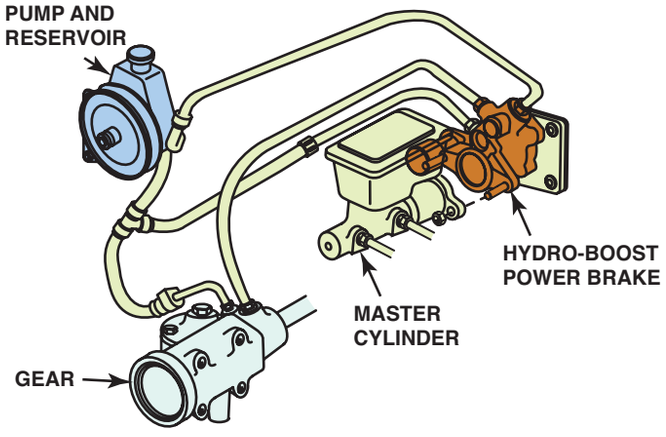

FIGURE 105–21 Hydro-Boost unit attaches between the bulkhead and the master cylinder and is powered by the power steering pump.

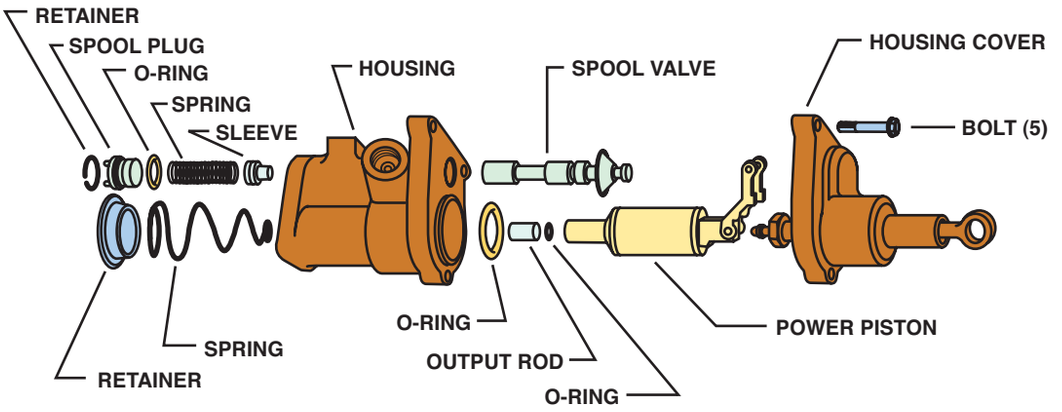

FIGURE 105–22 Exploded view of the Hydro-Boost unit.

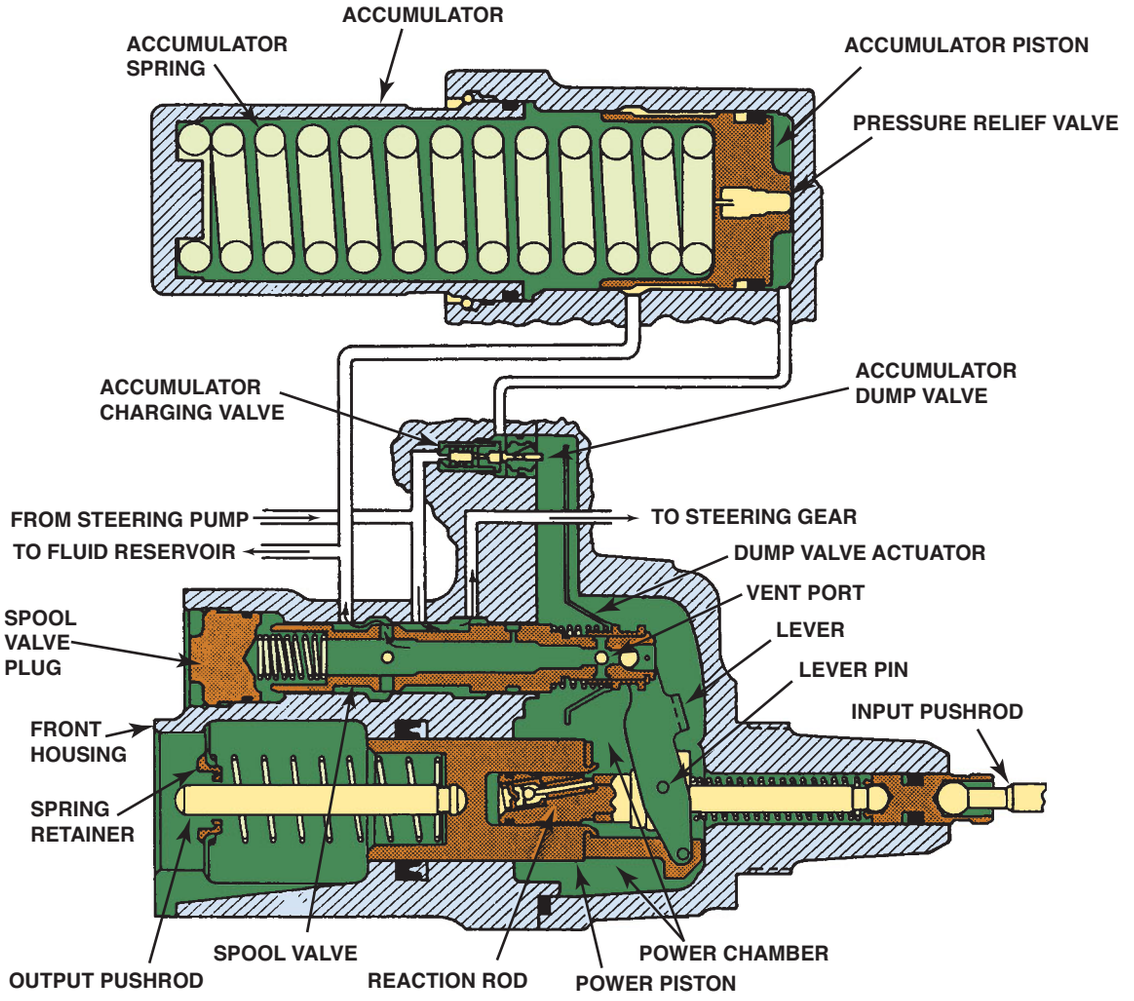

FIGURE 105–23 A Hydro-Boost hydraulic booster in the unapplied position.

power piston, which then applies force to the output rod that connects to the master cylinder piston. In the event of a power steering pump failure, power assist is still available for several brake applications. ● **SEE FIGURE 105–24.**

During operation, hydraulic fluid under pressure from the power steering pump pressurizes an accumulator. ● **SEE FIGURE 105–25.** While some units use a spring inside the accumulator, most Hydro-Boost units use nitrogen gas. The fluid trapped in the accumulator under pressure is used to provide power-assisted stops in the event of a hydraulic system failure.

DIAGNOSIS The power source for Hydro-Boost units comes from the power steering pump. The first step of troubleshooting is to perform a thorough visual inspection, including the following:

1. Checking for proper power steering fluid level
2. Checking for leaks from the unit or power steering pump
3. Checking the condition and tightness of the power steering drive belt
4. Checking for proper operation of the base brake system

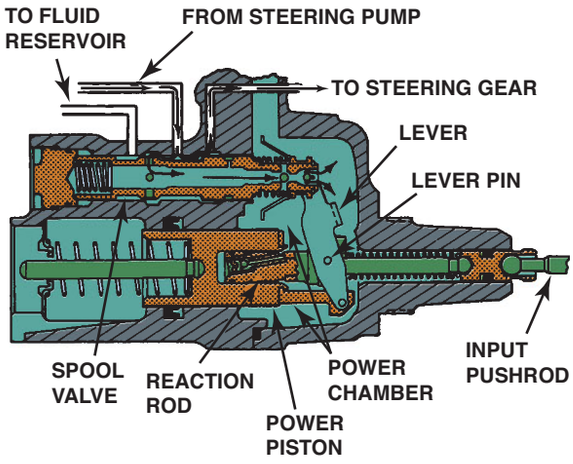

FIGURE 105–24 A Hydro-Boost hydraulic booster as the brakes are applied.

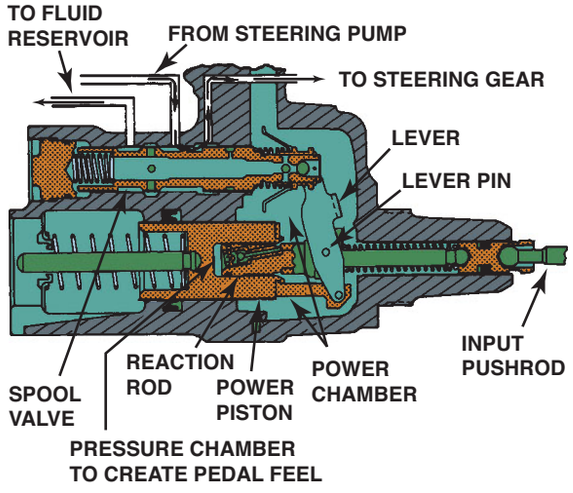

FIGURE 105–25 A Hydro-Boost hydraulic booster in the holding position.

After checking all of the visual components, check for proper pressure and volume from the power steering pump using a power steering pump tester, as shown in ● **FIGURES 105–26 AND 105–27.**

The pump should be capable of producing a minimum of 2 gallons (7.5 liters) with a maximum pressure of 150 PSI (1,000 kPa) with the steering in the straight-ahead position. With the engine "off," the accumulator should be able to supply a minimum of two power-assisted brake applications.

HYDRO-BOOST FUNCTION TEST With the engine off, apply the brake pedal several times until the accumulator is depleted completely. Depress the service brake pedal and start the engine. The pedal should fall and then push back against the driver's foot.

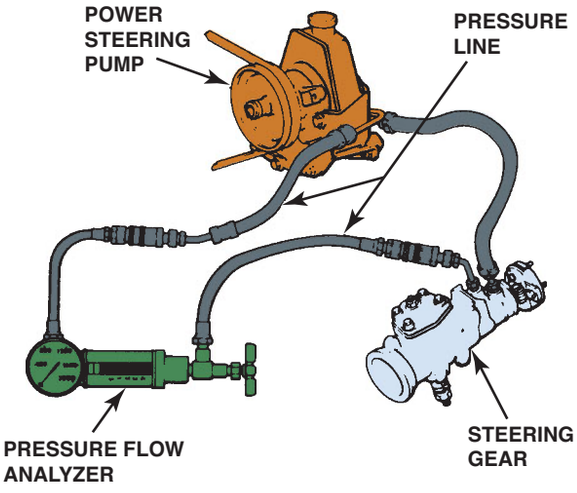

FIGURE 105–27 Pressure and flow analyzer installation to check the power steering pump output.

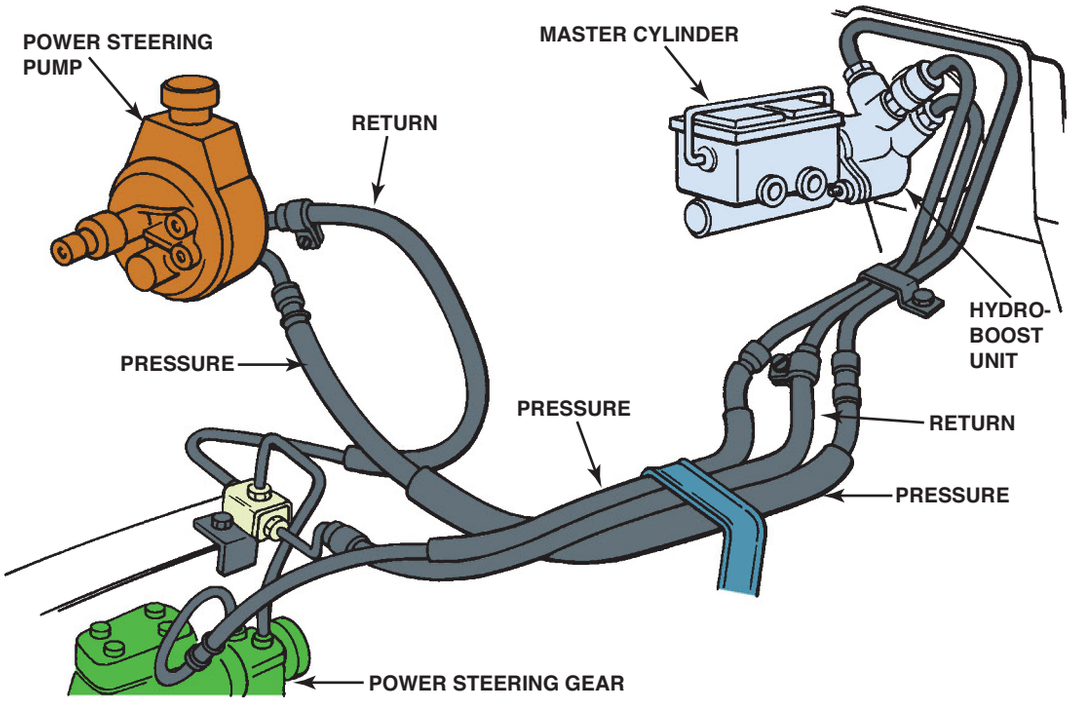

FIGURE 105–26 A typical Hydro-Boost hydraulic line arrangement showing the pump, steering gear, and brake booster assembly.

TECH TIP

The Hydro-Boost Accumulator Test

The accumulator stores hydraulic fluid under pressure to provide a reserve in the event of a failure of the power steering system. The accumulator is designed to provide three or more power-assisted stops with the engine off. **SEE FIGURE 105–28.**

If the accumulator fails, it does not hold pressure. To easily check whether the accumulator has lost its charge, simply grasp the accumulator with your hand and try to twist or move it. The accumulator should have so much pressure on it that it should not move or wiggle. If the accumulator moves, it has lost its ability to hold pressure and the Hydro-Boost unit should be replaced.

FIGURE 105–28 The accumulator should be able to hold pressure and feel tight when hand force is used to try to move it.

HYDRO-BOOST SYMPTOM-BASED GUIDE

EXCESSIVE BRAKE PEDAL EFFORT Possible causes for this include the following:

1. Loose or broken power steering pump belt
2. No fluid in the power steering reservoir
3. Leaks in the power steering, booster, or accumulator hoses
4. Leaks at tube fittings, power steering, booster, or accumulator connections
5. External leakage at the accumulator
6. Faulty booster piston seal, causing leakage at the booster flange vent
7. Faulty booster cover seal with leakage between the housing and cover
8. Faulty booster spool plug seal

SLOW BRAKE PEDAL RETURN Possible causes for this include the following:

1. Excessive seal friction in the booster
2. Faulty spool action
3. Broken piston return spring
4. Restriction in the return line from the booster to the pump reservoir
5. Broken spool return spring

GRABBY BRAKES Possible causes for this include the following:

1. Broken spool return spring
2. Faulty spool action caused by contamination in the system

BOOSTER CHATTERS—PEDAL VIBRATES Possible causes for this include the following:

1. Power steering pump belt slipping
2. Low fluid level in the power steering pump reservoir
3. Faulty spool operation caused by contamination in the system

REVIEW QUESTIONS

1. Describe the purpose and function of the one-way check valve used on vacuum brake booster units.
2. Explain how vacuum is used to assist in applying the brakes.
3. Describe how to perform a vacuum booster leak test and hydraulic system leak test.
4. Explain how a Hydro-Boost system functions.

CHAPTER QUIZ

1. Two technicians are discussing vacuum brake boosters. Technician A says that a low, soft brake pedal is an indication of a defective booster. Technician B says that there should be at least two power-assisted brake applications after the engine stops running. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. Technician A says that to check the operation of a vacuum brake booster, the brake pedal should be depressed until the assist is depleted and then start the engine. Technician B says that the brake pedal should drop when the engine starts, if the booster is okay. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

3. Brake pedal feedback to the driver is provided by the _____.
   a. Vacuum check-valve operation
   b. Reaction system
   c. Charcoal filter unit
   d. Vacuum diaphragm

4. The proper operation of a vacuum brake booster requires that the engine be capable of supplying at least _____.
   a. 15 in. Hg vacuum
   b. 17 in. Hg vacuum
   c. 19 in. Hg vacuum
   d. 21 in. Hg vacuum

5. The purpose of the charcoal filter in the vacuum hose between the engine and the vacuum brake booster is to _____.
   a. Filter the air entering the engine
   b. Trap gasoline vapors to keep them from entering the booster
   c. Act as a one-way check valve to help keep a vacuum reserve in the booster
   d. Direct the vacuum

6. A defective vacuum brake booster will cause a _____.
   a. Hard brake pedal
   b. Soft (spongy) brake pedal
   c. Low brake pedal
   d. Slight hiss noise when the brake pedal is depressed

7. An accumulator such as that used on hydraulic brake boosters _____.
   a. Reduces brake pedal noise
   b. Provides higher force being fed back to the driver's foot
   c. Provides a reserve in the event of a failure
   d. Works against engine vacuum

8. The first step in diagnosing a Hydro-Boost problem is _____.
   a. A pressure test of the pump
   b. A volume test of the pump
   c. To tighten the power steering drive belt
   d. A thorough visual inspection

9. A brake pedal feels spongy when depressed. Technician A says that a defective hydraulic brake booster could be the cause. Technician B says that a defective vacuum brake booster could be the cause. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

10. If the engine stops running, the Hydro-Boost will not be able to provide any power assist for the brakes.
   a. True
   b. False

chapter 106

ABS COMPONENTS AND OPERATION

OBJECTIVES: **After studying Chapter 106, the reader will be able to:** • Prepare for the Brakes (A5) ASE certification test content area "F" (Antilock Brake System Diagnosis and Repair). • Explain the reason for ABS. • Describe the purpose and function of the ABS components, such as wheel speed sensors, electrohydraulic unit, and electronic controller. • Discuss how the ABS components control wheel slippage.

KEY TERMS: Accumulator 1215 • Active sensor 1213 • Air gap 1213 • Antilock braking systems (ABS) 1208 • Channel 1211 • Control module 1210 • Flash codes 1214 • Integral ABS 1211 • Isolation solenoid 1214 • Nonintegral ABS 1211 • Pressure decay stage 1215 • Pressure dump stage 1215 • Pressure holding stage 1215 • Pressure increase stage 1215 • Pressure reduction stage 1215 • Pressure release stage 1215 • Rear Antilock Braking System (RABS) 1211 • Rear Wheel Antilock (RWAL) 1211 • Release solenoid 1215 • Select low principle 1211 • Solenoid valves 1210 • Tire pressure monitoring system (TPMS) 1217 • Tire slip 1209 • Tone ring 1212 • Traction 1208 • Wheel speed sensors (WSS) 1212

ANTILOCK BRAKING SYSTEM

OVERVIEW

Antilock braking systems (ABS) help prevent the wheels from locking during sudden braking, especially on slippery surfaces. This helps the driver maintain control.

Antilock brakes increase safety because they eliminate lockup and minimize the danger of skidding, allowing the vehicle to stop in a straight line. ABS also allows the driver to maintain steering control during heavy braking so the vehicle can be steered to avoid an obstacle or another vehicle.

ABS can improve braking when road conditions are less than ideal, as when making a sudden panic stop or when braking on a wet or slick road. ABS does this by monitoring the relative speed of the wheels to one another. It uses this information to modulate brake pressure as needed to control slippage and maintain traction when the brakes are applied.

ABS AND TIRE TRACTION

Preventing brake lockup is important because of the adverse effect a locked wheel has on tire **traction.** The brakes slow the rotation of the wheels, but it is friction between the tire and road that stops the vehicle and allows it to be

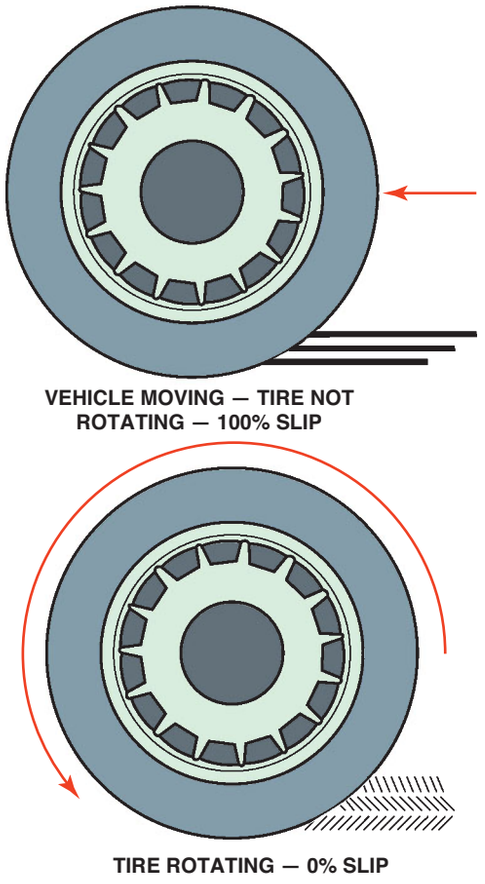

FIGURE 106–1 Maximum braking traction occurs when tire slip is between 10% and 20%. A rotating tire has 0% slip and a locked-up wheel has 100% slip.

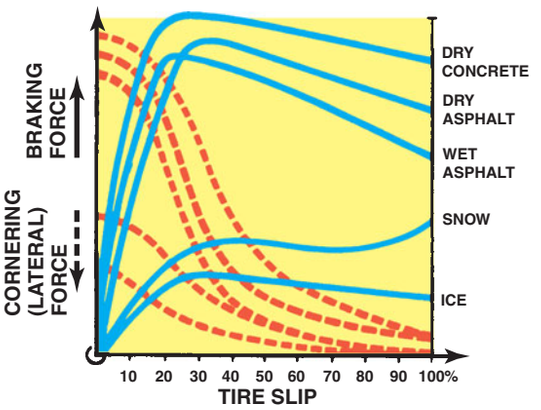

FIGURE 106–2 Traction is determined by pavement conditions and tire slip.

steered. If tire traction is reduced, stopping distances increase, and the directional stability of the vehicle suffers.

Traction is defined in terms of **tire slip,** which is the difference between the actual speed and the rate at which the tire tread moves across the road. A free-rolling wheel has nearly zero tire slip, while a locked wheel has 100% tire slip. ● **SEE FIGURE 106–1.**

When the brakes are applied, the rotational speed of the wheel drops, and tire slip increases because the tread moves across the road slower than the actual vehicle speed. This slip creates friction that converts kinetic energy into braking and cornering force.

TIRE SLIP AND BRAKING DISTANCE

On dry or wet pavement, maximum braking traction occurs when tire slip is held between approximately 15% and 30%. ● **SEE FIGURE 106–2.**

On snow- or ice-covered pavement, the optimum slip range is 20% to 50%. In each case, if tire slip increases beyond these levels, the amount of traction decreases. A skidding tire with 100% slip provides 20% to 30% less braking traction on dry pavement, and this is generally true on slippery roads as well. In nearly all cases, the shortest stopping distances are obtained when the brakes are applied with just enough force to keep the tire slip in the range where traction is greatest.

NOTE: All antilock braking systems stop controlling the wheel brakes when the vehicle speed drops to about 5 MPH (8 km/h). The wheel speed sensors are often not accurate that these low speeds and loss of vehicle control at this low speed is unlikely.

TECH TIP

Tire "Chirp" Noise during Hard Braking Is Normal

Sometimes customers state that they do not think that their antilock braking system (ABS) is working correctly because they heard the tires making noise (chirping sound) during hard braking. This is normal as the tires slip about 20% during an ABS stop.

TIRE SLIP AND VEHICLE STABILITY

A tire's contact patch with the road can provide only a certain amount of traction. When a vehicle is stopped in a straight line, nearly all of the available traction can be used to provide braking force. Only a small amount of traction is required to generate lateral force that keeps the vehicle traveling in a straight line. However, if a vehicle has to stop and turn at the same time, the available traction must be *divided* to provide both cornering (lateral) and braking force.

No tire can provide full cornering power and full braking power at the same time. When a brake is locked and the tire has 100% slip, all of the available traction is used for braking, and none is left for steering. As a result, a skidding tire follows the path of least resistance. This means that if the rear brakes lock, the back end of the vehicle will tend to swing around toward the front causing a spin. If the front brakes lock, steering control will be lost and the vehicle will slide forward in a straight line until the brakes are released to again make traction available for steering.

ABS AND BASE BRAKES

An antilock braking system is only an "add-on" to the existing base brake system. ABS only comes into play when traction conditions are marginal or during sudden panic stops when the tires lose traction and begin to slip excessively. The rest of the time ABS has no effect on normal driving, handling, or braking.

NOTE: All vehicles sold in the United States for the 2012 model year and newer are required to be equipped with electronic stability system. These systems require that the vehicle be equipped with antilock braking system (ABS) as standard equipment.

ABS also makes no difference in the maintenance, inspection, service, or repair of conventional brake system components. A vehicle with ABS brakes uses the same brake linings, calipers, wheel cylinders,

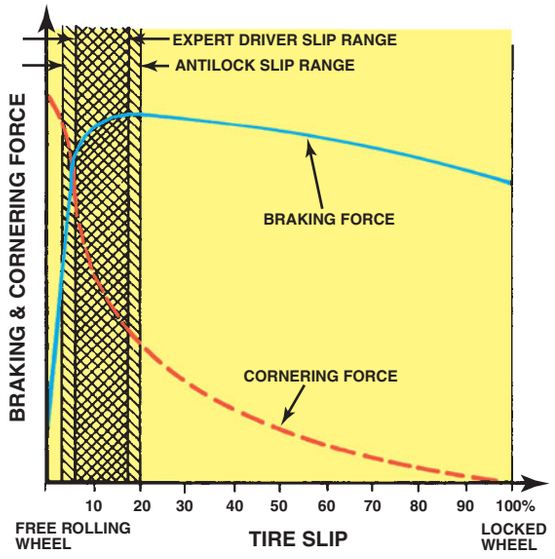

FIGURE 106–3 A good driver can control tire slip more accurately than an ABS if the vehicle is traveling on a smooth, dry road surface.

and other system components as a vehicle without ABS brakes. The only exception being the master cylinder on certain applications.

All ABS systems are also designed to be as "fail-safe" as possible. Should a failure occur that affects the operation of the ABS system, the system will deactivate itself and the vehicle will revert to normal braking. Therefore, an ABS failure will not prevent the vehicle from stopping.

ABS LIMITATIONS There are two situations in which an antilock brake system will *not* provide the shortest stopping distances. The first involves straight stops made on smooth, dry pavement by an *expert* driver. Under these conditions, a skilled driver can hold the tires consistently closer to the ideal slip rate than the ABS can. ● **SEE FIGURE 106–3.**

This is possible because current antilock braking systems may allow the amount of tire slip to drop as low as 5%, which is somewhat below the point where maximum tire traction is achieved. However, for the average driver, or under less than ideal conditions, antilock brakes will almost always stop the vehicle in a shorter distance.

The other situation in which antilock brakes will not provide the shortest stops is when braking on loose gravel or dirt, or in deep, fluffy snow. Under these conditions, a locked wheel will stop the vehicle faster because loose debris builds up and forms a wedge in front of the tire that helps stop the vehicle. ● **SEE FIGURE 106–4.**

An antilock braking system will prevent this wedge from forming, so some vehicles with antilock brakes have a switch on the instrument panel that allows the system to be deactivated when driving on these kinds of road surfaces.

ABS AND THE LAWS OF PHYSICS No ABS can overcome the laws of physics. The weight and speed of a moving vehicle give it a great deal of kinetic energy, and only so much of that energy can be converted into braking or cornering force at any given time. The limiting factor in this conversion is the traction between the tires and road.

Although a vehicle with four-wheel antilock brakes will stop in very nearly the shortest possible distance, this will still not prevent an accident if the brakes are applied too late to bring the vehicle to a complete stop before impact. However, because steering control is retained with four-wheel antilock brakes, it may be possible to drive the vehicle around a potential accident while in the process of braking.

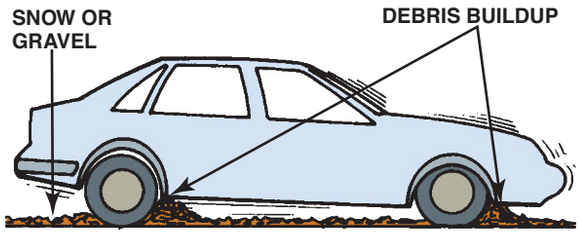

FIGURE 106–4 A wedge of gravel or snow in the front of a locked wheel can help stop a vehicle faster than would occur if the wheel brakes were pulsed on and off by an antilock braking system.

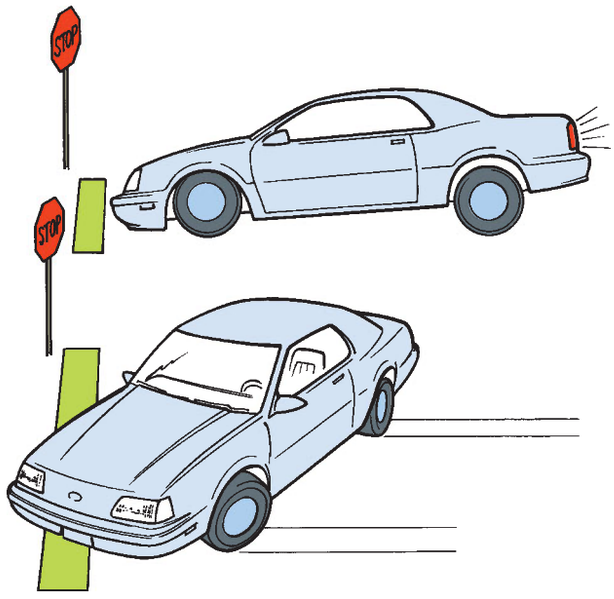

FIGURE 106–5 Being able to steer and control the vehicle during rapid braking is one major advantage of an antilock braking system.

Another situation where antilock brakes cannot defy the laws of physics occurs when a vehicle enters a corner traveling faster than it is physically possible to negotiate the turn. In this situation, antilock brakes will not prevent the vehicle from leaving the road. However, they will allow the vehicle to be slowed and steered in the process, thus lessening the severity of the eventual impact. ● **SEE FIGURE 106–5.**

ABS OPERATION

WHEEL SPEED SENSOR INPUT All ABS systems control tire slip by monitoring the relative deceleration rates of the wheels during braking. Wheel speed is monitored by one or more wheel speed sensors. If one wheel starts to slow at a faster rate than the others, or at a faster rate than that which is programmed in the antilock **control module,** it indicates a wheel is starting to slip and is in danger of losing traction and locking. The ABS responds by momentarily reducing hydraulic pressure to the brake on the affected wheel or wheels. This allows the wheel to speed up momentarily so it can regain traction. As traction is regained, brake pressure is reapplied to again slow the wheel. The cycle is repeated over and over until the vehicle stops or until the driver eases pressure on the brake pedal.

CONTROL VALVES Electrically operated **solenoid valves** (or motor-driven valves in the case of Delphi ABS-VI applications) are

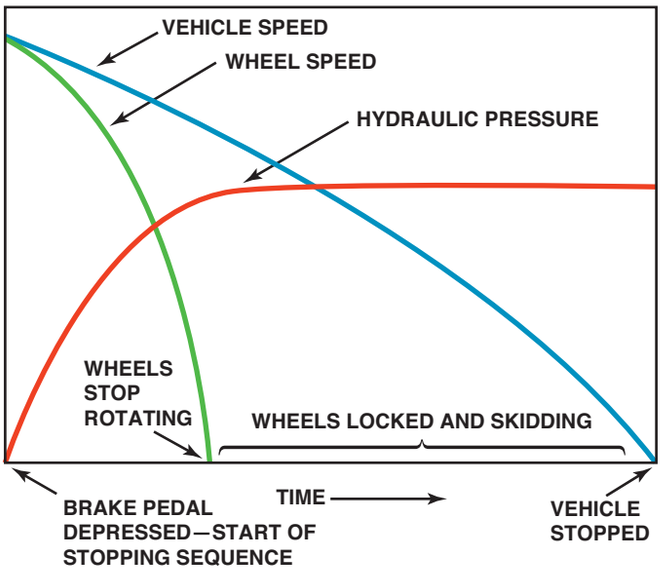

FIGURE 106–6 A typical stop on a slippery road surface without antilock brakes. Notice that the wheels stopped rotating and skidded until the vehicle finally came to a stop.

used to hold, release, and reapply hydraulic pressure to the brakes. This produces a pulsating effect, which can be felt in the brake pedal during hard braking. The rapid modulation of brake pressure in a given brake circuit reduces the braking load on the affected wheel and allows it to regain traction to prevent lockup. The effect is much the same as pumping the brakes, except that the ABS system does it automatically for each brake circuit, and at speeds that would be humanly impossible—up to 20 times per second depending on the system (some cycle faster than others). ● **SEE FIGURE 106–6.**

Once the rate of deceleration for the affected wheel catches up with the others, normal braking function and pressure resume, and antilock reverts to a passive mode.

SYSTEM CONFIGURATIONS

All ABS systems keep track of wheel deceleration rates with wheel speed sensors. The various ABS systems use a different number of sensors, depending on how the system is configured. These include four-channel, three-channel, and single-channel systems. ● **SEE FIGURE 106–7.**

FOUR-CHANNEL ABS SYSTEMS On some applications, each wheel is equipped with its own speed sensor. This type of arrangement is called a "four-wheel, four-channel" system since each wheel speed sensor provides input for a separate hydraulic control circuit or "channel" for that wheel.

The term **channel** always refers to the number of separate or individually controlled ABS hydraulic circuits in an ABS system, not the number of wheel speed sensor electrical circuits.

NOTE: For vehicle stability systems to function, there has to be four wheel speed sensors and four channels so the hydraulic control unit can pulse individual wheel brakes to help achieve vehicle stability.

THREE-CHANNEL ABS SYSTEMS Some four-wheel ABS systems have a separate wheel speed sensor for each front wheel

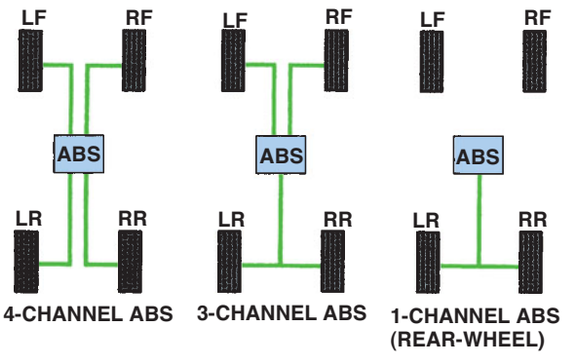

FIGURE 106–7 ABS configuration includes four-channel, three-channel, and single-channel.

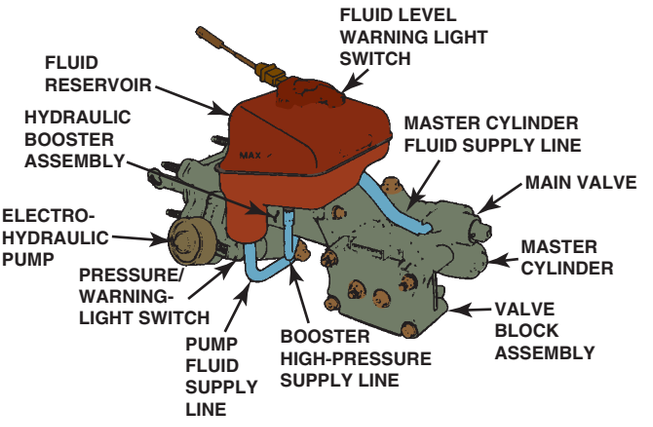

FIGURE 106–8 A typical integral ABS unit that combines the function of the master cylinder, brake booster, and antilock braking system in one assembly.

but use a common speed sensor for both rear wheels. These are called "three-channel" systems. The rear wheel speed sensor is mounted in either the differential or the transmission. The sensor reads the combined or average speed of both rear wheels. This type of setup saves the cost for an additional sensor and reduces the complexity of the system by allowing both rear wheels to be controlled simultaneously. This is known as the **select low principle.** Three-channel systems are the most common type of ABS setup used on rear-wheel-drive applications.

SINGLE-CHANNEL ABS SYSTEMS The single-channel rear-wheel-only ABS system is used on many rear-wheel-drive pickups and vans. Ford's version is called **Rear Antilock Braking System (RABS),** while General Motors and Chrysler call theirs **Rear Wheel Antilock (RWAL).** The front wheels have no speed sensors, and only a single speed sensor mounted in the differential or transmission is used for both rear wheels. Rear-wheel antilock systems are typically used on applications where vehicle loading can affect rear wheel traction, which is why it is used on pickup trucks and vans. ABS was first used in pickup trucks because when the truck brakes, the weight transfer that occurs when the stop unloads the rear of the truck especially if the bed of truck is empty.

INTEGRAL AND NONINTEGRAL Another distinction between ABS systems is whether they are **integral** or **nonintegral ABS.** Integral systems combine the brake master cylinder and ABS hydraulic modulator, electric pump, and accumulator into one assembly. ● **SEE FIGURE 106–8.**

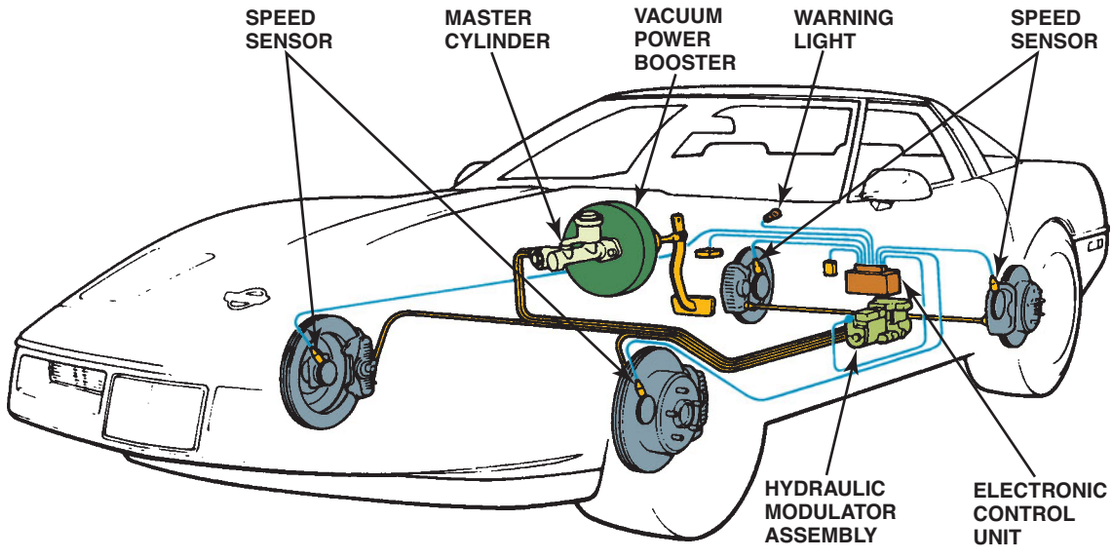

FIGURE 106–9 A typical nonintegral-type (remote) ABS.

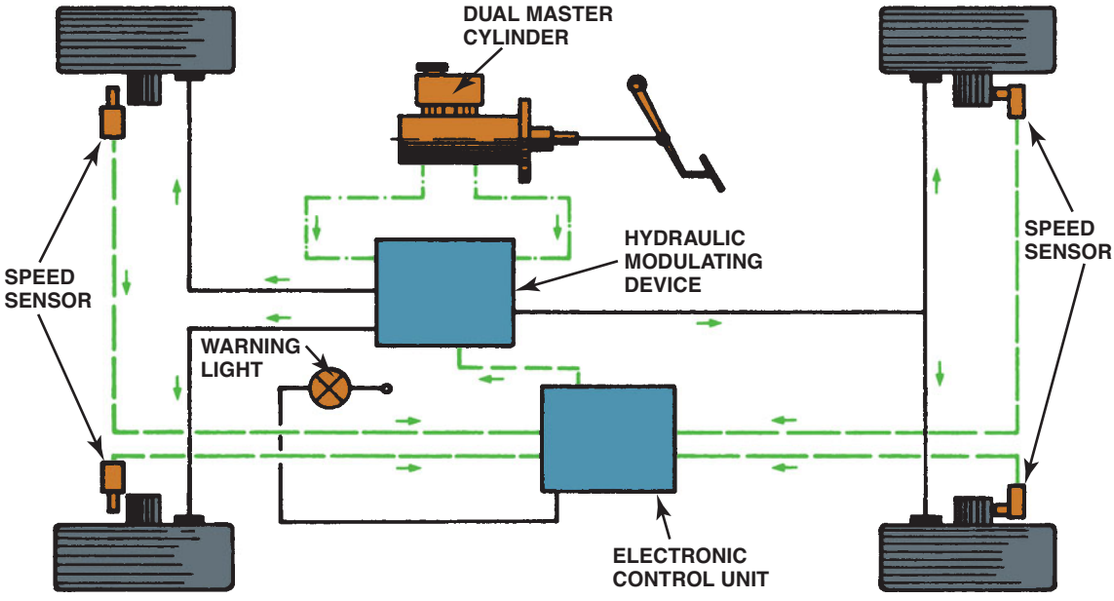

FIGURE 106–10 A schematic drawing of a typical antilock braking system.

Integral systems do not have a vacuum booster for power assist and rely instead on pressure generated by the electric pump for this purpose. Most of the older ABS applications are integral systems. Integral ABS systems include the Bendix 10 and Bendix 9 (Jeep) ABS systems, Bosch 3, Delco Moraine Powermaster III, and Teves Mark 2.

Nonintegral ABS systems, which are sometimes referred to as "add-on" systems, have become the most common type of ABS system because of their lower cost and simplicity. ● **SEE FIGURE 106–9.**

Nonintegral ABS systems have a conventional brake master cylinder and vacuum power booster with a separate hydraulic modulator unit. Some also have an electric pump for ABS braking (to reapply pressure during the ABS hold-release-reapply cycle), but do not use the pumps for normal power assist.

Nonintegral (add-on) systems include Bendix 3, Bendix 6, Bendix ABX-4, Bendix Mecatronic, Bosch 2, Bosch 2S Micro, Bosch 2U, Bosch 2E, Bosch 5, Delco Moraine ABS-VI, Kelsey-Hayes RABS/RWAL, 4WAL, EBC-5 and EBC-10, Sumitomo ABS, Teves Mark 4 ABS and MK20, and Toyota rear-wheel ABS.

ABS COMPONENTS

Basic components that are common to all antilock brake systems include the following.

- Wheel speed sensors
- Electronic control unit
- ABS warning lamp
- Hydraulic modulator assembly with electrically operated solenoid valves (or motor-driven valves in the case of Delphi ABS-VI)

● **SEE FIGURE 106–10.**

WHEEL SPEED SENSORS

Most **wheel speed sensors,** abbreviated **WSS,** consist of a magnetic pickup and a toothed sensor ring (usually called a **tone ring**). The sensor may be mounted in the steering knuckle, wheel hub, brake backing plate, transmission tailshaft, or differential housing. ● **SEE FIGURE 106–11.**

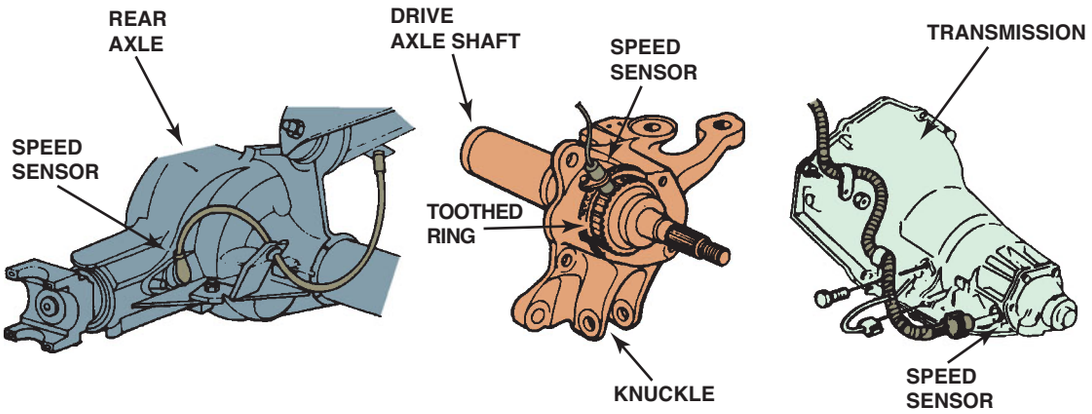

FIGURE 106–11 Wheel speed sensors for the rear wheels may be located on the rear axle, on the transmission, or on the individual wheel knuckle.

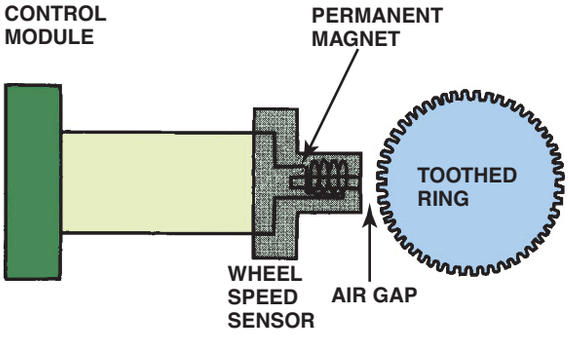

FIGURE 106–12 A schematic of a typical wheel speed sensor. The toothed ring is also called a *tone ring.*

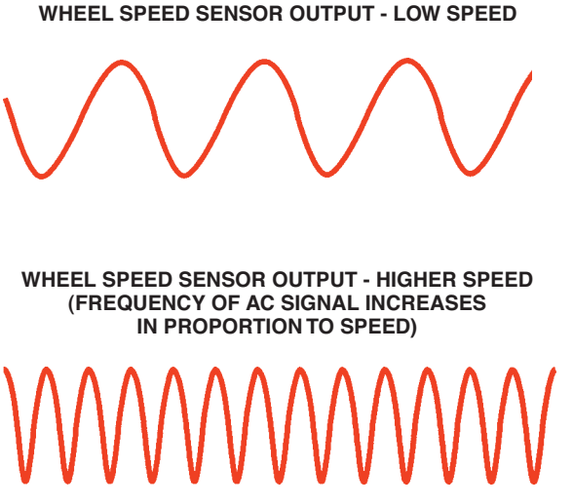

FIGURE 106–13 Wheel speed sensors produce an alternating current (AC) signal with a frequency that varies in proportion to wheel speed.

On some applications, the sensor is an integral part of the wheel bearing and hub assembly. The sensor rings may be mounted on the axle hub behind the brake rotors, on the brake rotors or drums, on the outside of the outboard constant velocity joints on a front-wheel-drive vehicle, on the transmission tailshaft, or inside the differential on the pinion gear shaft.

SENSOR OPERATION. The sensor pickup has a magnetic core surrounded by coil windings. ● **SEE FIGURE 106–12.**

As the wheel turns, teeth on the sensor ring move through the pickup's magnetic field. This reverses the polarity of the magnetic field and induces an alternating current (AC) voltage in the sensor windings. The number of voltage pulses per second induced in the pickup changes frequency. ● **SEE FIGURE 106–13.**

The frequency of the signal is therefore proportional to wheel speed. The higher the frequency, the faster the wheel is turning.

The signals are sent to the ABS control module (or an intermediate module in some General Motors rear-wheel ABS applications), where the AC signal is converted into a digital signal for processing. The control module then monitors wheel speed by counting the pulses from each of the wheel speed sensors. If the frequency signal from one wheel starts to change abruptly with respect to the others, it tells the module that wheel is starting to lose traction. The module then applies antilock braking if needed to maintain traction.

SENSOR AIR GAP. The distance or **air gap** between the end of the sensor and its ring is critical. A close gap is necessary to produce a strong, reliable signal. But metal-to-metal contact between the sensor and its ring must be avoided since this would damage both. The air gap must not be too wide or a weak or erratic signal (or no signal) may result. The air gap on some wheel speed sensors is adjustable, and is specified by the vehicle manufacturer.

SENSOR APPLICATIONS AND PRECAUTIONS. Wheel speed sensor readings are affected by the size of the wheels and tires on the vehicle. A tire with a larger overall diameter will give a slower speed reading than one with a smaller diameter. Because the ABS system is calibrated to a specific tire size, vehicle manufacturers warn against changing tire sizes. A different tire size or aspect ratio could have an effect on the operation of the ABS system.

Wheel speed sensors are also magnetic, which means they can attract metallic particles. These particles can accumulate on the end of the sensor and reduce its ability to produce an accurate signal. Removing the sensor and cleaning the tip may be necessary if the sensor is producing a poor signal.

DIGITAL WHEEL SPEED SENSORS. A conventional wheel speed sensor uses a permanent magnet with a surrounding coil of wire to produce an AC voltage signal that is proportional to wheel speed. The major problem with this type of sensor is that the voltage output and frequency are very low at slow speeds and therefore, cannot produce accurate wheel speed for ABS and traction control.

A digital wheel speed sensor, also called an **active sensor,** uses either a Hall-effect or a variable-reluctance circuit to produce a square waveform where the frequency is proportional to the wheel speed. A digital wheel speed sensor can also detect direction and can therefore be used by the controller for hill holding. The accuracy of these digital sensors also makes correlation to global positioning

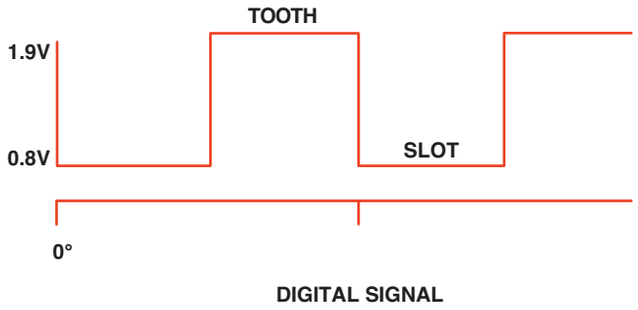

FIGURE 106–14 A digital wheel speed sensor produces a square wave output signal.

used in navigational systems more accurate, especially when the vehicle is being driven at slow speeds.

NOTE: While all GPS navigation systems use satellites for global positioning, the vehicle uses other sensors to keep track of minor changes in speed and vehicle direction.

The typical digital or Hall effect wheel speed sensor uses three wires:

1. A reference voltage from the controller which can be 5, 8 or 12 volts depending on the system
2. Signal wire that sends a digital on-off signal to the controller whose frequency is proportional to the vehicle speed.
3. A ground

The sensor voltage toggles between about 0.8V and 1.9V. ● **SEE FIGURE 106–14.**

ABS CONTROL MODULE

CONTROL MODULE TERMS The ABS electronic control module, which may be referred to as an "electronic brake control module" (EBCM), "electronic brake module" (EBM), or "controller antilock brakes" (CAB) module, is a digital microprocessor that uses inputs from its various sensors to regulate hydraulic pressure during braking to prevent wheel lockup. The module may be located on the hydraulic modulator assembly (as it is on many of the newer compact ABS systems), or it may be located elsewhere in the vehicle, such as the trunk, passenger compartment, or under the hood.

MODULE INPUTS The key inputs for the ABS control module come from the wheel speed sensors and the brake pedal switch. ● **SEE FIGURE 106–15.**

The brake pedal switch signals the control module when the brakes are being applied, which causes it to go from a "standby" mode to an active mode. At the same time, the wheel speed sensors provide information about what is happening to the wheels while the brakes are being applied.

NOTE: A fault with the brake switch will not prevent ABS operation. The brake switch allows the controller to react faster to an ABS event.

MODULE OPERATION If the control module detects a difference in the deceleration rate between one or more wheels when braking, or if the overall rate of deceleration is too fast and exceeds the limits programmed into the control module, it triggers the ABS control module to momentarily take over. The control module cycles the solenoid valves in the modulator assembly to pulsate hydraulic pressure in the affected brake circuit (or circuits) until sensor information indicates that the deceleration rates have returned to normal and braking is under control. Normal braking resumes. When the brake pedal is released or when the vehicle comes to a stop, the control module returns to a standby mode until it is again needed.

ABS WARNING LAMP Every ABS system has an amber indicator lamp on the instrument panel that warns the driver when a problem occurs within the ABS system. The lamp comes on when the ignition is turned on for a bulb check, then goes out after the engine starts. If the warning light remains on or comes on while driving, it usually indicates a fault in the ABS system that will require further diagnosis. On most applications, the ABS system disables if the ABS warning light comes on and remains on. This should have no effect on normal braking, unless the red brake warning lamp is also on. The ABS warning light is also used for diagnostic purposes when retrieving **flash codes** (trouble codes) from the ABS module.

HYDRAULIC MODULATOR ASSEMBLY

PURPOSE AND FUNCTION The modulator valve body is part of the master cylinder assembly in nonintegral antilock systems but separate in nonintegral systems. It contains solenoid valves for each brake unit (in Delphi ABS-VI applications, however, motor-driven valves are used instead of solenoids). The exact number of valves per circuit depends on the ABS system and the application. Some use a pair of on-off solenoid valves for each brake circuit while others use a single valve that can operate in more than one position.

ABS SOLENOID A solenoid consists of a wire coil with a movable core and a return spring. When current from the ABS control module energizes the coil, it pulls on the movable core. Depending on how the solenoid is constructed, this may open or close a valve that is attached to the movable core. When the control current is shut off, the solenoid snaps back to its normal or rest position.

Some solenoids are designed to do more than just switch on or off to open or close a valve. Some pull a valve to an intermediate position when a certain level of current is applied to the coil, then pull the valve to a third position when additional current is provided. ● **SEE FIGURE 106–16.**

This design allows a single solenoid to perform the same functions as two or even three single-position solenoids.

The solenoids in the hydraulic modulator assembly are used to open and close passageways between the master cylinder and the individual brake circuits. By opening or closing the modulator valves to which they're attached, brake pressure within any given circuit can be held, released, and reapplied to prevent lockup during hard braking.

ABS CONTROL PRESSURE STAGES The standard ABS control strategy that is used is a three-step cycle:

- The first step is to hold or isolate the pressure in a given brake circuit by closing an **isolation solenoid** in the modulator assembly. This solenoid is normally electrically and

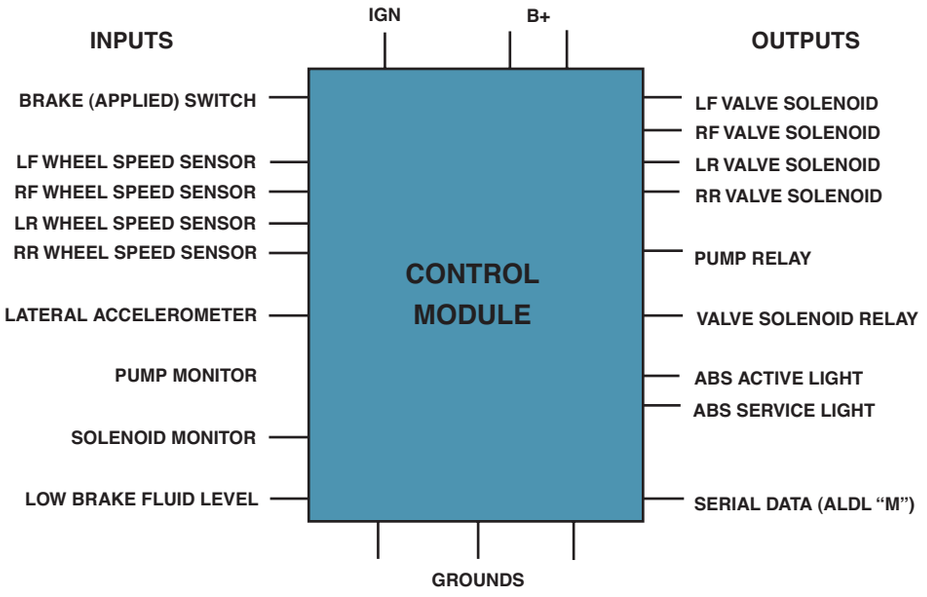

FIGURE 106–15 Typical inputs and outputs for brake control modules.

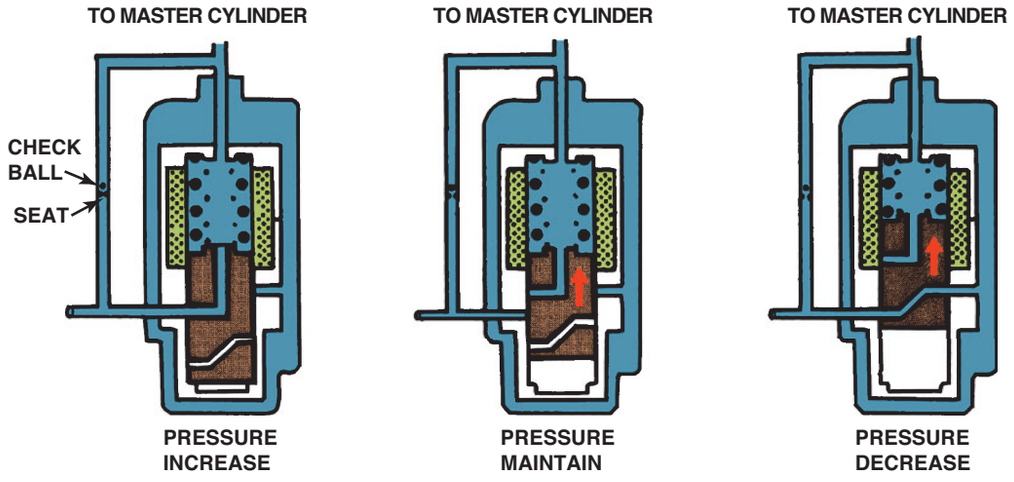

FIGURE 106–16 An ABS three-way solenoid can increase, maintain, or decrease brake pressure to a given brake circuit.

hydraulically open. ● **SEE FIGURE 106–17.** When the solenoid is electrically closed, it becomes hydraulically closed, which blocks off the line and prevents any further pressure from the master cylinder reaching the brake. This is called the **pressure holding stage.**

- If the wheel speed sensor continues to indicate the wheel is slowing too quickly and is starting to lock, the same solenoid or a second **release solenoid** is energized to open a vent port that releases pressure from the brake circuit. ● **SEE FIGURE 106–18.** The fluid is usually routed into a spring-loaded or pressurized storage reservoir (called an **accumulator**) so it can be reused as needed. Releasing pressure in the brake circuit allows the brake to loosen its grip so the wheel can speed up and regain traction. This is called **pressure reduction, pressure release, pressure decay,** or **pressure dump stage.** The pressure reduction solenoid is normally hydraulically closed and electrically opened.
- The release and/or isolation solenoid(s) are then closed and/or the additional solenoid energized so pressure can be reapplied to the brake from the master cylinder or accumulator to reapply the brake. ● **SEE FIGURE 106–19.** This is called the **pressure increase stage.** During the pressure increase stages, the isolation solenoid is electrically and hydraulically opened. The pressure reduction solenoid is electrically opened and hydraulically closed.

The hold-release-reapply cycle repeats as many times as needed until the vehicle either comes to a halt or the driver releases the brake pedal. The speed at which this occurs depends on the particular ABS system that is on the vehicle, but can range from a few times per second up to dozens of times per second.

PUMP MOTOR AND ACCUMULATOR

A high-pressure electric pump is used in some ABS systems to generate power assist for normal braking as well as the reapplication of brake pressure during ABS braking. ● **SEE FIGURE 106–20.** In some systems, it is used only for the reapplication of pressure during ABS braking.

The pump motor is energized by a relay, which is switched on and off by the ABS control module. The fluid pressure generated by the pump is stored in the accumulator. Some ABS systems have more than one accumulator. The accumulator on ABS systems, where the hydraulic modulator is part of the master cylinder assembly, consists of a pressure storage chamber filled with nitrogen gas.

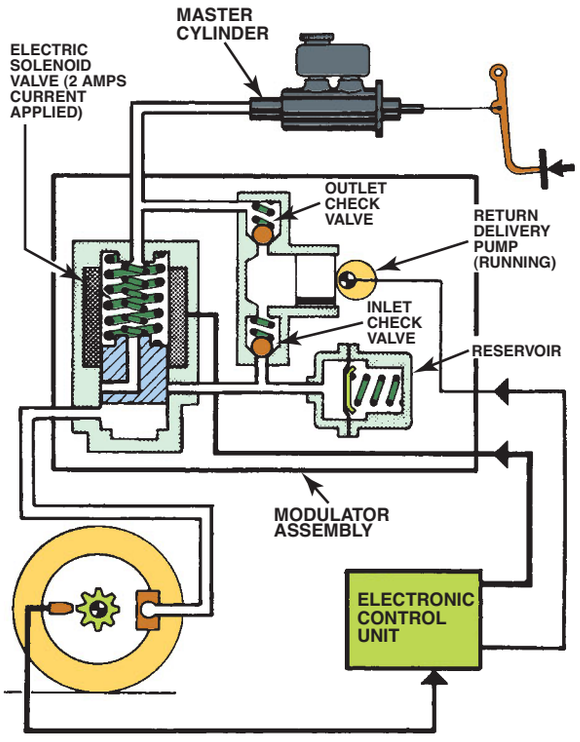

FIGURE 106–17 The isolation or hold phase of an ABS on a Bosch 2 system.

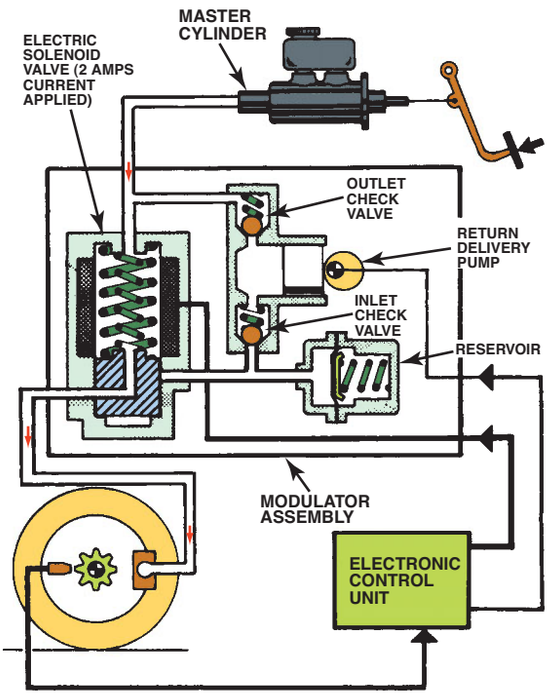

FIGURE 106–19 The control module reapplies pressure to the affected brake circuit once the tire achieves traction so that normal braking can continue.

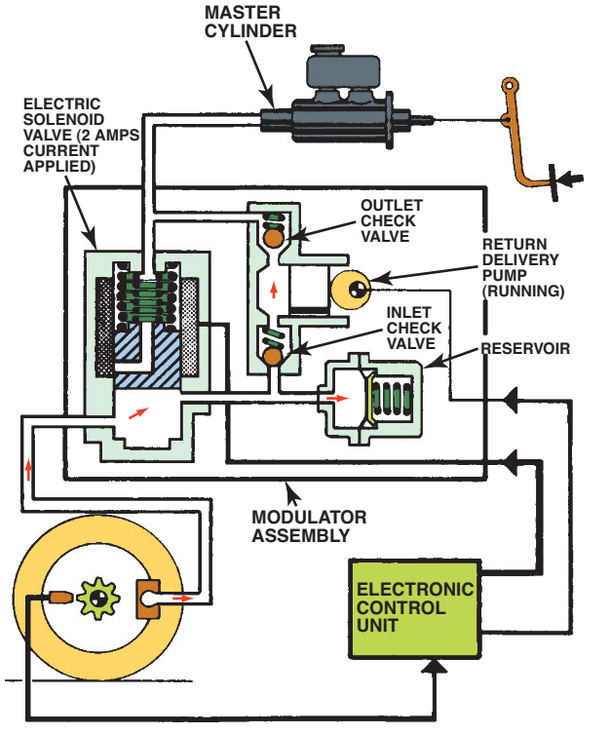

FIGURE 106–18 During the pressure reduction stage, pressure is vented from the brake circuit so the tire can speed up and regain traction.

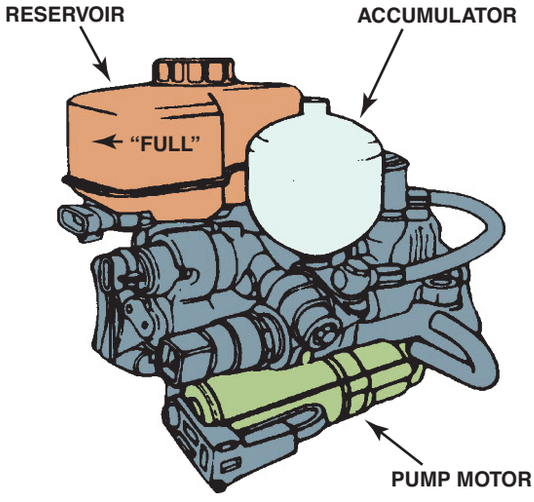

FIGURE 106–20 An integral ABS unit with a pump motor to provide power assist during all phases of braking and brake pressure during ABS stops.

A thick rubber diaphragm forms a barrier between the nitrogen gas and brake fluid. As fluid is pumped into the accumulator, it compresses the gas and stores pressure. When the brake pedal is depressed, pressure from the accumulator flows to the master cylinder to provide power assist.

A pair of pressure switches mounted in the accumulator circuit signals the ABS control module to energize the pump when pressure falls below a preset minimum, then to shut the pump off once pressure is built back up.

Should the pump fail (a warning lamp comes on when reserve pressure drops too low), there is usually enough reserve pressure in the accumulator for 10 to 20 power-assisted stops. After that, there is no power assist. The brakes still work, but with greatly increased effort.

On ABS systems that have a conventional master cylinder and vacuum booster for power assist, a small accumulator or pair of accumulators may be used as temporary storage reservoirs for brake fluid during the hold-release-reapply cycle. This type of accumulator typically uses a spring-loaded diaphragm rather than a nitrogen-charged chamber to store pressure.

ACCUMULATOR PRECAUTIONS A fully charged accumulator in an integral ABS system can store up to 2,700 PSI (19,000 kPa)

TECH TIP

Best to Keep Stock Tire Diameter

Vehicles equipped with antilock brakes are "programmed" to pulse the brakes at just the right rate for maximum braking effectiveness. A larger tire rotates at a slower speed and a smaller-than-normal tire rotates at a faster speed. Therefore, tire size affects the speed and rate of change in speed of the wheels as measured by the wheel speed sensors.

While changing tire size will not prevent ABS operation, it will cause less effective braking during hard braking with the ABS activated. Using the smaller spare tire can create such a difference in wheel speed compared with the other wheels that a false wheel speed sensor code may be set and an amber ABS warning lamp on the dash may light. However, most ABS systems will still function with the spare tire installed, but the braking performance will not be as effective. For best overall performance, always replace tires with the same size and type as specified by the vehicle manufacturer.

of pressure for power-assist braking and for reapplying the brakes during the hold-release-reapply cycle for antilock braking. This stored pressure represents a potential hazard for a brake technician who is servicing the brakes, so the accumulator should be depressurized prior to doing any type of brake service work by pumping the brake pedal 25 to 40 times with the ignition key off.

In nonintegral ABS systems where an accumulator is used to temporarily hold fluid during the release phase of the hold-release-reapply ABS cycle, the accumulator consists of a spring-loaded diaphragm. This type of accumulator does not have to be depressurized prior to performing brake service.

Always check service information for the exact procedures and precautions to follow when servicing any antilock braking system (ABS) service.

BRAKE PEDAL FEEDBACK

Many ABS units force brake fluid back into the master cylinder under pressure during an ABS stop. This pulsing brake fluid return causes the brake pedal to pulsate. Some vehicle manufacturers use the pulsation of the brake pedal to inform the driver that the wheels are tending toward lockup and that the ABS is pulsing the brakes.

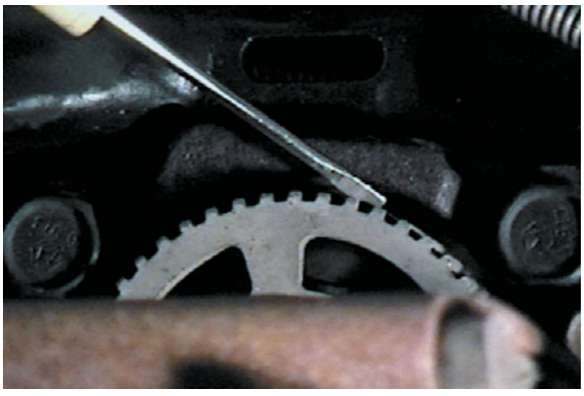
NOTE: A pulsating brake pedal may be normal only during an ABS stop. It is not normal for a vehicle with ABS to have a pulsating pedal during normal braking when the ABS system is not functioning. If the brake pedal is pulsating during a non-ABS stop, the brake drums or rotor may be warped.

Some manufacturers use an isolation valve that prevents brake pedal pulsation even during an ABS stop.

BRAKE PEDAL TRAVEL SWITCH (SENSOR)

PURPOSE AND FUNCTION Some ABS systems, such as the Teves Mark IV system, use a brake pedal travel switch (sensor). The purpose of the switch is to turn on the hydraulic pump when the brake pedal has been depressed to 40% of its travel. The pump runs and pumps brake fluid back into the master cylinder, which raises the brake pedal until the switch closes again, turning off the pump.

The brake pedal switch is an input for the electronic controller. When the brakes are applied, the electronic controller "gets ready" to act if ABS needs to "initialize" the starting sequence of events.

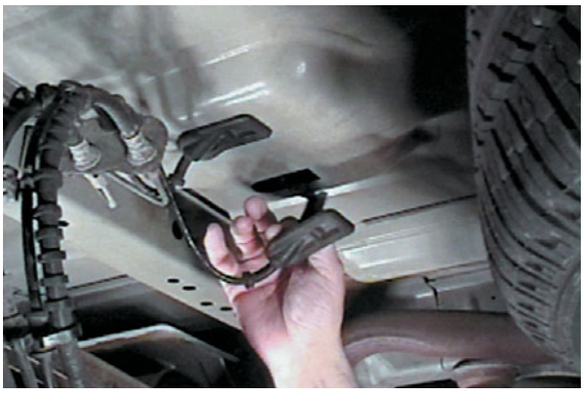


CAUTION: If the driver pumps the brakes during an ABS event, the controller will reset and reinitialization starts over again. This resetting process can disrupt normal ABS operation. The driver need only depress and hold the brake pedal down during a stop for best operation.

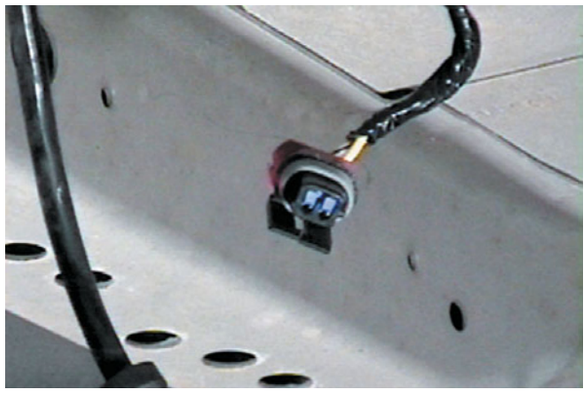
TIRE PRESSURE MONITORING SYSTEM (TPMS)

Tire pressure monitoring systems (TPMS) are required on all new vehicles. The type often used before the 2008 model year was an *indirect* system that used the wheel speed sensors. A tire that is underinflated will have a slightly smaller rolling radius than one that is properly inflated. This will create a difference in the wheel speed sensor reading if the difference in inflation pressure is 12 PSI or more. The ABS controller will then turn on the *low tire pressure* warning lamp to warn the driver that tires need attention. To help compensate for speed variation during cornering, an indirect tire pressure monitoring system checks the rotating speeds of diagonally opposed wheels. The system adds the speeds of the right front and left rear and then subtracts that value from the sum of the left front and right rear tires. If the total is less than or equal to a threshold value, no warning is given. However, if the total is greater than a predetermined value, the TPMS warning light is illuminated. The warning lamp will stay on until air is added to the tire and the ignition is cycled off and on.

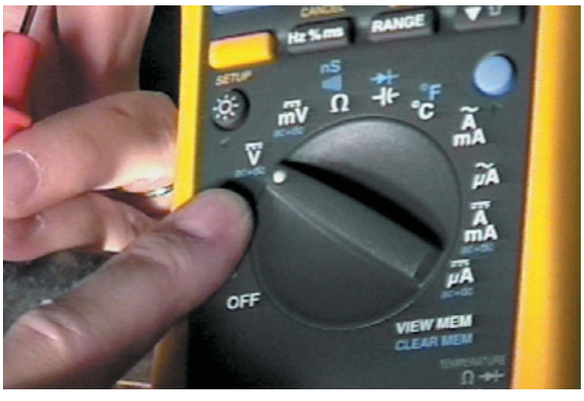
NOTE: This system cannot detect if all of the tires are underinflated, only if one tire is underinflated and this indirect system is not used in 2008 or newer vehicles because it does not directly measure tire inflation pressure as required by the Tread Act.



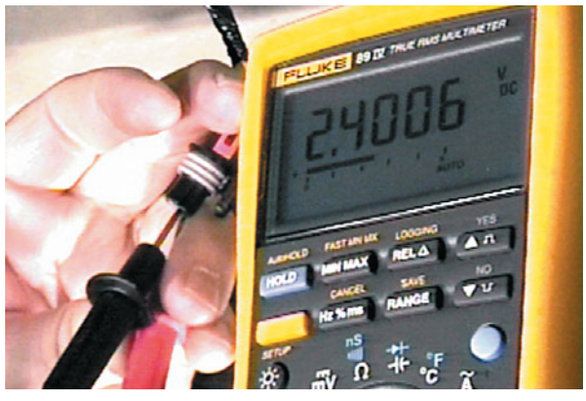
WHEEL SPEED SENSOR



1 A tone ring and a wheel speed sensor on the rear of a Dodge Caravan.



2 The wiring from the wheel speed sensor should be inspected for damage.



3 To test a wheel speed sensor, disconnect the sensor connector to gain access to the terminals.

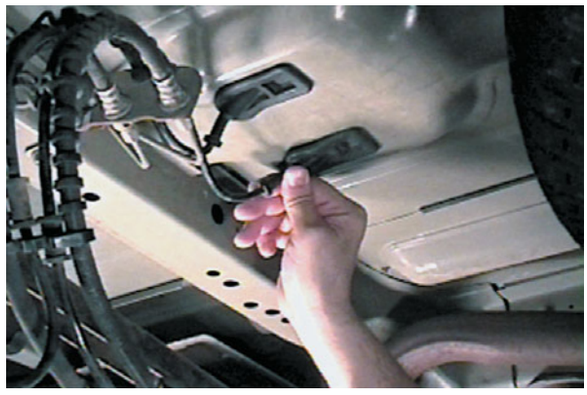
4 Pulling down the rubber seal reveals the connector.

5 The ABS controller (computer) on this vehicle supplies a 2.5-volt reference signal to the wheel speed sensors. Set the meter to read DC volts and test at the computer end of the connector for voltage.

6 The meter reads about 2.4 volts, indicating that the ABS controller is supplying the voltage to the wheel speed sensor.

7 Set meter to read Ohms. The test probes are touched to the terminals leading to the wheel speed sensor and the resistance is 1.1032 k ohms or 1,103.2 ohms.

8 With one lead connected to the sensor terminal and the other to a ground, The meter should (and does) read "OL," indicating that the wheel speed sensor and pigtail wiring is not shorted to ground.



9 To measure the output of the wheel speed sensor, select AC volts on the digital multimeter.

10 Rotate the wheel and tire assembly by hand while observing the AC voltage output on the digital multimeter.

11 A good wheel speed sensor should be able to produce at least 100 mV (0.1 V) when the wheel is spun by hand.

12 After testing, carefully reinstall the wiring connector into the body and under the rubber grommet.

REVIEW QUESTIONS

1. Describe how an antilock braking system (ABS) works.
2. List the three stages of ABS operation.
3. Explain how wheel speed sensors work.
4. Describe the difference between a three- and a four-channel system.

CHAPTER QUIZ

1. Technician A says that the ABS system may not result in shorter stopping distance compared to brakes without ABS. Technician B says that a pulsating brake pedal during normal braking is a characteristic feature of most ABS-equipped vehicles. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. The maximum traction between a tire and the road occurs when the tire is _____.
   a. Locked and skidding **c.** Slipping 10% to 20%
   b. Rotating freely **d.** Slipping 80% to 90%
3. Technician A says that ABS-equipped vehicles can stop quickly and without skidding on all road surfaces even if covered with ice. Technician B says that steering is possible during an ABS stop. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. A customer wanted the ABS checked because of tire chirp noise during hard braking. Technician A says that the speed sensors may be defective. Technician B says that tire chirp is normal during an ABS stop on dry pavement. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
5. Two technicians are discussing ABS wheel speed sensors. Technician A says that some ABS systems use a sensor located in the rear-axle pinion gear area. Technician B says that all ABS systems use a wheel speed sensor at each wheel. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
6. Technician A says that most ABS units are non-integral. Technician B says that the ABS is disabled (does not function) below about 5 mph (8 km/h). Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
7. Which type of antilock braking system (ABS) requires the use of four wheel speed sensors?
   a. one channel **c.** three channel
   b. two channel **d.** four channel
8. Technician A says that ABS brakes are designed to allow the front wheel to be steered during heavy braking. Technician B says that the ABS dash warning lamp is amber. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
9. The faster a wheel rotates, the higher the frequency produced by a wheel speed sensor.
   a. True **b.** False
10. Technician A says that some wheel speed sensors are enclosed in a wheel bearing assembly. Technician B says that some wheel speed sensors are exposed to possible damage from road debris. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 107

ABS DIAGNOSIS AND SERVICE

OBJECTIVES: **After studying Chapter 107, the reader will be able to:** • Prepare for Brakes (A5) ASE certification test content area "F" (Antilock Brake System Diagnosis and Repair). • Explain the purpose and function of the red brake warning lamp. • Describe normal ABS dash lamp operation. • Discuss visual inspection of the various types and brands of ABS. • Explain how to retrieve trouble codes. • List the methods used to clear trouble codes. • Explain the various methods for bleeding ABS systems. • Discuss methods and tools needed to diagnose and service an ABS-equipped vehicle.

KEY TERMS: Amber ABS warning lamp 1221 • Breakout box (BOB) 1221 • Red brake warning lamp (RBWL) 1221

ABS DIAGNOSTIC PROCEDURE

Customer concerns about a fault with the antilock braking system can be best handled by performing the following:

STEP 1 **Verify the customer concern.** This step is very important because often a problem with the base brakes is thought by the customer to be a fault with the antilock braking system. It is helpful for the owner to drive the vehicle with a service technician if the problem is not readily apparent.

STEP 2 **Perform a visual inspection.** If both the red and the amber brake warning lights are on, look for a fault in the hydraulic system, including leaks or faults at the following locations:

- Master cylinder
- Electrohydraulic control unit
- Flexible brake hoses
- Brake lines and fittings
- Calipers and/or wheel cylinders

STEP 3 **Check for stored diagnostic trouble codes (DTCs).** Use a scan tool or other necessary methods to retrieve diagnostic trouble codes. If found, follow the specified factory procedures to isolate and determine the cause.

STEP 4 **Complete the repair.** This step may involve replacing a hydraulic component. If so, then the hydraulic system should be bled using the factory-specified procedure. Clear all diagnostic trouble codes.

STEP 5 **Verify the repair.** Always test drive the vehicle under the same conditions that were needed to verify the problem to be sure that the cause has been corrected.

BRAKE WARNING LAMP OPERATION

The first step in the visual diagnosis of an antilock braking system problem is to check the status of the brake warning lamps. ● **SEE FIGURE 107–1.**

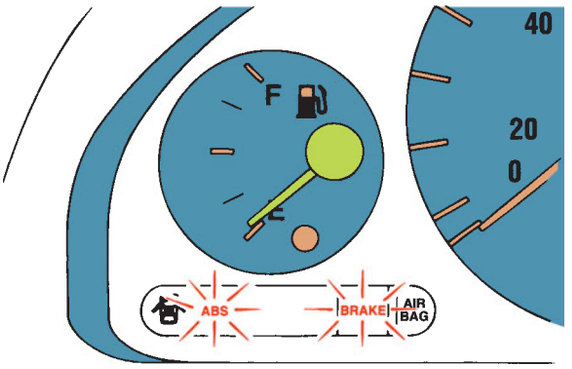


FIGURE 107–1 On most vehicles equipped with ABS, the amber ABS and red BRAKE warning lamp should come on as a bulb check when the ignition is first switched on.

FIGURE 107–2 A thorough visual inspection should include carefully inspecting around the electrohydraulic unit for signs of obvious problems or the installation of aftermarket devices such as alarm systems.

RED BRAKE WARNING LAMP

A **red brake warning lamp (RBWL)** warns of a possible dangerous failure in the base brakes, such as low brake fluid level or low pressure in half of the hydraulic system. The red brake warning lamp will also light if the parking brake is applied and may light due to an ABS failure, such as low brake pressure on an integral system.

AMBER ABS WARNING LAMP

The **amber ABS warning lamp** usually comes on after an engine start during the initialization or start-up self-test sequence. The exact time the amber lamp remains on after the ignition is turned on varies with the vehicle and the ABS design.

THOROUGH VISUAL INSPECTION

Many ABS-related problems can be diagnosed quickly if all the basics are carefully inspected. ● **SEE FIGURE 107–2.**

TECH TIP

Quick and Easy Wheel Speed Sensor Diagnosis

A fault in a wheel speed sensor (WSS) is a common ABS problem. A quick and easy test that works on most Bosch ABS systems (and perhaps others) involves the following steps:

STEP 1 Hoist the vehicle safely.

STEP 2 Turn the ignition on (engine off).

STEP 3 Spin a tire by hand as fast as possible.

STEP 4 The ABS amber warning light should come on, indicating that a speed was detected but not by all the wheel speed sensors.

STEP 5 Turn the ignition off to reset the ABS warning light.

STEP 6 Repeat the test on each of the remaining wheels.

If any wheel fails to turn on the ABS light, carefully inspect the wheel speed sensor for proper resistance and the tone ring and wiring. If the ABS light is on all the time and does not reset when the ignition is turned off, the problem is not caused by a wheel speed sensor.

FREQUENTLY ASKED QUESTION

What's That Noise and Vibration?

Many vehicle owners and service technicians have been disturbed to hear and feel an occasional groaning noise. It is usually heard and felt through the vehicle after first being started and driven. Because it occurs when first being driven in forward or reverse, many technicians have blamed the transmission or related driveline components. This is commonly heard on many ABS vehicles as part of a system check. As soon as the ABS controller senses speed from the wheel speed sensors after an ignition cycles on, the controller will run the pump either every time or whenever the accumulator pressure is below a certain level. This can occur while the vehicle is being backed out of a driveway or being driven forward because wheel sensors can only detect speed—not direction. Before serious and major repairs are attempted to "cure" a noise, make sure that it is not the normal ABS self-test activation sequence of events.

A thorough visual inspection should include the following items:

Brake fluid level	Check the condition and level of the brake fluid.
Brake fluid leaks	Check for cracks in flexible lines or other physical damage. Check for wetness at any fitting or steel brake line.
Fuses and fusible links	Check all ABS-related fuses.
Wiring and connections	Check all wiring, especially wheel speed sensor leads, for damage.
Wheel speed sensors	Check that the sensor ring teeth are not damaged. Clean debris from the sensor if possible.

NOTE: Most wheel speed sensors are magnetic and therefore can attract and hold metallic particles. Be sure to remove any metallic debris from around the magnetic wheel speed sensor.

Base brake components	All base brake components, such as disc brake calipers, drum brake wheel cylinders, and related components, must be in proper working condition.
Parking brake	Check that the parking brake is correctly adjusted and fully released.
Wheel bearings	All wheel bearings must be free of defects and adjusted properly.
Wheels and tires	Check for correct size, proper inflation, and legal tread depth.

TEST DRIVE AND VERIFY THE FAULT

A test drive is a very important diagnostic procedure. Many ABS systems and diagnostic trouble codes (DTCs) will not set unless the vehicle is moving. Often, the driver has noticed something like the self-test while driving and believed it to be a fault in the system.

NOTE: Some ABS units, such as the Delphi VI, will cause the brake pedal to move up and down slightly during cycling of the valves during the self-test. Each system has unique features. The service technician will have to learn to avoid attempting to repair a problem that is not a fault of the system.

Before driving, start the engine and observe the red and amber brake warning lamps. If the red brake warning lamp is on, the base brakes may not be functioning correctly. Do not drive the vehicle until the base brakes are restored to proper operation.

General Motors ABS Summary Guide

Type of ABS System	Code Clearing Procedure	Scan Tool* Code Retrieval
Teves IV Nonintegral	Yes	Yes
Bosch 2U Nonintegral	Yes	Yes
Delphi (Delco) VI	Yes	Yes
Bosch 2S	Yes	Yes
Delco Powermaster III	Yes	Yes
Kelsey-Hayes RWAL	Yes or disconnect the ABS fuse	Yes or flash codes
Kelsey-Hayes 4WAL	Yes	Yes

*A jumper key can be used for some systems. Not all scan tools can perform all functions.

Ford ABS Summary Guide

Type of ABS System	Code Clearing Procedure	Scan Tool* Code Retrieval
Teves IV Nonintegral	Drive the vehicle after the repair.	Yes
Kelsey-Hayes RABS	Drive the vehicle after the repair.	Flash codes
Teves 4WABS	Drive the vehicle after the repair.	Yes

*A jumper wire can be used on some systems. Not all scan tools can perform all functions.

NOTE: Some systems are diagnosed by "antilock" and "brake" warning lamps, vehicle symptoms, and the use of a breakout box.

Chrysler ABS Summary Guide

Type of ABS System	Code Clearing Procedure	Scan Tool* Code Retrieval
Bendix 6 Nonintegral	Yes or disconnect the battery	Yes
Bosch MMC	Yes	Yes
Bosch 2U Nonintegral	No codes available on this system	No codes available on this system
Teves Mark IV	Yes	Yes
Kelsey-Hayes RWAL	Disconnect the battery	Flash codes
Kelsey-Hayes 4WAL	Yes	Yes

*A jumper wire can be used on some systems. Not all scan tools can perform all functions.

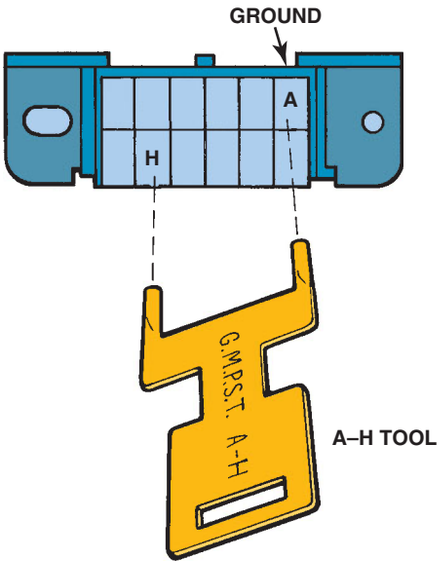

FIGURE 107–3 General Motors diagnostic connector on a pre-1996 vehicle. Flash codes are available by using a jumper wire to ground (terminal A) to terminal H.

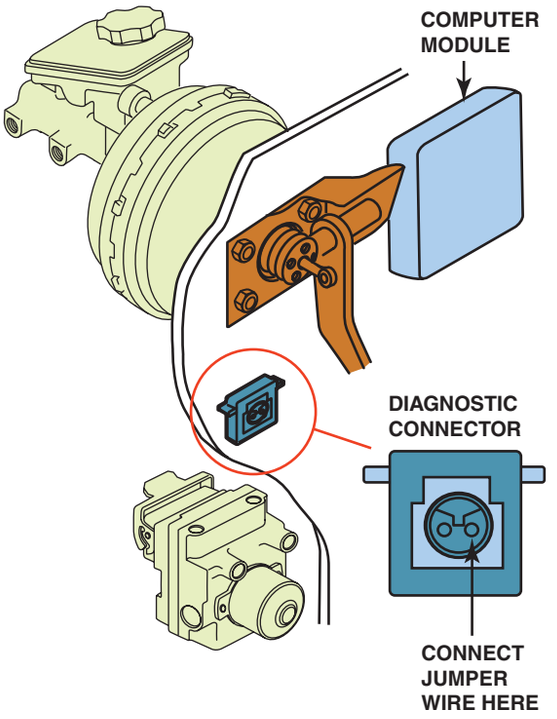

FIGURE 107–4 Connecting a jumper wire from the diagnostic connector to ground. The exact location of this diagnostic connector varies with the exact vehicle model and year.

RETRIEVING DIAGNOSTIC TROUBLE CODES

After performing a thorough visual inspection and after verifying the customer's complaint, retrieve any stored ABS-related diagnostic trouble codes (DTCs). The exact procedure varies with the type of ABS and with the make, model, and year of the vehicle.

Always consult factory service information for the vehicle being diagnosed. Some systems can only display flash codes (flashing ABS or brake lamp in sequence), whereas other systems can perform self-diagnosis and give all information to the technician through a scan tool.

NOTE: With some early antilock braking systems, the diagnostic trouble code is lost if the ignition is turned "off" before grounding the diagnostic connector.

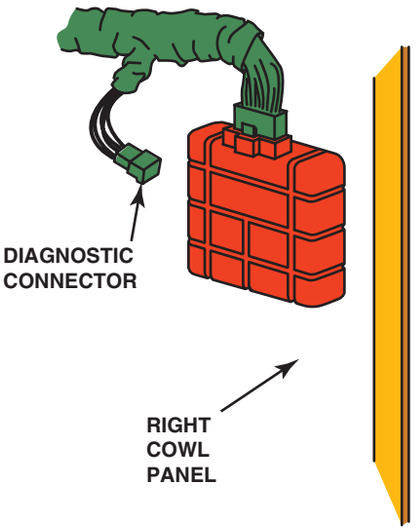

FIGURE 107–5 Chrysler diagnostic connector location varies with the model and year.

KELSEY-HAYES ANTILOCK (NONINTEGRAL)

The Kelsey-Hayes rear-wheel antilock uses two solenoids and valves to control the rear-wheel brakes. Kelsey-Hayes four-wheel antilock uses the computer to pulse the valves rather than turning them on or off. The pulsing is called pulse-width modulated (PWM) and the valve is called a PWM valve.

RETRIEVING DIAGNOSTIC TROUBLE CODES GM trucks' (RWAL) DTCs are retrieved by flash codes or scan data through the use of a scan tool or connect H to A at the data link connector (DLC). ● **SEE FIGURE 107–3.**

NOTE: Be sure that the brake warning lamp is on before trying to retrieve DTCs. If the lamp is not on, a false code 9 could be set.

Ford RABS DTCs are retrieved by jumper lead flash codes only. ● **SEE FIGURE 107–4.**

Dodge light truck DTCs are retrieved by ground diagnostic connections. ● **SEE FIGURE 107–5.**

NOTE: If the ignition is turned off, the failure code will be lost unless it is a hard code that will be present when the ignition is turned back on.

REAL WORLD FIX

RWAL Diagnosis

The owner of an S-10 pickup truck complained that the red brake warning lamp on the dash remained on even when the parking brake was released. The problem could be one of the following:

1. A serious hydraulic problem
2. Low brake fluid
3. A stuck or defective parking brake switch
4. If the brake lamp is dim, RWAL trouble is indicated.

The technician found that the brake lamp was on dimly, indicating that an antilock braking problem was detected. The first step in diagnosing an antilock braking problem with a dash lamp on is to check for stored trouble codes. The technician used a jumper between terminals A and H on the DLC (ALCL), and four flashes of the brake lamp indicated a code 4.

Checking a service manual, code 4 was found to be a grounded switch inside the hydraulic control unit. The hardest part about the repair was getting access to, and the replacement of, the defective (electrically grounded) switch. After bleeding the system and a thorough test drive, the lamp sequence and RWAL functioned correctly.

Kelsey-Hayes RWAL ABS Diagnostic Trouble Codes

Code	Description
2	Open isolation valve solenoid circuit or malfunctioning EBCM/VCM
3	Open dump valve solenoid circuit or malfunctioning EBCM/VCM
4	Grounded valve reset switch circuit
5	Excessive actuations of dump valve during antilock braking
6	Erratic speed signal
7	Shorted isolation valve circuit or faulty EBCM/VCM
8	Shorted dump valve circuit or faulty EBCM/VCM
9	Open or grounded circuit to vehicle speed sensor
10	Brake switch circuit
12 to 17	Computer malfunction

NOTE: A scan tool may or may not be able to retrieve or display diagnostic trouble codes. Check with the technical literature for the specific vehicle being scanned.

BOSCH 2 ABS (NONINTEGRAL)

The Bosch 2U/2S ABS is used on many domestic and imported brands of vehicles.

RETRIEVING DIAGNOSTIC TROUBLE CODES

On General Motors vehicles, DTCs can be retrieved by connecting A to H at the data link connector (DLC). On most Bosch 2 systems, a scan tool can and should be used if available to retrieve DTC.

REAL WORLD FIX

The Nervous Taurus

A customer complained that, sometimes during normal braking, the ABS would be activated just before coming to a stop. However, the ABS light would not come on. The service technician was able to duplicate the condition and there were no DTCs stored. Using a scan tool to monitor the wheel speed sensors, the technician discovered that the left front wheel speed was slightly different than the others. A thorough visual inspection revealed that the tone wheel (sensor ring) was cracked. This crack created a different wheel speed signal to the ABS controller than the other wheels and the controller activated the ABS as it would normally—that was why there were no DTCs.

Other things that could have caused this problem, which is often called "false modulation," include a bent wheel, mismatched tire sizes, or metal debris around the sensor.

Kelsey-Hayes 4WAL Diagnostic Trouble Codes

Code	Description
12	System normal (2WD applications)
13	System normal—brake applied (2WD applications)
14	System normal (4WD/AWD applications)
15	System normal—brake applied (4WD/AWD applications)
21 RF	Speed sensor circuit open
25 LF	
31 RR	
35 LR	
35	VSS circuit open
22 RF	Missing speed sensor signal
26 LF	
32 RR	
36 LR	
36	Missing VSS signal
23 RF	Erratic speed sensor signal
27 LF	
33 RR	
37 LR	
37	Erratic VSS signal
28	Simultaneous dropout of front-wheel speed sensors
29	Simultaneous dropout of all speed sensors
35	Vehicle speed sensor circuit open
36	Missing LR or vehicle speed sensor signal
37	Erratic LR or vehicle speed sensor signal
38	Wheel speed error
41 to 66	Malfunctioning BPMV/EHCU
67	Open motor circuit or shorted EBCM output
68	Locked motor or shorted motor circuit
71 to 74	Memory failure
81	Open or shorted brake switch circuit
86	Shorted ABS warning lamp
88	Shorted red brake warning lamp (RBWL)

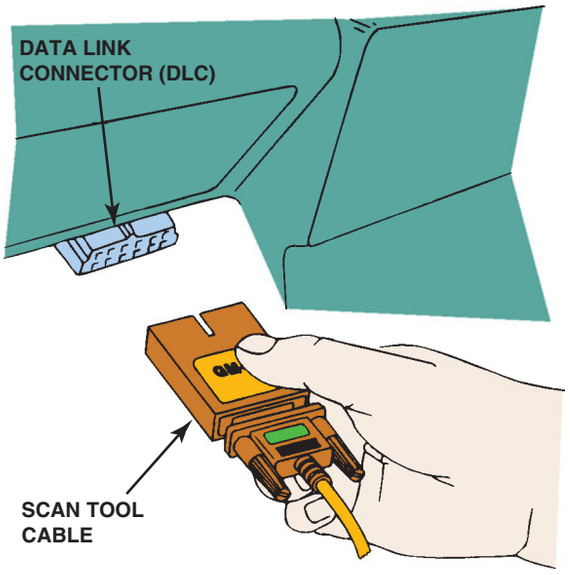

FIGURE 107–6 A scan tool is the recommended method to use to access General Motors Teves Mark IV systems.

Bosch 2U/2S ABS Diagnostic Trouble Codes

Code	Description
12	Diagnostic system operational
21 RF	Wheel speed sensor fault
25 LF	
32 RR	
35 LR	
35	Rear-axle speed sensor fault

36	Rear-axle toothed wheel frequency error
41 RF	Valve solenoid fault
45 LF	
55	Rear valve solenoid fault
61	Pump motor or motor relay fault
63	Solenoid valve relay fault
71	Electronic brake control module (EBCM) fault
72	Serial data link fault
74	Low voltage
75	Lateral acceleration sensor fault
76	Lateral acceleration sensor fault

TEVES MARK IV

The Teves Mark IV is a nonintegral (remote) ABS system.

RETRIEVING DIAGNOSTIC TROUBLE CODES Trouble codes are accessed only by a bidirectional scan tool connected to the data link connector (DLC). ● **SEE FIGURE 107–6.**

Teves Mark IV ABS Diagnostic Trouble Codes

Code	Description
21	RF speed sensor circuit open
22	RF speed sensor signal erratic
23	RF wheel speed is 0 mph
25	LF speed sensor circuit open
26	LF speed sensor signal erratic
27	LF wheel speed is 0 mph
31	RR speed sensor circuit open
32	RR speed sensor signal erratic
33	RR wheel speed is 0 mph
35	LR speed sensor circuit open
36	LR speed sensor signal erratic
37	LR wheel speed is 0 mph
41	RF inlet valve circuit
42	RF outlet valve circuit
43	RF speed sensor noisy
45	LF inlet valve circuit
46	LF outlet valve circuit
47	LF speed sensor noisy
51	RR inlet valve circuit
52	RR outlet valve circuit
53	RR speed sensor noisy
55	LR inlet valve circuit
56	LR outlet valve circuit
57	LR speed sensor noisy
61	Pump motor test fault
62	Pump motor fault in ABS stop
71	EBCM check sum error
72	TCC/antilock braking switch circuit
73	Fluid level switch circuit

CLEARING DIAGNOSTIC TROUBLE CODES A scan tool is required to clear DTCs on some vehicles. Driving the vehicle over 20 mph (32 km/h) will clear the codes on some vehicles. Disconnecting the battery will also clear the codes but will cause other "keep-alive" functions of the vehicle to be lost.

DELPHI (DELCO) ABS-VI (NONINTEGRAL)

The Delphi (Delco) ABS-VI is unique from all other antilock systems because it uses motor-driven ball screws and pistons for brake pressure to reduce, hold, and apply. ● **SEE FIGURE 107–7.**

RETRIEVING DIAGNOSTIC CODES The Delphi (Delco) VI antilock braking system has extensive self-diagnostic capability. Access to this vast amount of information requires the use of a scan tool designed to interface (work) with the Delphi VI system.

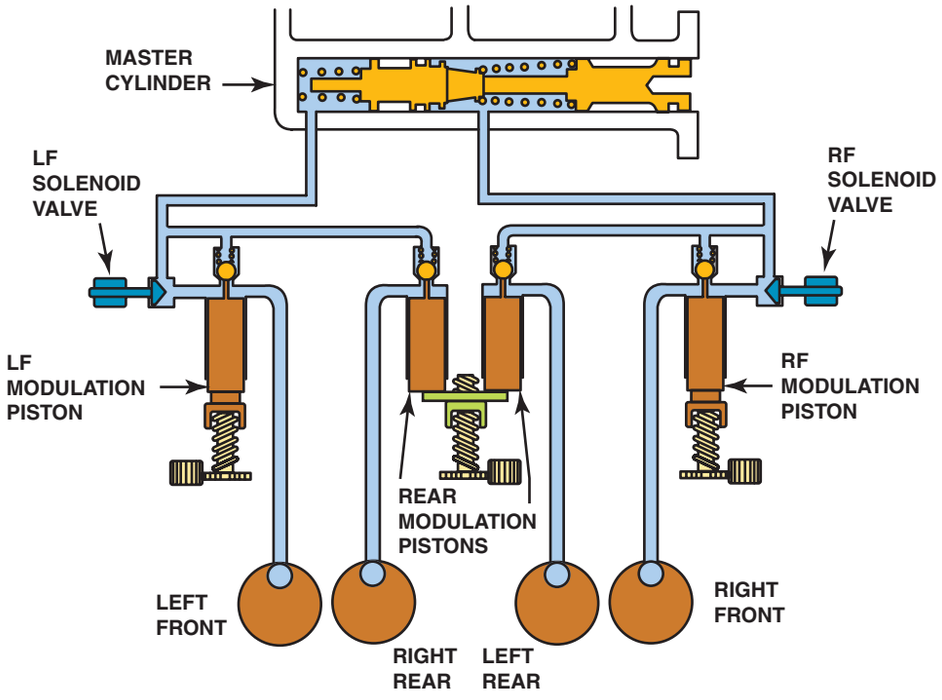

FIGURE 107–7 The Delphi (Delco) VI attaches to the side of the master cylinder and connects hydraulically through transfer tube assemblies.

Delphi (Delco) ABS-VI Diagnostic Trouble Codes

Code	Description
11	ABS lamp open or shorted to ground
13	ABS lamp circuit shorted to battery
14	Enable relay contacts open, fuse open
15	Enable relay contacts shorted to battery
16	Enable relay coil circuit open
17	Enable relay coil shorted to ground
18	Enable relay coil shorted to B1 or 0 ohms
21	Left-front wheel speed
23	Left-rear wheel speed
24	Right-rear wheel speed
25	Excessive left-front wheel acceleration
26	Excessive right-front wheel acceleration
27	Excessive left-rear wheel acceleration
28	Excessive right-rear wheel acceleration
31	Two-wheel speed sensors open
36	System voltage is low
37	System voltage is high
38	Left-front EMB will not hold motor
41	Right-front EMB will not hold motor
42	Rear-axle ESB will not hold motor
44	Left-front EMB will not release motor, gears frozen
45	Right-front EMB will not release motor, gears frozen
46	Rear-axle ESB will not release motor, gears frozen
47	Left-front nut failure (motor free-spins)
48	Right-front nut failure (motor free-spins)
51	Rear-axle nut failure (motor free-spins)
52	Left-front channel in release too long
53	Right-front channel in release too long

Code	Description
54	Rear axle in release too long
55	Motor driver interface (MDI) fault detected
56	Left-front motor circuit open
57	Left-front motor circuit shorted to ground
58	Left-front motor circuit shorted to battery
61	Right-front motor circuit open
62	Right-front motor circuit shorted to ground
63	Right-front motor circuit shorted to battery
64	Rear-axle motor circuit open
65	Rear-axle motor circuit shorted to ground
66	Rear-axle motor circuit shorted to battery
67	Left-front EMB release circuit open or shorted to ground
68	Left-front EMB release circuit shorted to battery or driver open
71	Right-front EMB release circuit open or shorted to ground
72	Right-front EMB release circuit shorted to battery or driver open
76	Left-front solenoid circuit open or shorted to battery
77	Left-front solenoid circuit shorted to ground or driver open
78	Right-front solenoid circuit open or shorted to battery
81	Right-front solenoid circuit shorted to battery or driver open
82	Calibration memory failure
86	ABS controller turned “on”; red brake telltale circuit fault
87	Red brake telltale circuit open

Code	Description
88	Red brake telltale circuit shorted to battery or driver open
91	Open brake switch contacts (deceleration detected)
92	Open brake switch contacts
93	Test 91 or 92 failed last or current ignition cycle
94	Brake switch contacts shorted
95	Brake switch circuit open
96	Brake lamps open, brake lamp ground open, center high-mounted stop lamp open during four-way flasher operations

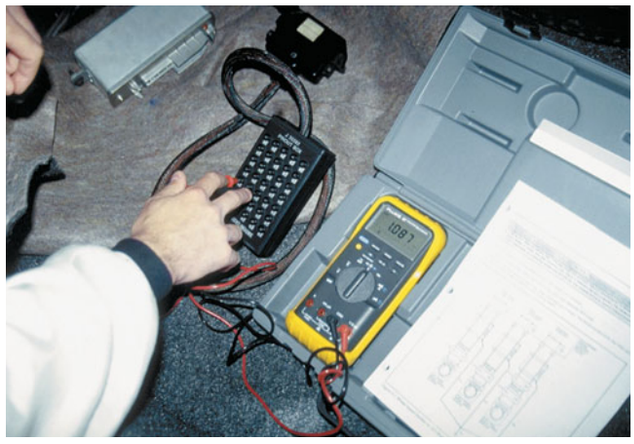

FIGURE 107–8 A breakout box is being used to diagnose an ABS problem. The controller (computer) is located in the trunk of this vehicle, and a digital multimeter is being used to measure resistance and voltage at various points in the system, following the service manual procedure.

REAL WORLD FIX

The Mystery ABS Amber Warning Light

The owner of an Acura Legend complained to a service technician that the ABS warning light would come on but only while driving down from a parking garage. When the driver turned off the ignition and restarted the engine, the ABS amber light was not on and did not come on again until the vehicle was again driven down the spiral parking garage ramp. The service technician used a scan tool and found that no DTCs had been stored.

NOTE: Some ABS systems will not retain a DTC unless the problem is currently present and the ABS amber warning light is on.

All of the brakes were in excellent condition, but the brake fluid level was down a little. After topping off the master cylinder with clean DOT 3 brake fluid, the vehicle was returned to the customer with the following information:

- The ABS amber warning light may have been triggered by the brake fluid level switch. While driving down the steep parking garage ramp, the brake fluid moved away from the fluid level sensor.

  NOTE: While the brake fluid level sensor normally would turn on the red brake warning light, in some systems it turns on the amber ABS light if the brake fluid falls below a certain level in the ABS reservoir.

- The difference in wheel speed between the outboard and the inboard wheels could have triggered a fault code for a wheel speed sensor during the drive down the spiral parking garage ramp.

TECH TIP

Sometimes It Pays to Look at the Entire Vehicle

There are often strange electrical problems that can occur including false DTCs or intermittent operation of electrical sensors, ABS, accessories, or gauges. Sometimes the root of these problems is due to rust and corrosion after a vehicle is involved in a flood. Here are some telltale signs that a vehicle may have been in a flood or in deep water.

- Mud, silt, or caked dust under the dash and inside the doors
- Corroded electrical connectors at the computer, fuse box, or ABS controller (computer)
- Visible water line in the doors or behind panels
- Rust in abnormal places such as seat springs or brackets behind the dash
- Moisture in lenses
- Musty smell and/or strong air freshener smell
- Powdery corrosion on aluminum parts such as intake manifold and inside the throttle bore
- Rust or moisture inside electrical switches or relays
- Areas that are normally dusty such as an ashtray or glove box are very clean

WHEEL SPEED SENSOR DIAGNOSIS

Wheel speed sensor (WSS) circuits are often the cause of many ABS problems. ● **SEE FIGURE 107–8.** These components may suffer from physical damage, buildup of metallic debris on the sensor tip, corrosion, poor electrical connections, and damaged wiring.

Test a WSS by measuring its output voltage and circuit continuity. A **breakout box (BOB)** cable connects to the ABS harness near the ABS module. All WSS resistance checks, including the wiring to the sensors, can be measured at one location. ● **SEE FIGURE 107–9.**

Follow the equipment manufacturer's instructions for connecting the breakout box to the vehicle, and for probing the appropriate pins on the breakout box.

RESISTANCE MEASUREMENT The resistors of most WSS range from 800 Ω to 1,400 Ω. Therefore, a reading of about 1,000 ohms or 1 KΩ would indicate proper sensor coil resistance. ● **SEE FIGURE 107–10.**

CHECKING FOR SHORT-TO-GROUND Connect either lead of the ohmmeter to one of the WSS wires and the other to a good,

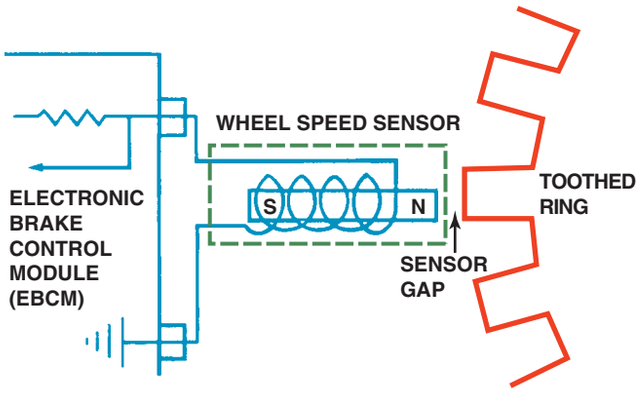

FIGURE 107–9 Typical wheel speed sensor. When a tooth on the sensor ring is close to the sensor, the strength of the magnetic field is stronger because the metal of the tooth conducts magnetic lines of force better than air. When the tooth moves away, the magnetic field strength is reduced. It is this changing magnetic field strength that produces the changing voltage. Frequency of the signal is determined by the speed of the rotating sensor.

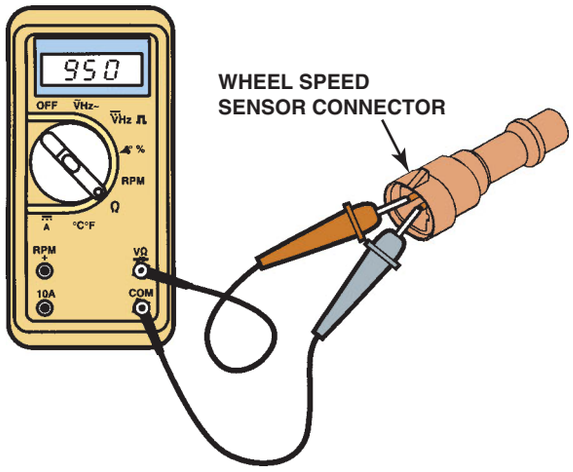

FIGURE 107–10 Measuring the resistance of a wheel speed sensor.

clean chassis ground. The resistance should be infinity (OL). If a low resistance reading is obtained, the sensor or sensor wiring is shorted-to-ground and must be replaced.

AC VOLTAGE CHECK Connect a digital meter to the WSS terminals or input to the controller in the breakout box and set the meter to read AC volts. Rotate the wheel by hand at a rate of one revolution per second. A good WSS should produce voltage of at least 0.1 volt (100 mV). A sensor voltage of lower than 0.1 volt (100 mV) may be caused by three things.

1. Excessive clearance between the sensor and the tone ring.
2. Buildup of debris on the end of the sensor. Most wheel speed sensors are magnetic and can attract metallic particles, which can affect the operation of the sensor.
3. Excessive resistance in the sensor or sensor wiring, which can also cause a weak signal to be produced by the WSS.

DC BIAS VOLTAGE Some ABS system apply a 2.5 volt DC voltage to the wheel speed sensors. This DC voltage is a called a bias voltage and is used by the ABS controller to detect fault in the sensor or sensor wiring such as an open circuit or a short to ground.

SCOPE TESTING Attach the scope leads to the sensor terminals or to the input connector on the breakout box. Rotate the wheel by hand or by using engine power with the vehicle safely hoisted with all four wheels off the ground.

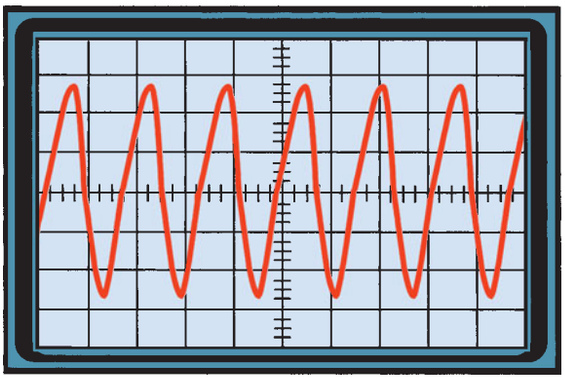

FIGURE 107–11 A scope can be used to check for proper operation of a wheel speed sensor.

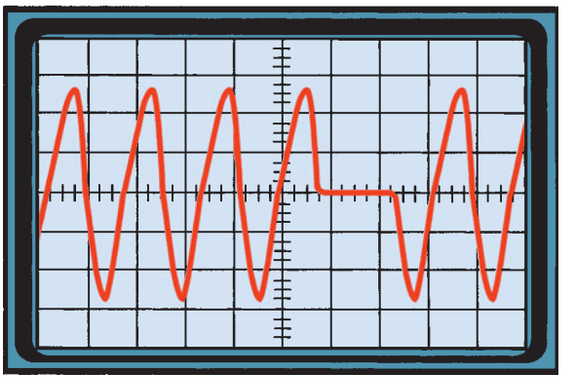

FIGURE 107–12 A broken tooth on a wheel speed sensor tone ring shows on the scope trace as a missing wave.

- A good WSS should produce an alternating current (AC) sine wave signal that increases in frequency and amplitude with increasing wheel speed. ● **SEE FIGURE 107–11.**
- Damaged or missing teeth on the tone ring will cause flat spots or gaps in the sine wave pattern. ● **SEE FIGURE 107–12.**
- A bent axle or hub will produce a wavelike pattern that fluctuates as the strength of the sensor signal changes with each revolution.

SCAN TOOL TESTING A scan tool can be used to check for the proper operation of the WSS. As an assistant drives the vehicle, connect the scan tool and monitor the speed of all of the sensors. All of the sensors should indicate the same speed. If a sensor shows a slower or faster speed than the others, carefully check the tone ring for damage such as a crack.

WHEEL SPEED SENSOR ADJUSTMENT

Some ABS applications use adjustable wheel speed sensors. Most sensors adjust by first loosening a set screw, then inserting a nonmagnetic brass or plastic feeler gauge between the tip of the sensor and a high point on the tone ring. ● **SEE FIGURE 107–13.**

Adjust the position of the sensor so there is a slight drag on the feeler gauge, and then tighten the setscrew to lock the sensor in place.

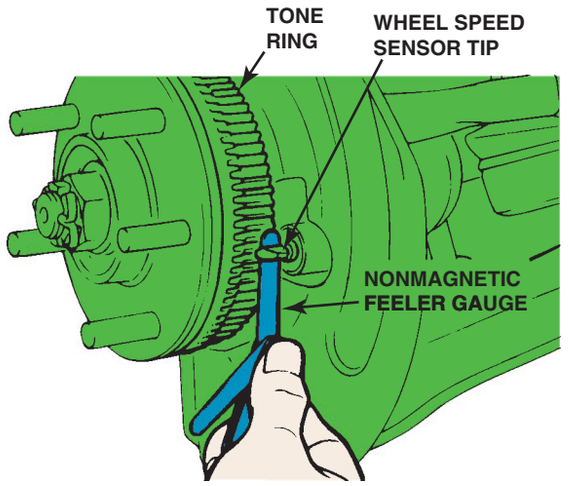

FIGURE 107–13 Use a nonmagnetic brass or plastic feeler gauge to check wheel speed sensor gap. A steel gauge would be attracted by the magnet in the sensor and would produce a drag on the gauge as it is moved between the sensor and the tone ring. This drag could be interpreted as a correct clearance reading.

When installing new sensors, look for a piece of paper or plastic on the tip end of the unit. This is more than a protective covering and must be left in place during installation. The paper or plastic is the precise thickness to guarantee a correct air gap between the tip of the sensor and the tone ring. Adjust the sensor so the tip just touches the tone ring and you can slip the paper or plastic out without ripping it. Tighten the setscrew and the air gap is properly set. ● **SEE FIGURE 107–14.**

Some manufacturers recommend leaving a paper covering in place. The motion of the tone ring removes it after the vehicle is driven for several miles.

DIGITAL WHEEL SPEED SENSOR DIAGNOSIS

Test a digital WSS by first checking that battery voltage is available at the sensor with the key on, engine off. If the sensor does not have 12 volts, then the problem is most likely in the ABS controller or the wiring between the controller and the sensor.

If there are 12 volts at the sensor, measure the signal voltage. The voltage should switch from about 0.8V to about 1.9V as the wheel is rotated by hand.

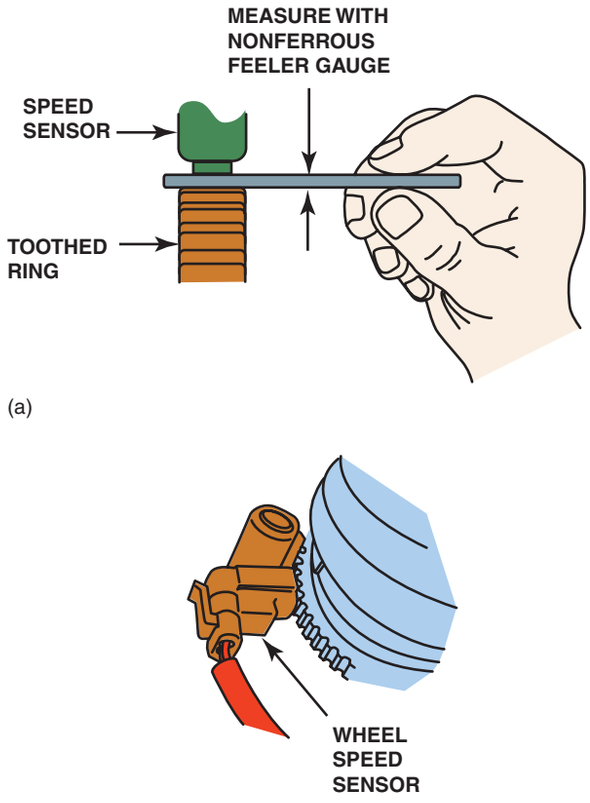

FIGURE 107–14 (a) Always use a nonferrous (brass or plastic) feeler (thickness) gauge when measuring the gap between the toothed ring and the wheel speed sensor. (b) Sometimes a sensor is equipped with a paper spacer that is the exact thickness of the spacing required between the toothed ring and the sensor. If equipped, the sensor is simply installed with the paper touching the toothed wheel. A typical gap ranges from 0.020 to 0.050 in. (0.5 to 1.3 mm).

TECH TIP

Space Saver Spare Tire May Trigger Wheel Speed Fault Code

If a vehicle has been using a small space saver-type spare tire, then the difference in outside diameter may trigger a wheel speed sensor diagnostic trouble code (DTC) and turn on the amber ABS warning lamp. Try to find out from the customer if they had driven on a spare tire before replacing a wheel speed sensor based on a stored DTC.

OBD-II ABS DIAGNOSIS

VEHICLES 1996 AND NEWER

Most vehicle built since 1996 use the OBD-II diagnostic connector to transmit ABS diagnostic trouble code information to a scan tool. A factory scan tool or an enhanced factory level scan tool will be needed to retrieve ABS diagnostic trouble codes (DTCs) and scan tool data such as wheel speed sensor information.

SCAN TOOLS NEEDED FOR ABS DIAGNOSIS

Scan tools are the workhorse for any diagnostic work on all vehicles. Scan tools can be divided into two basic groups:

1. **Factory scan tools.** These are the scan tools required by all dealers that sell and service the brand of vehicle. Examples of factory scan tools include the following:
   - **General Motors**—Tech 2. ● **See FIGURE 107–8.**
   - **Ford**—New Generation Star (NGS) and IDS (Integrated Diagnostic Software).
   - **Chrysler**—DRB III, Star Scan or wiTECH for CAN-equipped vehicles.
   - **Honda**—HDS or Master Tech
   - **Toyota**—Techstream

   All factory scan tools are designed to provide bidirectional capability, which allows the service technician the opportunity to operate components using the scan tool, thereby confirming that the component is able to work when commanded. Also, all factory scan tools are capable of displaying all factory parameters.

2. **Aftermarket scan tools.** These scan tools are designed to function on more than one brand of vehicle. Examples of aftermarket scan tools include the following:
   - *Snap-on* (various models including the MT2500 and Modis) *OTC* (various models including Pegasus, Genisys and Task Master)
   - *AutoEnginuity* and other programs that use a laptop or handheld computer for the display While many aftermarket scan tools can display most if not all of the parameters of the factory scan tool, there can be a difference when trying to troubleshoot some faults.

DIAGNOSTIC PROCEDURE To diagnosis a fault in the antilock brake system, check service information for the exact procedure to follow. These steps usually include:

STEP 1 Verify the fault. Make sure that the fault is in the antilock system and not caused by a fault in the base brakes.

STEP 2 Retrieve any stored diagnostic trouble codes. See ● **see CHART 107–1** for a list of generic antilock braking system related "C" codes.

STEP 3 Perform detailed tests to find the root cause.

STEP 4 Verfity the repair of the fault and clear any stored diagnostic trouble codes.

ABS SAFETY PRECAUTIONS

1. Avoid mounting the antenna for the transmitting device near the ABS control unit. Transmitting devices include cellular (cell) telephones, citizen-band radios, and so on.
2. Avoid mounting tires of different diameter than that of the original tires. Different size tires generate different wheel speed sensor frequencies, which may not be usable by the ABS controller.
3. Never open a bleeder valve or loosen a hydraulic line while the ABS is pressurized. The accumulator must be depressurized according to the manufacturer's recommended procedures.
4. If arc welding on a vehicle, disconnect all computers (electronic control modules) to avoid possible damage due to voltage spikes.
5. Do not pry against or hit the wheel speed sensor ring.

REVIEW QUESTIONS

1. Describe the proper operation of the red and amber brake warning lamps.
2. List the items that should be checked as part of a thorough visual inspection.
3. Explain how to retrieve a diagnostic trouble code from a General Motors vehicle equipped with Kelsey-Hayes RWAL ABS.
4. Describe how to use a breakout box to check for proper wheel speed sensor operation.

CHAPTER QUIZ

1. The red brake warning lamp is on and the amber ABS lamp is off. Technician A says that a fault is possible in the base brake system. Technician B says that the red brake warning lamp can be turned on by a low brake fluid level in the master cylinder. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. Two technicians are discussing magnetic-type wheel speed sensors. Technician A says that wheel speed sensors are magnetic. Technician B says that the toothed sensor ring is magnetic. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B

3. Technician A says that using the space-saving small spare tire may trigger an ABS amber warning lamp. Technician B says the use of the small spare tire may trigger the red brake warning lamp. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. Technician A says that, with some antilock braking systems, the diagnostic trouble code may be lost if the ignition is turned off before retrieving the code. Technician B says that some antilock braking systems require that a terminal be grounded to cause the amber ABS warning lamp to flash diagnostic trouble codes. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
5. Technician A says that a scan tool may be required to retrieve data and diagnostic trouble codes from some antilock braking systems. Technician B says that a jumper wire can be used to retrieve diagnostic trouble codes on some antilock braking systems. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
6. Technician A says that a breakout box is sometimes required to diagnose an antilock braking system. Technician B says that a breakout box requires the use of a digital multimeter. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
7. Technician A says that a noise or vibration may be sensed by the driver when the ABS performs a self test. Technician B says that the ABS fuse may have to be removed to erase some ABS diagnostic codes if a scan tool is not used. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
8. The ABS computer uses what signal characteristic from a wheel speed sensor?
   a. Voltage **c.** Resistance
   b. Frequency **d.** Electromagnetic
9. Most wheel speed sensors should measure how much resistance?
   a. 800 to 1,400 ohms **c.** 1 to 3 ohms
   b. 100 to 300 ohms **d.** 0.1 to 1 ohm
10. Technician A says that the ABS electrohydraulic unit can be bled using bleeder screws and the manual method. Technician B says that a scan tool is often required to bleed the ABS electrohydraulic unit. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 108 ELECTRONIC STABILITY CONTROL SYSTEMS

OBJECTIVES: **After studying Chapter 108, the reader will be able to:** • Prepare for Brakes (A5) ASE certification test content area "F" (Antilock Brake System Diagnosis and Repair). • Discuss how an electronic stability system works. • List the sensors needed for the ESC system. • Explain how the ESC system helps keep the vehicle under control. • Describe how a traction control system works. • List the steps in the diagnostic process for ESC and TC system faults.

KEY TERMS: Electronic brake control module (EBCM) 1234 • ESC 1232 • Hand-wheel position sensor 1234 • Lateral acceleration sensor 1235 • Oversteer 1233 • Positive slip 1236 • Sine with dwell (SWD) test 1233 • Steering wheel position sensor 1234 • Telltale light 1233 • Traction control (TC) 1236 • Understeer 1233 • Vehicle speed (VS) sensor 1234 • Yaw rate sensor 1235

THE NEED FOR ELECTRONIC STABILITY CONTROL

PURPOSE AND FUNCTION **Electronic stability control (ESC)** is a system designed to help drivers maintain control of their vehicles in situations where the vehicle is beginning to lose control. Keeping the vehicle on the road prevents run-off-road crashes, which are the conditions that lead to most single-vehicle accidents and rollovers.

SYSTEM REQUIREMENTS The ESC is defined as a system that has all of the following features:

1. Helps vehicle directional stability by applying and controlling individual wheel brakes to help bring the vehicle back to the intended direction.
2. Uses sensors to determine when the vehicle is not under control.

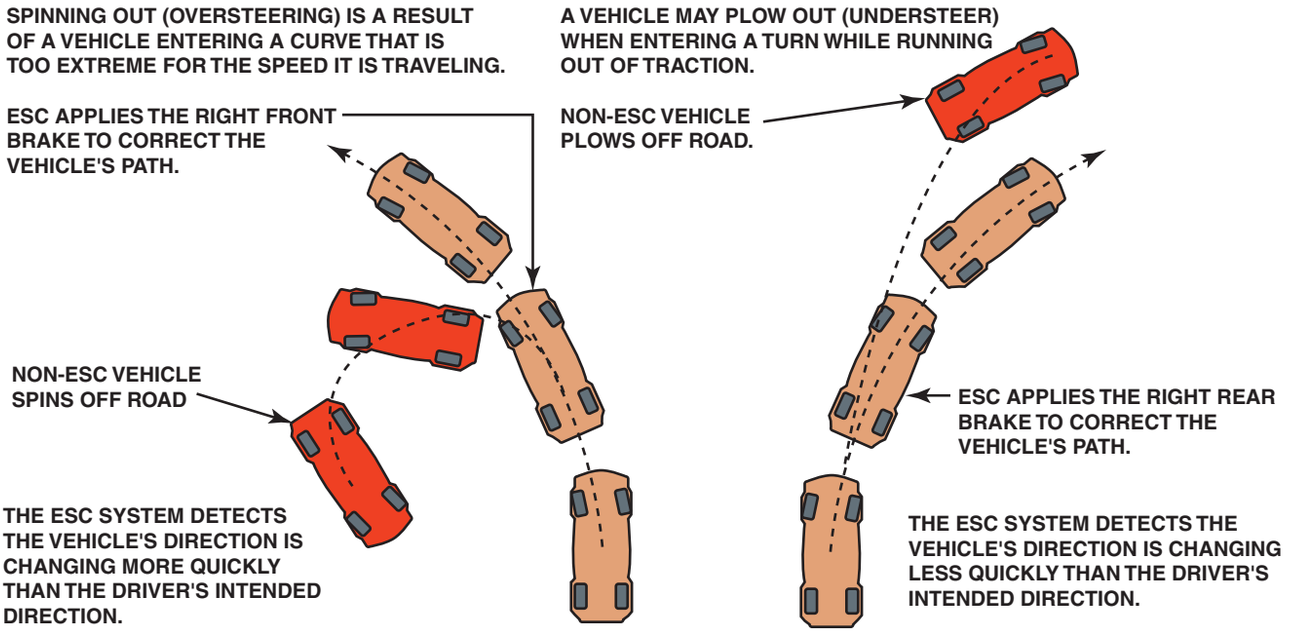

FIGURE 108–1 The electronic stability control (ESC) system applies individual wheel brakes to keep the vehicle under control of the driver.

3. Uses a steering wheel position sensor to determine the intended direction of the driver.
4. Operates at all vehicle speeds, except at low speeds where loss of control is unlikely.

The electronic stability control (ESC) system applies individual wheel brakes to bring the vehicle under control if either of the following conditions occur:

- **Oversteering**—In this condition, the rear of the vehicle tends to move outward or breaks loose, resulting in the vehicle spinning out of control. This condition is also called *loose.* If the condition is detected during a left turn, the ESC system would apply the right front brake to bring the vehicle back under control.
- **Understeering**—In this condition, the front of the vehicle tends to continue straight ahead when turning, a condition that is also called *plowing* or *tight.* If this condition is detected during a right turn, the ESC system would apply the right rear wheel brake to bring the vehicle back under control. ● **SEE FIGURE 108–1.**

NOTE: When the brakes are applied during these corrections, a thumping sound and vibration may be sensed.

TELLTALE LAMP. The ESC lamp, called a **telltale light,** is required to remain on for as long as a malfunction exists, whenever the ignition is in "On" ("Run") position. The ESC malfunction telltale will flash to indicate when the ESC system is operating to help restore vehicle stability.

ESC SWITCH. Some, but not all, vehicle manufacturers install a switch to temporarily disable or limit the ESC functions. This allows the driver to disengage ESC or limit the operation when the full ESC might not be needed such as:

- When a vehicle is stuck in sand/gravel
- When the vehicle is being operated on a racetrack for maximum performance

The electronic stability control system is turned back on when the ignition is turned off and then back on and is in the default position.

FEDERAL MOTOR VEHICLE SAFETY STANDARD (FMVSS) NO. 126

Federal Motor Vehicle Safety Standard (FMVSS) No. 126 (June 26, 2008), Electronic Stability Control Systems, requires that all passenger cars, multipurpose passenger vehicles, trucks, and buses that have a gross vehicle weight rating (GVWR) of 10,000 pounds (4,536 kg) or less to be equipped with an electronic stability control (ESC) system by September 1, 2011 (2012 model year vehicles).

The ESC system must meet the following requirements:

1. The ESC system must be able to apply all four brakes individually. This means that the vehicle must be equipped with a four-channel antilock braking system (ABS) which uses a wheel speed sensor at each wheel.
2. The ESC must be programmed to work during all phases of driving including acceleration, coasting, and deceleration (including braking).
3. The ESC system must work when the antilock brake system (ABS) or Traction Control is activated.

SINE WITH DWELL TEST

The standardized test used to determine if an electronic stability control system functions normally is called the **sine with dwell (SWD) test.** A vehicle is driven at 50 mph (80 km/h) on a curved course that looks like a sine wave or the letter "S" on its side. Then the vehicle is held in a straight-ahead position for 0.5 second (500 milliseconds) and before being steered back onto the curved section of the test. ● **SEE FIGURE 108–2.**

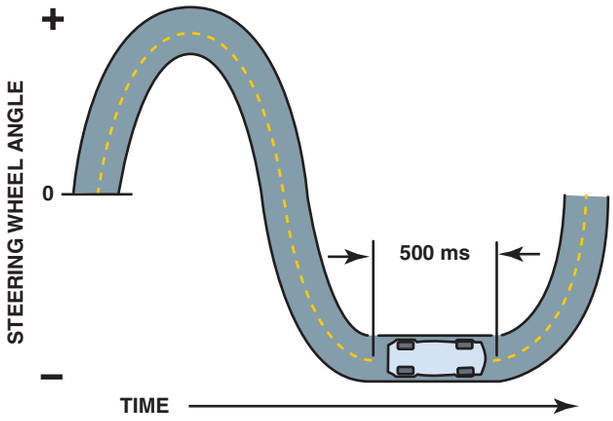

FIGURE 108–2 The sine with dwell test is designed to test the electronic stability control (ESC) system to determine if the system can keep the vehicle under control.

? **FREQUENTLY ASKED QUESTION**

Can a Vehicle with a Modified Suspension Pass the Test?

Yes, if the system is properly engineered. To be sure, check with the company offering a suspension kit to verify that the vehicle will still be able to pass the sine with dwell (SWD) test. This ensures that any changes are within the range where the ESC system can control the vehicle during emergency maneuvers. ● **SEE FIGURE 108–3.**

The quick changes involved in this test are designed to upset the chassis of the vehicle and cause the electronic stability control system to act to keep the vehicle under control during the entire test.

NAMES OF VARIOUS ESC SYSTEMS

Stability control systems are offered under the following names:

- **Acura:** Vehicle Stability Assist (VSA)
- **Audi:** Electronic Stabilization Program (ESP)
- **BMW:** Dynamic Stability Control (DSC), including Dynamic Traction Control
- **Chrysler:** Electronic Stability Program (ESP)
- **Dodge:** Electronic Stability Program (ESP)
- **Ferrari:** Controllo Stabilita (CST)
- **Ford:** AdvanceTrac and Interactive Vehicle Dynamics (IVD)
- **General Motors:** StabiliTrak (except Corvette—Active Handling)
- **Hyundai:** Electronic Stability Program (ESP)
- **Honda:** Electronic Stability Control (ESC), Vehicle Stability Assist (VSA), and Electronic Stability Program (ESP)
- **Infiniti:** Vehicle Dynamic Control (VDC)
- **Jaguar:** Dynamic Stability Control (DSC)
- **Jeep:** Electronic Stability Program (ESP)
- **Kia:** Electronic Stability Program (ESP)
- **Land Rover:** Dynamic Stability Control (DSC)

FIGURE 108–3 Using a simulator is the most cost-effective way for vehicle and aftermarket suspension manufacturers to check that the vehicle is able to perform within the FMVSS No. 126 standard for vehicle stability.

- **Lexus:** Vehicle Dynamics Integrated Management (VDIM) with Vehicle Stability Control (VSC) and Traction Control (TRAC) systems
- **Lincoln:** Advance Trak
- **Maserati:** Maserati Stability Program (MSP)
- **Mazda:** Dynamic Stability Control (DSC)
- **Mercedes:** Electronic Stability Program (ESP)
- **Mercury:** AdvanceTrak
- **Mini Cooper:** Dynamic Stability Control (DSC)
- **Mitsubishi:** Active Skid and Traction Control MULTIMODE
- **Nissan:** Vehicle Dynamic Control (VDC)
- **Porsche:** Porsche Stability Management (PSM)
- **Rover:** Dynamic Stability Control (DSC)
- **Saab:** Electronic Stability Program (ESP)
- **Saturn:** StabiliTrak
- **Subaru:** Vehicle Dynamics Control Systems (VDCS)
- **Suzuki:** Electronic Stability Program (ESP)
- **Toyota:** Vehicle Dynamics Integrated Management (VDIM) with Vehicle Stability Control (VSC)
- **Volvo:** Dynamic Stability and Traction Control (DSTC)
- **VW:** Electronic Stability Program (ESP)

ESC SENSORS

STEERING WHEEL POSITION SENSOR

Depending on the vehicle, the **steering wheel position sensor** may also be called a **hand-wheel position sensor.** The function of this sensor is to provide the computer with signals related to steering wheel position, speed and direction. ● **SEE FIGURES 108–4 AND 108–5.**

VEHICLE SPEED SENSOR

The **vehicle speed (VS) sensor** is used by the **Electronic Brake Control Module (EBCM)** to help control the suspension system. The vehicle speed sensor is a magnetic sensor and generates an analog signal whose frequency increases as the speed increases. ● **SEE FIGURE 108–6.**

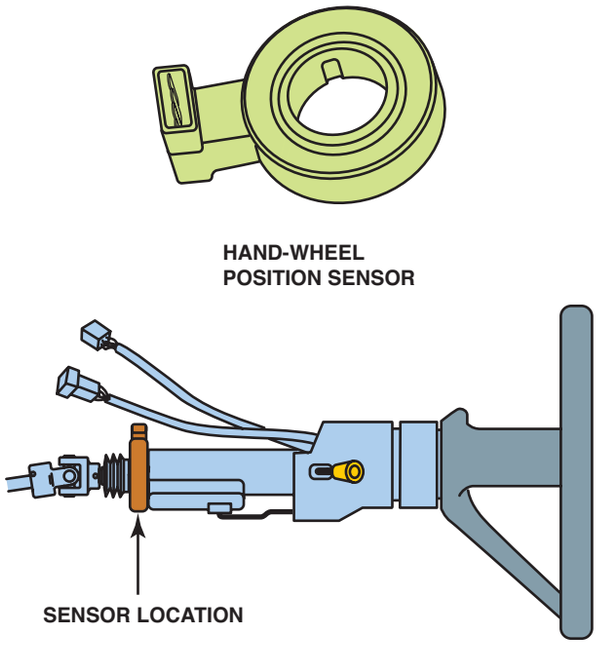

FIGURE 108–4 The hand-wheel position sensor is usually located at the base of the steering column.

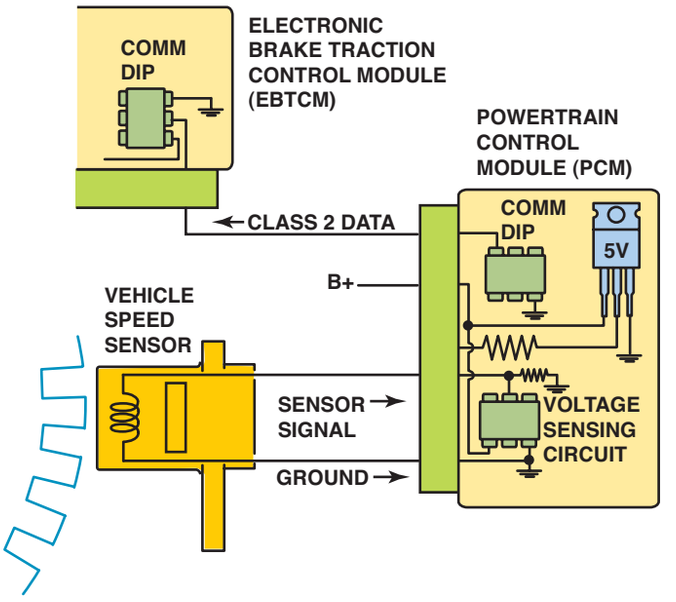

FIGURE 108–6 The VS sensor information is transmitted to the EBCM by Class 2 serial data.

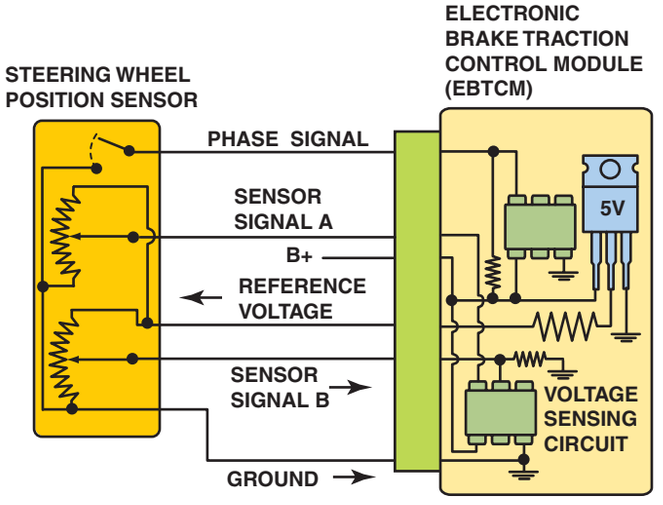

FIGURE 108–5 Hand-wheel (steering wheel) position sensor schematic.

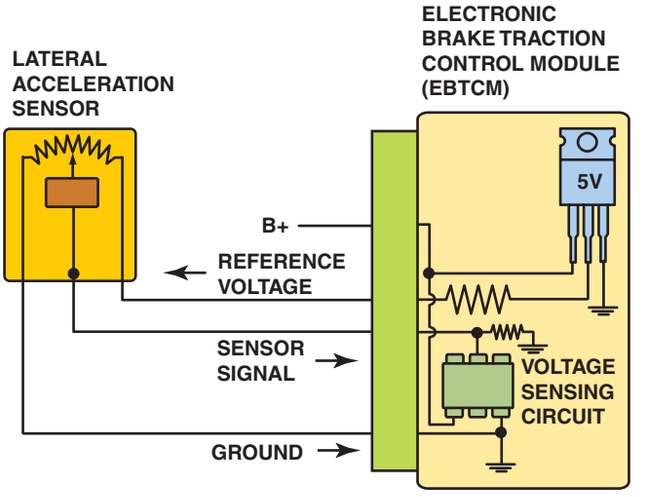

FIGURE 108–7 A schematic showing the lateral acceleration sensor and EBCM.

LATERAL ACCELERATION SENSOR

The function of the **lateral acceleration sensor** is to provide the suspension control module with feedback regarding vehicle cornering forces. This type of sensor is also called a G-sensor, with the letter "G" representing the force of gravity. For example, when a vehicle enters a turn, the sensor provides information as to how hard the vehicle is cornering. This information is processed by the suspension control module to provide appropriate damping on the inboard and outboard dampers during cornering events.

This sensor can be either a stand-alone unit or combined with the yaw rate sensor.

Typically, the sensor is mounted in the passenger compartment:

- under a front seat
- in the center console
- on the package shelf

● **SEE FIGURE 108–7.**

TECH TIP

Quick and Easy Lateral Acceleration Sensor Test

Most factory scan tools will display the value of sensors, including the lateral acceleration sensor. However, the sensor value will read zero unless the vehicle is cornering. A quick and easy test of the sensor is to simply unbolt the sensor and rotate it 90 degrees with the key on engine off. ● **SEE FIGURE 108–8.** Now the sensor is measuring the force of gravity and should display 1.0 G on the scan tool. If the sensor does not read close to 1.0 G or reads zero all of the time, the sensor or the wiring is defective.

YAW RATE SENSOR

The **yaw rate sensor** provides information to the suspension control module and the EBCM. This information is used to determine how far the vehicle has deviated from the driver's intended direction.

FIGURE 108–8 The lateral accelerometer sensor (G-sensor) is usually located under the center console.

This sensor can be either a stand-alone unit or combined with the lateral acceleration sensor. Typically, the sensor is mounted in the passenger compartment under the front seat, in the center console, or on the rear package shelf.

This sensor does set DTC codes. These codes can be found in service information. ● **SEE FIGURE 108–9.**

TRACTION CONTROL

PURPOSE AND FUNCTION

Traction control (TC) can be separate or used as part of the electronic stability control (ESC) system. Traction control allows an ABS system to control wheel spin during acceleration. When tires lose traction during acceleration, it is called **positive slip.**

Low-speed traction control uses the braking system to limit positive slip up to a vehicle speed of about 30 mph (48 km/h). Traction control is usually a part of the electronic stability control system. ● **SEE FIGURE 108–10.**

Traction control uses the same wheel speed sensors as ABS, but requires additional programming in the control module so the system monitors wheel speed continuously, not just when braking. Traction control also requires:

- Additional solenoids in the hydraulic modulator so the brake circuits to the drive wheels can be isolated from the non-drive wheels when braking is needed to control wheel spin.
- A pump and accumulator is used to generate and store pressure for traction control braking. If a wheel speed sensor detects wheel spin in one of the drive wheels during acceleration, the control module energizes a solenoid that allows stored fluid pressure from the accumulator to apply the brakes on the wheel that is spinning. This slows the wheel that is spinning and redirects engine torque through the differential to the opposite drive wheel to restore traction.

Traction control works just as well on front-wheel-drive vehicles as it does on rear-wheel-drive vehicles.

SYSTEM COMPONENTS

The main controller for the traction can include one of the following, depending on make, model, and year of vehicle:

1. The body control module (BCM)
2. The powertrain control module (PCM)
3. The antilock brake system (ABS) controller

The controller uses inputs from several sensors to determine if a loss of traction is occurring. The input signals used for traction control include:

- **Throttle position (TP) sensor** —This indicates the position of the throttle, which is the driver command for power.
- **Wheel speed sensor (WSS)** —The controller monitors all four wheel speed sensors. If one wheel is rotating faster than the other, this indicates that the tire is slipping or has lost traction.
- **Engine speed (RPM)** —This information is supplied from the engine controller powertrain control module (PCM) and indicates the speed of the engine.
- **Transmission range switch** —Determines which gear the driver has selected so that the PCM can take corrective action.

TRACTION CONTROL OPERATION

The outputs of the traction control system can include one or more of the following:

- Retard ignition timing to reduce engine torque.
- Decrease the fuel injector pulse-width to reduce fuel delivery to the cylinder to reduce engine torque.
- Reduce the amount of intake air if the engine is equipped with an electronic throttle control (ETC). Reduced airflow will reduce engine torque.
- Upshift the automatic transmission/transaxle. If the transmission is shifted into a higher gear, the torque applied to the drive wheels is reduced.

Most traction control systems are capable of reducing positive wheel slip at all vehicle speeds. Most speed traction control systems use accelerator reduction and engine power reduction to limit slip before applying the brakes to the wheel that is spinning. This action helps reduce the possibility of overheating the brakes if the vehicle were being driven on an icy or snow-covered road. ● **SEE FIGURE 108–11.**

Therefore the controller usually performs actions to restore traction in the following order:

1. Reduces engine torque to the drive wheels.
2. Applying individual wheel brakes to slow or stop the wheel from spinning. The ABS controller supplies to the wheel brake only the pressure that is required to prevent tire slipping during acceleration. The amount of pressure varies according to the condition of the road surface and the amount of engine power being delivered to the drive wheels. A program inside the controller will disable traction control if brake system overheating is likely to occur.
3. Lights a low traction or traction control warning light on the dash.
   ● **SEE FIGURE 108–12.**

TRACTION ACTIVE LAMP

On most applications, a "TRAC CNTL" indicator light or "TRACTION CONTROL ACTIVE" message flashes on the instrumentation when the system is engaging traction control. This helps alert the driver that the wheels are losing traction.

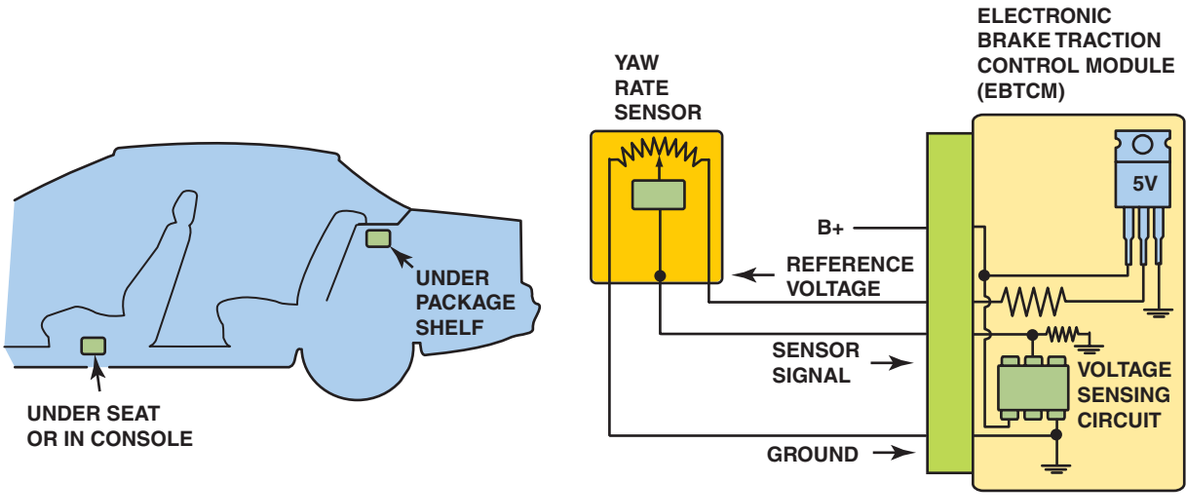

FIGURE 108–9 Yaw rate sensor showing the typical locations and schematic.

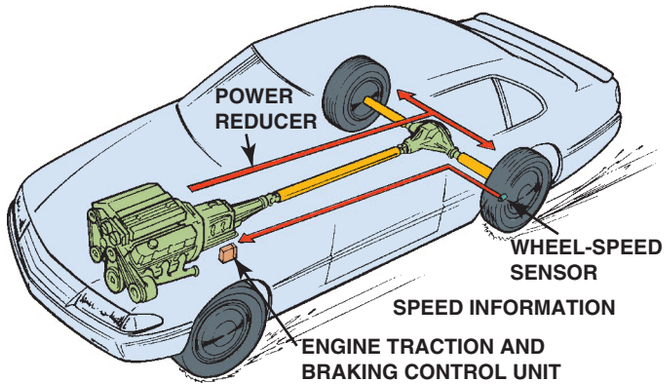

FIGURE 108–10 Typical traction control system that uses wheel speed sensor information and the engine controller (PCM) to apply the brakes at lower speeds and also reduce engine power applied to the drive wheels.

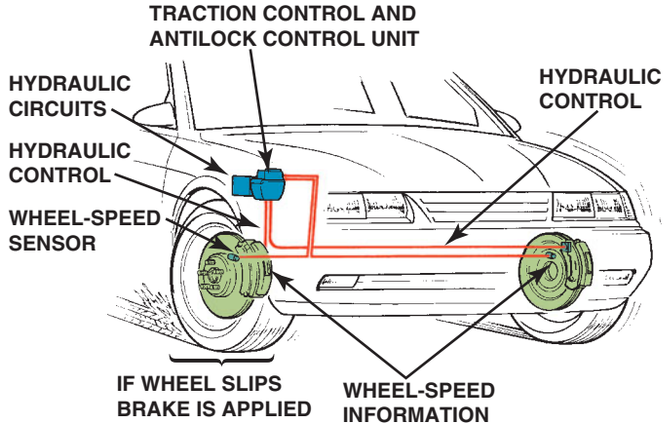

FIGURE 108–11 Wheel speed sensor information is used to monitor if a drive wheel is starting to spin.

In most applications, the message does not mean there is anything wrong with the system—unless the ABS warning lamp also comes on, or the traction control light remains on continuously.

TRACTION DEACTIVATION SWITCH Many vehicles with traction control have a dash-mounted switch that allows the driver to deactivate the system when desired (as when driving in deep snow). An indicator light shows when the system is on or off, and may

FIGURE 108–12 A traction control or low traction light on the dash is confusing to many drivers. When the lamp is on or flashing, it indicates that a low traction condition has been determined and the traction control system is working to restore traction. A flashing traction dash light does not indicate a fault.

FREQUENTLY ASKED QUESTION

Does Traction Control Engage Additional Drive Wheels?

When the term *traction control* is used, many people think of four-wheel-drive or all-wheel-drive vehicles and powertrains. Instead of sending engine torque to other drive wheels, it is the purpose and function of the traction control system to prevent the drive wheel(s) from slipping during acceleration. A slipping tire has less traction than a nonslipping tire—therefore, if the tire can be kept from slipping (spinning), more traction will be available to propel the vehicle. Traction control works with the engine computer to reduce torque delivery from the engine, as well as the controller to apply the brakes to the spinning wheel if necessary to regain traction.

FIGURE 108–13 The use of a factory scan tool is often needed to diagnose the ESC system.

also signal the driver when the traction control system is actively engaged during acceleration.

ESC/TC DIAGNOSIS

Because the electronic stability control (ESC) and traction control (TC) systems use some of the same sensors and controllers, the diagnosis for them is about the same. To diagnose faults with either system, follow the recommended procedures found in service information. The usual procedure involves the following steps.

STEP 1 **Verify the customer concern (complaint).** This step includes trying to duplicate what the customer or driver is concerned about the system. If the traction control or ESC light is flashing, this indicates that it is trying to bring the vehicle under control. This may be normal operation if the following conditions exist:
- Icy or slippery road conditions
- Worn tires that lack traction

STEP 2 **Perform a thorough visual inspection** including:
- Check that all tires are the same size and tread depth.

NOTE: Using a spare tire on the drive wheel could cause the traction control and/or ESC amber warning light to flash because the controller is seeing that the smaller tire is rotating faster than the other side.

STEP 3 **Check service information** for the specified procedure to follow to retrieve diagnostic trouble codes as well as any related technical service bulletins (TSBs). Most vehicles require the use of a factory-brand scan tool. **SEE FIGURE 108–13.**

STEP 4 **Follow the troubleshooting procedure** as specified to fix the root cause of the problem. This means following the instructions displayed on the scan tool or service information. The steps usually include all or many of the following:
- Brake fluid level
- Wheel speed sensor resistance
- Fault with the base brake system, such as air in the lines that could prevent the traction control controller from applying the wheel brakes

STEP 5 **Repair the fault.**

STEP 6 **Road test the vehicle** under the same conditions that were performed to verify the fault to be sure that the fault has been repaired.

REVIEW QUESTIONS

1. What is the difference between oversteering and understeering?
2. What is the "sine with dwell" test?
3. What are some of the other names used to identify an electronic stability control (ESC) system?
4. What sensors are used in the electronic stability control system?
5. What action does the traction control system perform to help the drive wheels maintain traction during acceleration?
6. What is the typical diagnostic procedure to follow when troubleshooting a fault with the electronic stability control or traction control system?

CHAPTER QUIZ

1. The electronic stability control (ESC) system requires that the vehicle be equipped with what type of brake system?
   a. Four-wheel disc brakes
   b. Four-channel ABS
   c. Three-channel ABS
   d. Front disc with rear drum brakes
2. Which Federal Motor Safety Standard requires electronic stability control to be on all vehicles by 2011?
   a. 126
   b. 113
   c. 109
   d. 101
3. What is the name of the standard test that is performed to verify ESC operation?
   a. ESC plus
   b. Vehicle stability enhancement test
   c. Sine with dwell
   d. Anti-skid test
4. What other name is used to describe an electronic stability control (ESC) system?
   a. Vehicle Stability Assist (VSA)
   b. Electronic Stability Program (ESP)
   c. Vehicle Dynamic Control (VDC)
   d. Any of the above

5. Which sensor is used by the ESC controller to determine the driver's intended direction?
   a. Yaw sensor
   b. Steering wheel (hand-wheel) position sensor
   c. Vehicle speed (VS) sensor
   d. Lateral acceleration sensor

6. A diagnostic trouble code (DTC) has been set for a fault with lateral acceleration sensor or circuit. What test could be performed to check if the sensor is working?
   a. Unplug it and see if the scan tool reads 1.0G
   b. Disconnect the sensor and hold it sideways to see if a scan tool reads 0.0G
   c. Disconnect the sensor and hold it sideways to see if a scan tool reads 1.0G
   d. Drive the vehicle in a circle to see if the scan tool reads 0.0G

7. A lateral acceleration sensor is usually located where in the vehicle?
   a. Under the front seat
   b. In the center console
   c. On the package shelf
   d. Any of the above locations

8. If a vehicle tends to continue straight ahead while cornering, this condition is called _____.
   a. Understeer
   b. Plowing
   c. Tight
   d. All of the above

9. Traction control uses the antilock braking system and other devices to limit _____ of the drive wheels during acceleration.
   a. Positive slip
   b. Negative slip

10. A traction control system can often control all *except* _____.
    a. Limit engine torque delivered to the drive wheel
    b. Engage four-wheel drive
    c. Upshift the automatic transmission
    d. Apply the wheel brake to the wheel that is losing traction

chapter 109 TIRES AND WHEELS

OBJECTIVES: After studying Chapter 109, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "E" (Wheel and Tire Diagnosis and Repair). • Discuss how tires are constructed. • Describe how Run Flat tires work. • Discuss tire sizes and ratings. • Describe tire purchasing considerations and maintenance. • Explain the construction and sizing of steel and alloy wheels and attaching hardware. • Demonstrate the correct lug nut tightening procedure and torque.

KEY TERMS: Aspect ratio 1243 • Back spacing 1255 • Bead 1241 • Belt 1212 • Body ply 1241 • Bolt circle 1256 • Carcass ply 1241 • Center section 1254 • Conicity 1247 • DOT tire code 1251 • E-metric tire 1253 • Green tire 1242 • High-flotation tires 1245 • Hydroplaning 1240 • Inner liner 1242 • JWL 1256 • Load index 1246 • LRR 1253 • Lug nuts 1257 • Major splice 1242 • Offset 1254 • Ply steer 1247 • Rim width 1249 • Run-flat tires 1252 • Schrader valve 1257 • Sidewall 1241 • Speed ratings 1246 • Spider 1254 • TPC 1253 • Tread 1240 • Unsprung weight 1257 • UTQGS 1250 • Wear bars 1240

INTRODUCTION TO TIRES

PURPOSE OF TIRES The friction (traction) between the tire and the road determines the handling characteristics of any vehicle. Think about this statement for a second. The compounding, construction, and condition of tires are some of the most important aspects of the steering, suspension, alignment, and braking systems of any vehicle. A vehicle that handles poorly or that pulls, darts, jumps, or steers "funny" may be suffering from defective or worn tires. Understanding the construction of a tire is important for the technician to be able to identify tire failure or vehicle handling problems.

FUNCTION OF TIRES Tires are mounted on wheels that are bolted to the vehicle to provide the following:

1. Shock absorber action when driving over rough surfaces
2. Friction (traction) between the wheels and the road

All tires are assembled by hand from many different component parts consisting of various rubber compounds, steel, and various types of fabric material. Tires are also available in many different designs and sizes.

PARTS OF A TIRE

TREAD **Tread** refers to the part of the tire that contacts the ground. *Tread rubber* is chemically different from other rubber parts of a tire, and is compounded for a combination of traction and tire wear. *Tread depth* is usually 11/32 in. deep on new tires (this could vary, depending on manufacturer, from 9/32 to 15/32 in.). ● **FIGURE 109–1** shows a tread depth gauge.

NOTE: The tread depth gauge is used to measure the thickness of the tire tread. A tread depth is always expressed in 1/32s of an inch, even if the fraction can be reduced to 1/16s or 1/8s.

Wear indicators are also called **wear bars.** When tread depth is down to the legal limit of 2/32 in., bald strips appear across the tread. ● **SEE FIGURE 109–2.**

Tie bars are molded into the tread of most all-season-rated tires. These rubber reinforcement bars are placed between tread blocks on the outer tread rows to prevent unusual wear and to reduce tread noise. As the tire wears normally, the tie bars will gradually appear. This should not be mistaken for an indication of excess outer edge wear. A tire tread with what appears to be a solid band across the entire width of the tread is what the service technician should consider the wear bar indicator.

Grooves are large, deep recesses molded in the tread and separating the tread blocks. These grooves are called *circumferential grooves* or *kerfs.* Grooves running sideways across the tread of a tire are called *lateral grooves.* ● **SEE FIGURE 109–3.**

Grooves in both directions are necessary for wet traction. The trapped water can actually cause the tires to ride up on a layer of water and lose contact with the ground, as shown in ● **FIGURE 109–4.** This is called **hydroplaning.** With worn tires, hydroplaning can occur at

(a)

(b)

FIGURE 109–1 (a) A typical tire tread depth gauge. The center movable plunger is pushed down into the groove of the tire. (b) The tread depth is read at the top edge of the sleeve. In this example, the tread depth is 6/32 in.

FIGURE 109–2 Wear indicators (wear bars) are strips of bald tread that show when the tread depth is down to 2/32 in., the legal limit in many states.

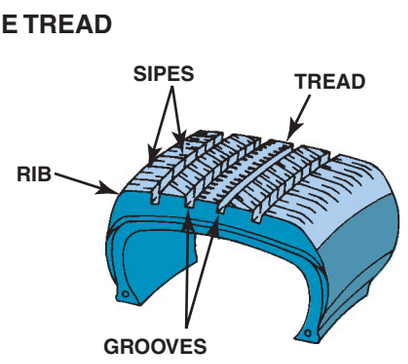

FIGURE 109–3 The tire tread runs around the circumference of the tire, and its pattern helps maintain traction. The ribs provide grip, while the grooves direct any water on the road away from the surface. The sipes help the tire grip the road.

speeds as low as 30 mph on wet roads. Stopping and cornering is impossible when hydroplaning occurs. *Sipes* are small slits in the tread area to increase wet and dry traction.

SIDEWALL

The **sidewall** is that part of the tire between the tread and the wheel. The sidewall contains all the size and construction details of the tire.

Some tires turn brown on the sidewalls after a short time. This is due to ozone (atmosphere) damage that actually causes the rubber to oxidize. Premium-quality tires contain an anti-oxidizing chemical additive blended with the sidewall rubber to prevent this discoloration.

WHITE SIDEWALL/LETTERED. When pneumatic tires were first constructed in the early 1900s, only natural rubber was used. The entire tire was white. When it was discovered that carbon black greatly increased the toughness of a tire, it was used. The public did not like the change from white tires to black, so tire manufacturers put the carbon black (lamp black) only in the rubber that was to be used for the tread portion of the tire. This tire lasted a lot longer because

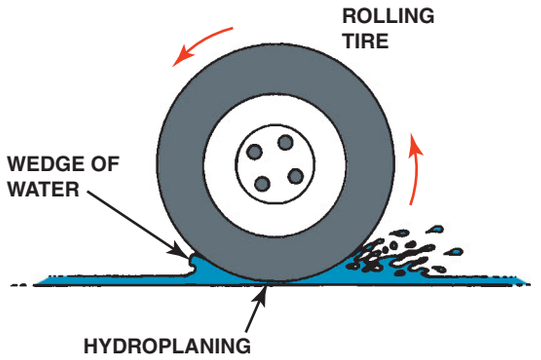

FIGURE 109–4 Hydroplaning can occur at speeds as low as 30 mph (48 km/h). If the water is deep enough and the tire tread cannot evacuate water through its grooves fast enough, the tire can be lifted off the road surface by a layer of water. Hydroplaning occurs at lower speeds as the tire becomes worn.

the black rubber tread that touched the ground was stronger and tougher; it sold well because the sidewalls were white.

White sidewall or white lettered tires actually contain a strip of white rubber under the black sidewall. This is ground off at the factory to reveal the white rubber. Only whitewalls or white letter lines contain this expensive white rubber. Various widths of whitewalls are made possible simply by changing the width of the grinding wheel.

BEAD

The **bead** is the foundation of the tire and is located where the tire grips the inside of the wheel rim.

1. The bead is constructed of many turns of copper- or bronze-coated steel wire.
2. The main body plies (layers of material) are wrapped around the bead.

   CAUTION: If the bead of a tire is cut or damaged, the tire must be replaced!
3. Most radial-ply tires and all truck tires wrap the bead with additional material to add strength.

BODY PLY

A tire gets its strength from the layers of material wrapped around both beads under the tread and sidewall rubber. This creates the main framework, or "carcass," of the tire; these **body plies** are often called **carcass plies.** A 4-ply tire has four separate layers of material. If the body plies overlap at an angle (bias), the tire is called a *bias-ply* tire. If only one or two body plies are used and they do not cross at an angle, but lie directly from bead to bead, then the tire is called *radial ply.* ● **SEE FIGURE 109–5.**

1. Rayon is a body ply material used in many tires because it provides a very smooth ride. A major disadvantage of rayon is that it rots if exposed to moisture.
2. Nylon is a strong body ply material. Though it is still used in some tires, it tends to "flat-spot" after sitting overnight.
3. Aramid is the generic name for aromatic polyamide fibers developed in 1972. Aramid is several times stronger than steel (pound for pound), and is used in high-performance-tire construction. Kevlar is the DuPont brand name for aramid and a registered trademark of E.I. Dupont de Nemours and Co.
4. Polyester is the most commonly used tire material because it provides the smooth ride characteristics of rayon with the rot resistance and strength of nylon.

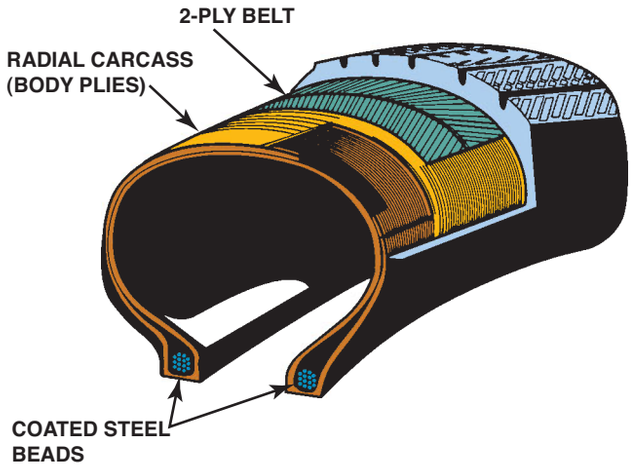

FIGURE 109–5 Typical construction of a radial tire. Some tires have only one body ply, and some tires use more than two belt plies.

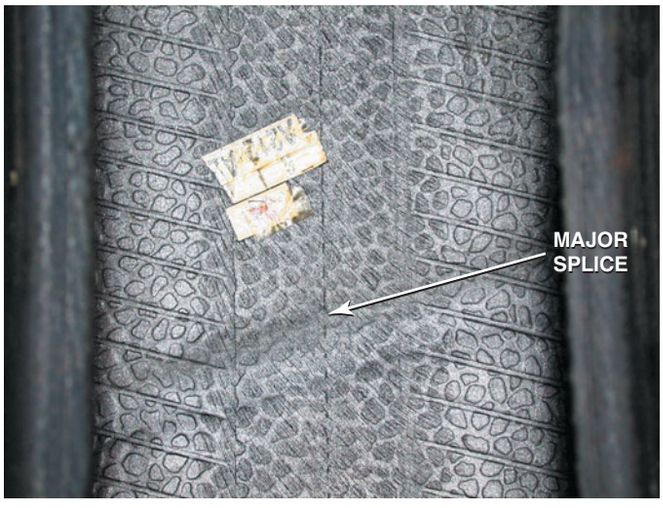

FIGURE 109–6 The major splice of a tire can often be seen and felt on the inside of the tire. The person who assembles (builds) the tire usually places a sticker near the major splice as a means of identification for quality control.

BELT A tire **belt** is two or more layers of material applied over the body plies and under the tread area only, to stabilize the tread and increase tread life and handling.

1. Belt material can consist of the following:
   - **a.** Steel mesh
   - **b.** Nylon
   - **c.** Rayon
   - **d.** Fiberglass
   - **e.** Aramid
2. **All radial tires are belted.**

NOTE: Most tires rated for high speed use a nylon "overlay" or "cap belt" between the 2-ply belt and the tread of the tire. This overlay helps stabilize the belt package and helps hold the tire together at high speeds, when centrifugal force acts to tear a tire apart.

INNER LINER The **inner liner** is the soft rubber lining (usually a butyl rubber compound) on the inside of the tire that protects the body plies and helps provide for self-sealing of small punctures.

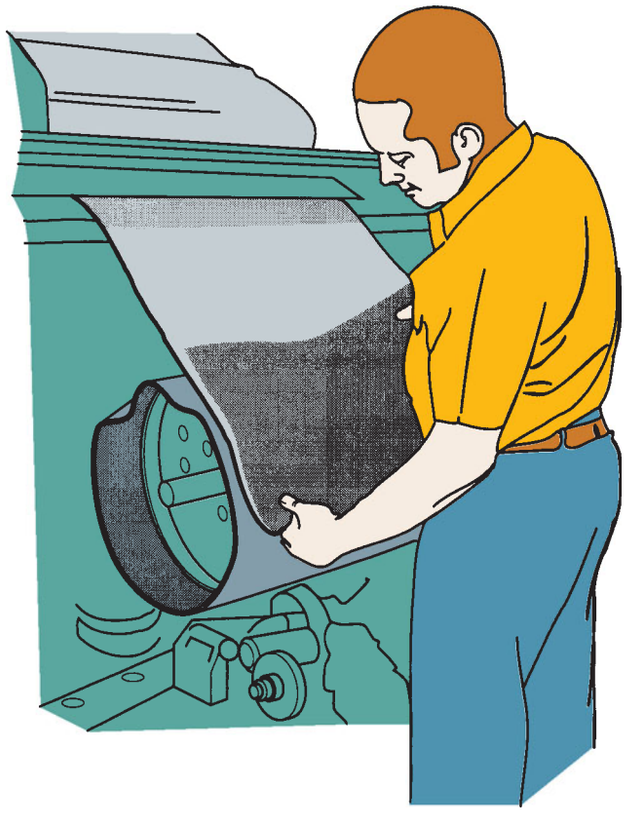

FIGURE 109–7 Tire construction is performed by assembling the many parts of a tire together on a tire-building machine.

MAJOR SPLICE When the tire is assembled by a craftsperson on a tire-building machine, the body plies, belts, and tread rubber are spliced together. The fabric is overlapped approximately five threads. The point where the majority of these overlaps occur is called the **major splice,** which represents the stiffest part of the tire. This major splice is visible on most tires on the inside, as shown in ● **FIGURE 109–6.**

NOTE: On most new vehicles and/or new tires, the tire manufacturer paints a dot on the sidewall near the bead, indicating the largest diameter of the tire. The largest diameter of the tire usually is near the major splice. The wheel manufacturer either marks the wheel or drills the valve core hole at the smallest diameter of the wheel. Therefore, the dot should be aligned with the valve core or marked for best balance and minimum radial runout.

TIRE MOLDING

After the tire has been assembled by the tire builder, it is called a **green tire.** ● **SEE FIGURE 109–7.** At this stage in construction, the rubber can be returned and reused because it has not been changed chemically. The completed green tire is then placed in a mold where its shape, tread design, and all sidewall markings are formed. ● **SEE FIGURE 109–8.**

While in the mold, a steam bladder fills the inside of the tire and forces the tire against the outside of the mold. After approximately 30 minutes at 300°F (150°C), the heat changes the chemistry of the rubber. The tire is no longer called a green tire but a *cured tire,* and after inspection and cleaning, it is ready for shipment.

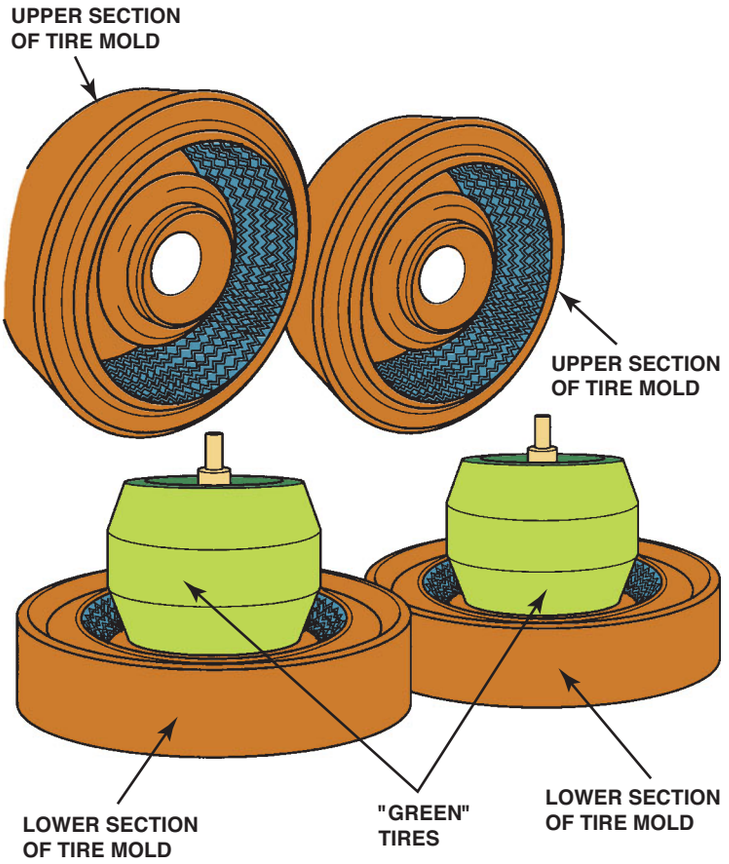

FIGURE 109–8 After the entire tire has been assembled into a completed "green" tire, it is placed into a tire-molding machine where the tire is molded into shape and the rubber is changed chemically by the heat. This nonreversible chemical reaction is called vulcanization.

FREQUENTLY ASKED QUESTION

Why Do I Get Shocked by Static Electricity When I Drive a Certain Vehicle?

Static electricity builds up in insulators due to friction of the tires with the road. Newer tires use silica and contain less carbon black in the rubber, which makes the tires electrically conductive. Because the tires cannot conduct the static electricity to the ground, static electricity builds up inside the vehicle and is discharged through the body of the driver and/or passenger whenever the metal door handle is touched.

NOTE: Toll booth operators report being shocked by many drivers as money is being passed between the driver and the toll booth operator.

Newer tire sidewall designs that use silica usually incorporate carbon sections that are used to discharge the static electricity to ground. To help reduce the static charge buildup, spray the upholstery with an antistatic spray available at discount and grocery stores.

TIRE SIZE DESIGNATIONS

METRIC DESIGNATION European and Japanese tires use metric designations. For example, 185SR × 14 denotes the following:

FREQUENTLY ASKED QUESTION

How Much Does Tire Pressure Change with a Change in Temperature?

As the temperature of a tire increases, the pressure inside the tire also increases. The general amount of pressure gain (when temperatures increase) or loss (when temperatures decrease) is as follows:

10°F increase causes 1 PSI increase

10°F decrease causes 1 PSI decrease

For example, if a tire is correctly inflated to 35 PSI when cold and then driven on a highway, the tire pressure may increase 5 PSI or more.

CAUTION: DO NOT LET AIR OUT OF A HOT TIRE! If air is released from a hot tire to bring the pressure down to specifications, the tire will be *underinflated* when the tire has cooled. The tire pressure specification is for a cold tire.

Always check the tire pressures on a vehicle that has been driven fewer than 2 miles (3.2 km).

Air pressure in the tires also affects fuel economy. If all four tires are underinflated (low on air pressure), fuel economy is reduced about **0.1 mile per gallon (mpg) for each 1 PSI low.** For example, if all four tires were inflated to 25 PSI instead of 35 PSI, not only is tire life affected but fuel economy is reduced by about 1 mile per gallon (10 × 0.1 = 1 mpg).

185	the tire is 185 millimeters (mm) wide (cross-sectional width)
S	the speed rating
R	radial design
14	fits a 14-in.-diameter wheel

The European size indicates the exact physical size (width) of the tire and the speed ratings. Because of the lack of speed limits in many countries, this information is important. Because of tire design changes needed for H- and V-rated tires, their cost is usually much higher. European sizes also include the tire's aspect ratio, for example, 185/70SR × 14. If the aspect ratio of a European-sized tire is not indicated, it is generally 83% for most radials.

AMERICAN METRIC TIRE SIZE DESIGNATIONS After 1980, American tires were also designated using the metric system. For example, P205/75R × 14 denotes the following:

P	passenger vehicle
205	205-mm cross-sectional width
75	75% aspect ratio. The height of the tire (from the wheel to the tread) is 75% as great as its cross-sectional width (the width measured across its widest part). This percentage ratio of height to width is called the **aspect ratio.** (A 60 series tire is 60% as high as it is wide.)
R	radial
14	14-in.-diameter wheel

If a tire is constructed as a bias-ply tire only, then its size designation uses the letter D to indicate *diagonal:* P205/75D × 14.

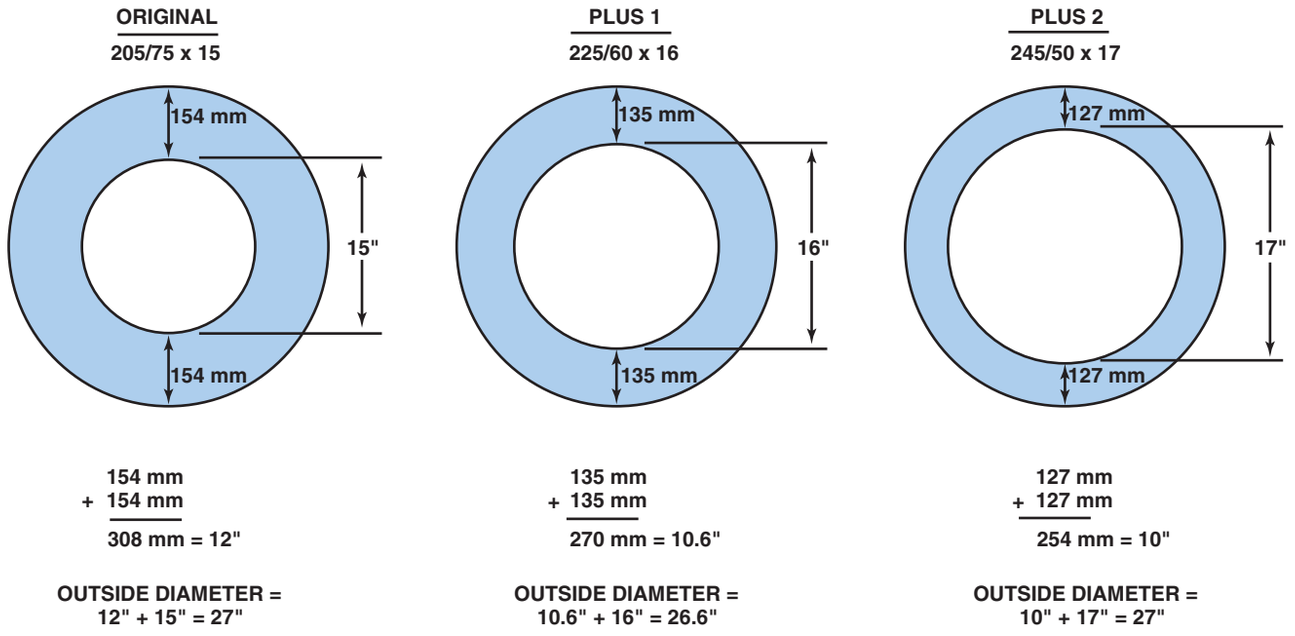

FIGURE 109–9 Notice that the overall outside diameter of the tire remains almost the same and at the same time the aspect ratio is decreased and the rim diameter is increased.

FREQUENTLY ASKED QUESTION

How Much Bigger Can I Go?

Many owners think they can improve their vehicle by upgrading the tire size over the size that comes from the factory to make their vehicle look sportier and ride and handle better. When changing tire size, there are many factors to consider:

1. The tire should be the same outside diameter as the original to maintain the proper suspension, steering, and ride height specifications.
2. Tire size affects vehicle speed sensor values, ABS brake wheel sensor values that can change automatic transmission operation, and ABS operation.
3. The tire should not be so wide as to contact the inner wheel well or suspension components.
4. Generally, a tire that is 10 mm wider is acceptable. For example, an original equipment tire size 205/75 × 15 (outside diameter = 27.1 in.) can be changed to 215/75 × 15 (outside diameter = 27.6 in.). This much change is less than 1/2 in. in width and increases the outside diameter by 1/2 in.

NOTE: Outside diameter is calculated by adding the wheel diameter to the cross-sectional height of the tire, multiplied by 2. ● **SEE FIGURE 109–9.**

5. Whenever changing tires, make sure that the load capacity is the same or greater than that of the original tires.
6. If wider tires are desired, a lower aspect ratio is required to maintain the same, or close to the same, overall outside diameter of the tire.

Old	New
P205/75 × 15	P215/70 × 15
205 × 0.75 = 154 mm	215 × 0.70 = 151 mm

Notice that the overall sidewall height is generally maintained.

If even larger tires are needed, then 225/60 × 15s may be OK–let's check the math:

225 × 0.60 = 135 mm

Notice that this is much too short a sidewall height when compared with the original tire (see no. 6).

7. Use the "plus 1" or "plus 2" concept. When specifying wider tires, the sidewall height must be reduced to maintain the same, or close to the same, original equipment specifications. The "plus 1" concept involves replacing the wheels with wheels 1 in. larger in diameter to compensate for the lower aspect of wider tires.

Original	Plus 1
205/75 × 15	225/60 × 16

The overall difference in outside diameter is only 0.5 in., even though the tire width has increased from 205 mm to 225 mm and the wheel diameter has increased by 1 in. If money is no object and all-out performance is the goal, a "plus 2" concept can also be used (use a P245/50 × 17 tire and change to 17-in.-diameter wheels).

Here the overall diameter is within 1/20″ of the original tire/wheel combination, yet the tire width is 1.6 inches (40 mm) wider than the original tire. Refer to the section entitled "Wheels" later in this chapter for proper wheel back spacing and offset when purchasing replacement wheels.

FREQUENTLY ASKED QUESTION

What Effect Does Tire Size Have on Overall Gear Ratio?

Customers often ask what effect changing tire size has on fuel economy and speedometer readings. If larger (or smaller) tires are installed on a vehicle, many other factors also will change. These include the following:

1. **Speedometer reading.** If larger-diameter tires are used, the speedometer will read slower than you are actually traveling. This can result in speeding tickets!
2. **Odometer reading.** Even though larger tires are said to give better fuel economy, just the opposite can be calculated! Since a larger-diameter tire travels farther than a smaller-diameter tire, the larger tire will cause the odometer to read a shorter distance than the vehicle actually travels. For example, if the odometer reads 100 miles traveled on tires that are 10% oversized in circumference, the actual distance traveled is 110 miles.
3. **Fuel economy.** If fuel economy is calculated on miles traveled, the result will be *lower* fuel economy than for the same vehicle with the original tires.

$$\text{Calculation: mph} = \frac{\text{RPM} \times \text{diameter} \times 3.14}{\text{gear ratio}}$$

$$\frac{\text{RPM} = \text{mph} \times \text{gear ratio}}{\text{diameter} \times 3.14}$$

$$\frac{\text{gear ratio} = \text{RPM} \times \text{diameter} \times 3.14}{\text{mph}}$$

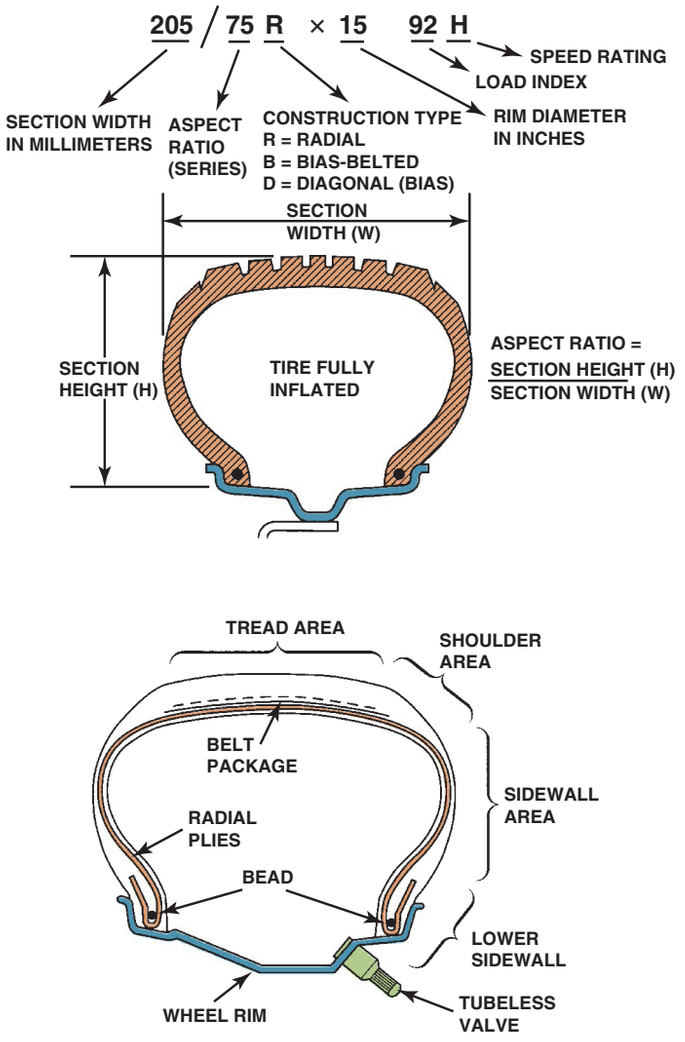

FIGURE 109–10 Cross-sectional view of a typical tire showing the terminology.

NOTE: Many "temporary use only" spare tires are constructed with diagonal (bias) plies; the size designation is *T* for *temporary*.

If a tire is constructed as a bias ply with a belt of additional material under the tread area, its size designation uses the letter B to indicate belted: P205/75B × 14. Some tires use letters at the end of the tire size (suffixes) to indicate special applications, including the following:

LT	light truck
ML	mining and logging
MH	mobile home
ST	special trailer
TR	truck

SERVICE DESCRIPTION

Tires built after 1990 use a "service description" method of sidewall information in accordance with ISO 4000 (International Standards Organization) that includes size, load, and speed rating together in one easy-to-read format. ● **SEE FIGURE 109–10.**

P-Metric Designation	Service Description
P205/75HR × 15	205/75R × 15 92H
P passenger vehicle	205 cross-sectional width in mm
205 cross-sectional width in mm	75 aspect ratio
75 aspect ratio	R radial construction
H speed rating (130 mph/210 km/h)	15 rim diameter in inches
R radial construction	92 load index
15 rim diameter in inches	H speed rating (130 mph/210 km/h)

HIGH-FLOTATION TIRE SIZES

High-flotation tires for light trucks are designed to give improved off-road performance on sand, mud, and soft soil and still provide acceptable hard-road surface performance. These tires are usually larger than conventional tires and usually require a wider-than-normal wheel width. High-flotation tires have a size designation such as 33 × 12.50R × 15LT:

33	approximate overall tire diameter in inches
12.50	approximate cross-sectional width in inches
R	radial-type construction
15	rim diameter in inches
LT	light-truck designation

FREQUENTLY ASKED QUESTION

If I Have an Older Vehicle, What Size Tires Should I Use?

Newer radial tires can be used on older-model vehicles if the size of the tires is selected that best matches the original tires. See the following cross-reference chart.

Cross-Reference Chart
(This Chart Does Not Imply Complete Interchangeability.)

Pre-1964	1965 to 1972	80 Series Metric	Alpha Numeric 78 Series	P-Metric 75 Series Radial	P-Metric 70 Series Radial
590-13	600-13	165-13	A78-13	P165/75R13	P175/70R13
640-13	650-13	175-13	B78-13	P175/75R13	P185/70R13

650-15	685-15	175-15	C78-15	P175/75R15	P185/70R15
640-15	735-15	185-15	E78-15	P195/75R15	P205/70R15
670-15	775-15	195-15	F78-15	P205/75R15	P215/70R15
710-15	815-15	205-15	G78-15	P215/75R15	P225/70R15
760-15	855-15	215-15	H78-15	P225/75R15	P235/70R15
800-15	885-15	230-15	J78-15	P225/75R15	P235/70R15
820-15	900-15	235-15	L78-15	P235/75R15	P255/70R15

NOTE: Vehicles designed for older bias-ply tires may drive differently when equipped with radial tires.

LOAD INDEX AND EQUIVALENT LOADS

The **load index,** as shown in ● **FIGURE 109–11,** is an abbreviated method to indicate the load-carrying capabilities of a tire. The weights listed in the chart represent the weight that *each tire* can safely support. Multiply this amount by 4 to get the maximum that the vehicle should weigh fully loaded with cargo and passengers.

SPEED RATINGS

Tires are rated according to the maximum *sustained* speed. A vehicle should never be driven faster than the **speed rating** of the tires. ● **SEE CHART 109–1.**

CAUTION: A high speed rating does not guarantee that the tires will not fail, even at speeds much lower than the rating. Tire condition, inflation, and vehicle loading also affect tire performance.

As the speed rating of a tire increases, fewer compromises exist for driver comfort and low noise level. The higher speed rating does not mean a better tire. To survive, a high-speed tire must be built with stiff tread compounds, reinforced body (carcass) construction, and fabric angles that favor high speed and high performance over other considerations. For example, a V-rated tire often has less tread depth than a similar tire with an H-speed rating, and therefore will often not give as long of a service life. Since the speed ratings were first developed in Europe, the letters correspond to metric speed in kilometers per hour, with a conversion to miles per hour as noted.

TIRE PRESSURE AND TRACTION

All tires should be inflated to the specifications given by the vehicle manufacturer. Most vehicles have recommended tire inflation figures written in the owner's manual or on a placard

FREQUENTLY ASKED QUESTION

What Does the Little "e" Mean on the Sidewall?

Most countries have government agencies that regulate standards for motor vehicles sold and/or driven within their jurisdiction. In the United States, the U.S. Department of Transportation and National Highway Traffic Safety Administration are responsible for developing many of the nationwide standards for vehicles. Tires that are certified by their manufacturers to meet U.S. standards are branded with "DOT" (Department of Transportation) preceding the Tire Identification Code on their sidewall.

In Europe, because so much personal and commercial travel extends beyond the borders of any one country, the Economic Commission for Europe (E.C.E.) helps develop uniform motor vehicle standards for its member countries to regulate and standardize passenger and commercial vehicle components.

Besides physical specifications, the E.C.E. standards now require tire "pass-by" noise to meet specific limits. These standards were phased-in starting in 2004. The tires must pass noise emission testing, and the standards will continue to expand in scope until 2009, when the standards will be applied to all tires sold in Europe.

The E.C.E. symbol on a tire's sidewall identifies that the manufacturer certifies that the tire meets all regulations, including the load index and speed symbol that appear in its service description.

The letter "e" and number code combination (positioned in a circle or rectangle) identify the country originally granting approval, followed by two digits indicating the Regulation Series under which the tire was approved. Tires that have also been tested and meet the "pass-by" noise limits can have a second E.C.E. branding followed by an "-s" (for *sound*). ● **SEE FIGURE 109–12.**

The following list indicates selected E.C.E. codes and the countries they represent:

Code	Country	Code	Country
E1	Germany	E14	Switzerland
E2	France	E15	Norway
E3	Italy	E16	Finland
E4	Netherlands	E17	Denmark
E5	Sweden	E18	Romania
E6	Belgium	E19	Poland
E7	Hungary	E20	Portugal
E8	Czech Republic	E21	Russian Federation
E9	Spain	E22	Greece
E10	Yugoslavia	E23	Ireland
E11	United Kingdom	E24	Croatia
E12	Austria	E25	Slovenia
E13	Luxembourg	E26	Slovakia

or sticker on the door post or glove compartment. ● **SEE FIGURE 109–13.**

The pressure number molded into the sidewall of a tire should be considered the maximum pressure when the tire is cold. (Pressures higher than that stated on the sidewall may be measured on a hot tire.)

LETTER	MAXIMUM RATED SPEED
L	120 km/h (75 mph)
M	130 km/h (81 mph)
N	140 km/h (87 mph)
P	150 km/h (93 mph)
Q	160 km/h (99 mph)
R	170 km/h (106 mph)
S	180 km/h (112 mph)
T	190 km/h (118 mph)
U	200 km/h (124 mph)
H	210 km/h (130 mph)
V	240 km/h (149 mph)
W	270 km/h (168 mph)
Y	300 km/h (186 mph)
Z	open-ended*

CHART 109–1

Speed ratings are based on continuous operation at the speed rating speed.
*The exact speed rating for a particular Z-rated tire is determined by the tire manufacturer and may vary according to size. For example, not all Brand X Z-rated tires are rated at 170 mph, even though one size may be capable of these speeds.

TIRE CONICITY AND PLY STEER

Tire **conicity** can occur during the construction of any radial or belted tire when the parts of the tire are badly positioned, causing the tire to be smaller in diameter on one side. When this tire is installed on a vehicle, it can cause the vehicle to pull to one side of the road due to the cone shape of the tire. ● **SEE FIGURE 109–14.**

Since the cause of conicity is due to the construction of the tire itself, there is nothing the service technician can do to correct the condition except to replace the tire. The exact cause of the conicity is generally due to the slight movement of the belt and tread in the mold during inflation. If a vehicle pulls to one side of the road, the service technician should switch tires left to right (left-side tires to the right side and the right-side tires to the left side of the vehicle). If this swap of tires corrects the pulling condition, then tire conicity was the possible cause.

NOTE: *Radial pull* or *radial tire pull* are other terms often used to describe tire conicity.

Ply steer is another term that describes a slight pulling force on a vehicle due to tire construction. Ply steer is due to the angle of the cords in the belt layers, as seen in ● **FIGURE 109–15,** and not in the ply layer of the carcass (body), as the name implies. Ply steer will cause a slight drift regardless of its direction of rotation. Switching tires left to right will *not* correct a ply steer condition.

NOTE: Whenever a wheel and tire assembly is switched from one side of a vehicle to the other, the tire revolves in the opposite direction.

Load Index	Load (kg)	Load (lb)	103	875	1,929
75	387	853	104	900	1,934

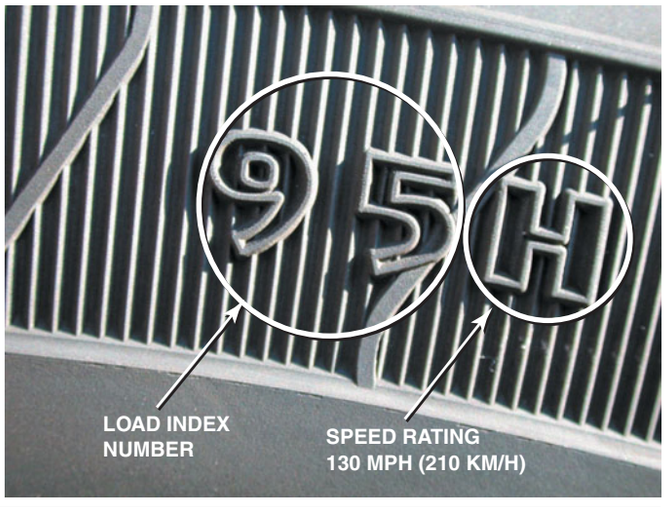

FIGURE 109–11 Typical sidewall markings for load index and speed rating following the tire size.

FIGURE 109–12 The E.C.E. symbol on a sidewall of a tire. Notice the small -s at the end, indicating that the tire meets the "pass-by" noise limits.

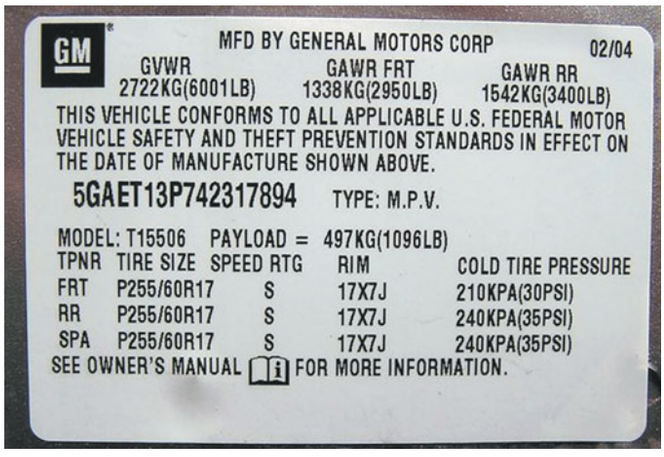

FIGURE 109–13 A typical door placard used on a General Motors vehicle indicating the recommended tire inflation. Note that the information also includes the tire size and speed rating of the tire as well as the recommended wheel size.

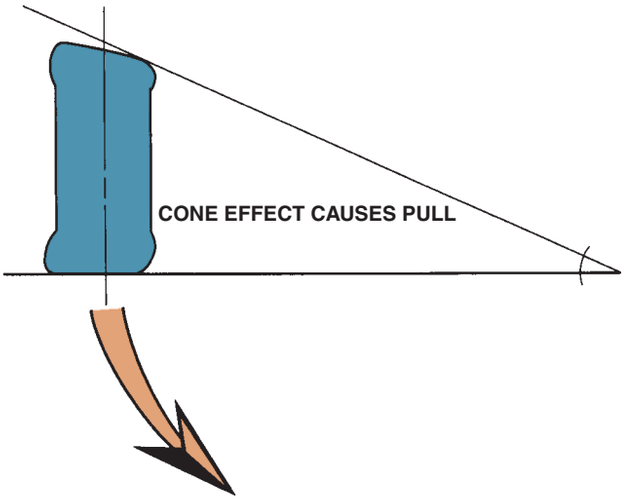

FIGURE 109–14 Conicity is a fault in the tire that can cause the vehicle to pull to one side due to the cone effect (shape) of the tire.

Ply steer is built into the tire during construction. There is nothing a service technician can do to correct ply steer, except to compensate for it with alignment angles. (See Chapter 93 for details on alignment diagnosis and correction.)

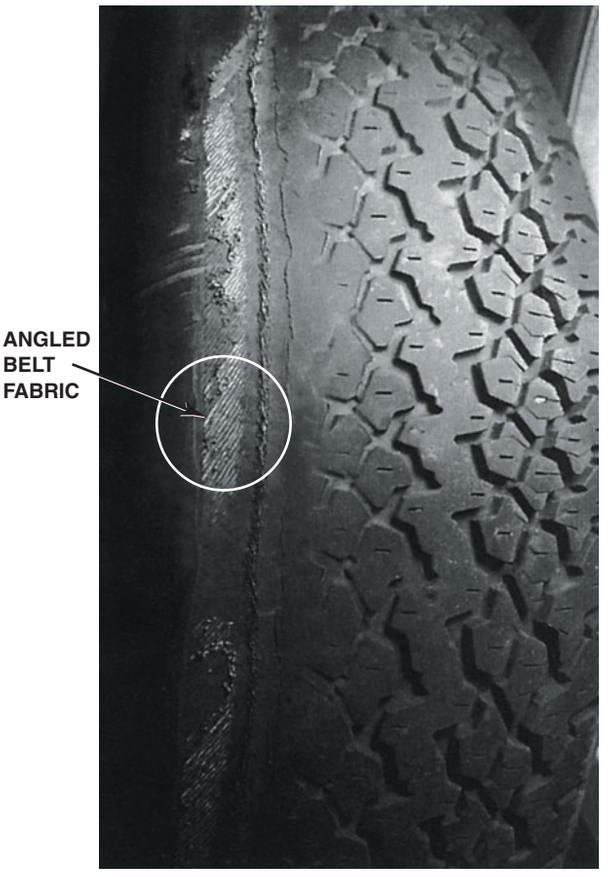

FIGURE 109–15 Notice the angle of the belt material in this worn tire. The angle of the belt fabric can cause a "ply steer" or slight pulling force toward one side of the vehicle.

VEHICLE HANDLING AND TIRE SLIP ANGLE

The tire surface contact area or tire patch size is about one-half the area of one page of this book. All accelerating, braking, and cornering forces of a vehicle are transferred to the pavement at just four spots. The combined area of these four spots is about equal to the size of this opened book.

Think about this whenever braking or cornering. As a vehicle is turned, the wheels are moved while the tires remain in contact with the road. These actions "twist" the carcass of the tire and create a slip angle between the direction the wheel is pointing and the direction the tread is pointing. ● **SEE FIGURE 109–16.**

The contact patch is deformed and snaps back into place as the twisted tire carcass returns to its original shape. This movement causes a slight delay in the turning of the vehicle and causes tire wear as the tread rubber moves in relation to the pavement during cornering.

RIM WIDTH AND TIRE SIZE

As a general rule, for a given **rim width** it is best not to change tire width more than 10 mm (either wider or narrower). For a given tire width, it is best not to vary rim width more than 1/2 in. in either direction. For example, if the original tire size is 195/70 × 14, then either a 185/70 × 14 (−10 mm) or a 205/70 × 14 (+10 mm) *could* be used on the original rim (wheel) without undue harm *if* the replacement tire has proper clearance with the body and suspension components.

? FREQUENTLY ASKED QUESTION

Is There a Rule-of-Thumb for Rim Size?

According to the Tire and Rim Association, Inc., the answer is no. Each tire size has a designated rim width on which it is designed to be mounted so as to provide the best performance and wear. The width of the specified rim also varies with rim diameter. A 235/45 × 17 tire may require a 7.5-in. rim but a 235/45 × 19 tire may require an 8.0-in. rim. A rule-of-thumb that has been used is to multiply the width of the rim by 33.55 to determine the approximate tire size for the rim. For example, consider the following.

Rim width 5.0 in. × 33.55 = 167.85 (165 mm) tire
Rim width 5.5 in. × 33.55 = 184.50 (185 mm) tire
Rim width 6.0 in. × 33.55 = 201.30 (195 mm) tire
Rim width 6.5 in. × 33.55 = 218.00 (215 mm) tire
Rim width 7.0 in. × 33.55 = 234.90 (235 mm) tire
Rim width 7.5 in. × 33.55 = 252.00 (245 mm) tire
Rim width 8.0 in. × 33.55 = 268.00 (265 mm) tire
Rim width 8.5 in. × 33.55 = 285.00 (285 mm) tire
Rim width 9.0 in. × 33.55 = 302.00 (305 mm) tire
Rim width 10.0 in. × 33.55 = 335.60 (335 mm) tire

Always check with the tire manufacturer as to the specified tire rim width that should be used.

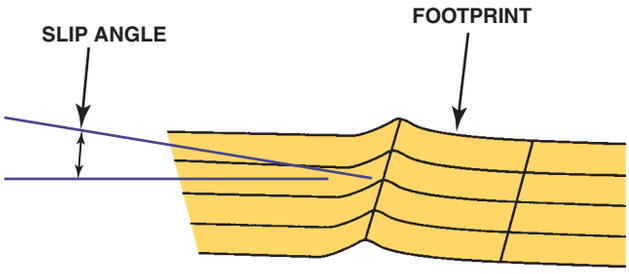

FIGURE 109–16 Slip angle is the angle between the direction the tire tread is heading and the direction it is pointed.

Installing a tire on too narrow a wheel will cause the tire to wear excessively in the center of the tread. Installing a tire on too wide a wheel will cause excessive tire wear on both edges.

See a tire store representative for recommended tire sizes that can be safely installed on your rims.

UNIFORM TIRE QUALITY GRADING SYSTEM

The U.S. Department of Transportation (DOT) and the National Highway Traffic Safety Administration (NHTSA) developed a system of tire grading, the **Uniform Tire Quality Grading System (UTQGS),** to help customers better judge the relative performance of tires. The three areas of tire performance are tread wear, traction, and temperature resistance, as shown in ● **FIGURE 109–17.**

NOTE: All tires sold in the United States must have UTQGS ratings molded into the sidewall.

TREAD WEAR The tread wear grade is a comparison rating based on the wear rate of a standardized tire, tested under carefully controlled conditions, which is assigned a value of 100. A tire rated 200 should have a useful life twice as long as the standard tire's.

NOTE: The standard tire has a rating for tread wear of 100. This value has generally been accepted to mean a useful life of 20,000 miles of normal driving. Therefore, a tire rated at 200 could be expected to last 40,000 miles.

Tread Wear Rating Number	Approximate Number of mi/km
100	20,000/32,000
150	30,000/48,000
200	40,000/64,000
250	50,000/80,000
300	60,000/96,000
400	80,000/129,000
500	100,000/161,000

The tread wear life of any tire is affected by driving habits (fast stops, starts, and cornering will decrease tread life), tire rotation (or lack of tire rotation), inflation, wheel alignment, road surfaces, and climate conditions.

TRACTION Traction performance is rated by the letters AA, A, B, and C, with AA being the highest.

FIGURE 109–17 Typical "Uniform Tire Quality Grading System" (UTQGS) ratings imprinted on the tire sidewall.

NOTE: The traction rating is for wet braking distance only! It does not include cornering traction or dry braking performance.

The traction rating is only one of many other factors that affect wet braking traction, including air inflation, tread depth, vehicle speed, and brake performance.

TEMPERATURE RESISTANCE Temperature resistance is rated by the letters A, B, and C, with A being the highest rating. Tires generate heat while rotating and flexing during normal driving conditions. A certain amount of heat buildup is desirable because tires produce their highest coefficient of traction at normal operating temperatures. For example, race car drivers frequently swerve their cars left and right during the pace laps, causing increased friction between the tire and the road surface, which warms their tires to operating temperature. However, if temperatures rise too much, a tire can start to come apart–the oils and rubber in the tire start to become a liquid! Grade C is the minimum level that all tires must be able to pass under the current Federal Motor Vehicle Safety Standard No. 109.

ALL-SEASON TIRE DESIGNATION

DESIGNATION LABELS Most all-season tires are rated and labeled as *M & S, MS,* or *M + S,* and therefore must adhere to general design features as specified by the Rubber Manufacturers Association (RMA).

Tires labeled M & S are constructed with an aggressive tread design as well as tread compounds and internal construction that are designed for mud and snow. One design feature is that the tire has at least 25% void area. This means that the tread blocks have enough open space around them to allow the blocks to grab and clean themselves of snow and mud. Block angles, dimensional requirements, and minimum cross-sectional width are also a requirement for the M & S designation.

RUBBER COMPOUND DIFFERENCES The tread rubber used to make all-season tires is also more flexible at low temperatures. This rubber compound is low-bounce (called high-hysteresis)

REAL WORLD FIX

Tire Date Code Information Saved Me Money!

This author was looking at a three-year-old vehicle when I noticed that the right rear tire had a build date code newer than the vehicle. I asked the owner, "How badly was this vehicle hit?" The owner stumbled and stuttered a little, then said, "How did you know that an accident occurred?" I told the owner that the right rear tire, while the exact same tire as the others, had a date code indicating that it was only one year old, whereas the original tires were the same age as the vehicle. The last three numbers of the DOT code on the sidewall indicate the week of manufacture (the first two numbers of the three-digit date code) followed by the last number of the year.

The owner immediately admitted that the vehicle slid on ice and hit a curb, damaging the right rear tire and wheel. Both the tire and wheel were replaced and the alignment checked. The owner then dropped the price of the vehicle $500! Knowing the date code helps assure that fresh tires are purchased and can also help the technician determine if the tires have been replaced. For example, if new tires are found on a vehicle with 20,000 miles, then the technician should check to see if the vehicle may have been involved in an accident or may have more miles than indicated on the odometer.

and is more likely to remain in contact with the road surface. The rubber compound is also called *hydrophilic,* meaning that the rubber has an affinity for water (rather than being *hydrophobic* rubber, which repels water).

NOTE: Most vehicle manufacturers recommend that the same *type* of tire be used on all four wheels even though the size of the tire may vary between front and rear on some high-performance vehicles. Therefore, if all-season replacement tires are purchased, a complete set of four should be used to be assured of proper handling and uniform traction characteristics. While *tire* manufacturers have been recommending this for years—since the late 1980s—most *vehicle* manufacturers are also recommending that all four tires be of the same construction and tread type to help ensure proper vehicle handling.

DOT TIRE CODE

All tires sold in the United States must be approved by the U.S. Federal Department of Transportation (DOT). The **DOT tire code** requirements include resistance to tire damage that could be caused by curbs, chuckholes, and other common occurrences for a tire used on public roads.

NOTE: Most race tires are *not* DOT-approved and must never be used on public streets or highways.

Each tire that is DOT-approved has a DOT number molded into the sidewall of the tire. This number is usually imprinted on only one side of the tire and is usually on the side *opposite the whitewall.* The DOT code includes letters and numbers, such as **MJP2CBDX264.** See appendix 2 for a list of where tires are built.

FIGURE 109–18 Typical DOT date code. This tire was built the sixth week of 2005.

The first two letters identify the manufacturer and location. For this example, the first two letters (MJ) mean that the tire was made by the Goodyear Tire and Rubber Company in Topeka, Kansas. The last three numbers are the build date code. The last of these three numbers is the year (1994), and the 26 means that it was built during the 26th week of 1994. Starting with tires manufactured after January 1, 2000, the tire build date includes four digits rather than three digits. A new code such as "3406" means the 34th week of 2006 ("3406"). ● **SEE FIGURE 109–18.**

SPARE TIRES

Most vehicles today come equipped with space-saver spare tires that are smaller than the wheels and tires that are on the vehicle. The reason for the small size is to reduce the size and weight of the entire vehicle and to increase fuel economy by having the entire vehicle weigh less by not carrying a heavy spare tire and wheel around. The style and type of these spare tires have changed a great deal over the last several years, and different makes and types of vehicles use various types of spare tires.

CAUTION: Before using a spare tire, always read the warning label (if so equipped) and understand all use restrictions. For example, some spare tires are not designed to exceed 50 mph (80 km/h) or be driven more than 500 miles (800 km).

Many small, space-saving spare tires use a higher-than-normal air inflation pressure, usually 60 PSI (414 kPa). Even though the tire often differs in construction, size, diameter, and width from the vehicle's original tires, it is amazing that the vehicle usually handles the same during normal driving. Obviously, these tires are not constructed with the same durability as a full-size tire and should be removed from service as soon as possible.

NOTE: When was the last time you checked the tire pressure in your spare tire? The spare tire pressure should be checked regularly.

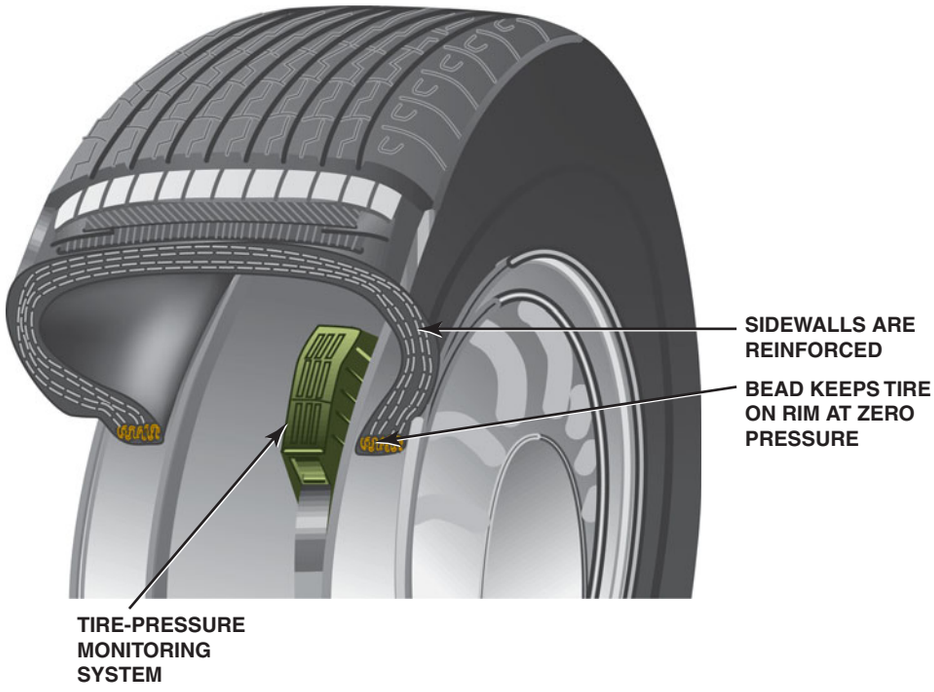

FIGURE 109–19 Cutaway of a run-flat tire showing the reinforced sidewalls and the required pressure sensor.

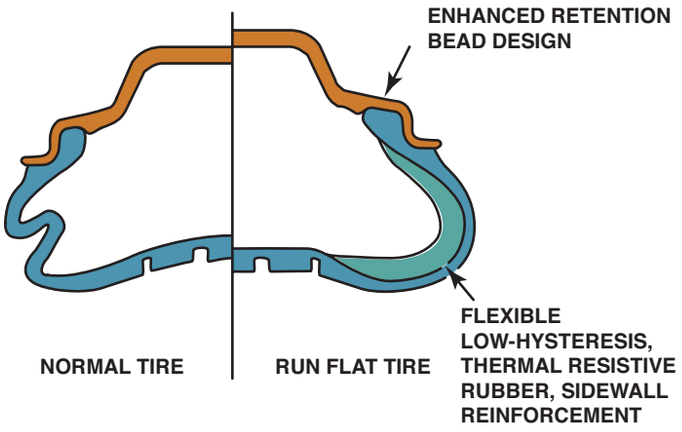

FIGURE 109–20 A conventional tire on the left and a run-flat tire on the right, showing what happens when there is no air in the tire.

RUN-FLAT TIRES

Run-flat tires (abbreviated RFT) are designed to operate without any air for a limited distance (usually 50 miles at 55 mph). This feature allows vehicle manufacturers to build vehicles without the extra room and weight of a spare tire and jack assembly.

A typical run-flat tire (also called *extended mobility tire* [EMT] or *zero pressure* [ZP] *tire*) requires the use of an air pressure sensor/transmitter and a dash-mounted receiver to warn the driver that a tire has lost pressure. Because of the reinforced sidewalls, the vehicle handles almost the same with or without air pressure. ● **SEE FIGURES 109–19 AND 109–20.**

CAUTION: Tire engineers warn that rapid cornering should be avoided if a run-flat tire has zero air pressure. The handling during quick maneuvers is often unpredictable and could be dangerous.

TECH TIP

PAX Replacement Tip

In most cases, the fastest and easiest approach to follow if a PAX tire requires replacement is to purchase a replacement tire/wheel assembly. While more expensive than replacing just the tire, this approach is often used to help the vehicle owner get back on the road faster without any concerns as to whether the replacement tire was properly installed.

PAX RUN-FLAT TIRES

Michelin developed a run-flat tire that has three unique components:

- A special wheel that has two bead seats that are of different diameters. The outside bead seat is 10 mm smaller in diameter than the inside bead seat. This means that a conventional tire cannot be installed on a PAX-style wheel.
- A urethane support ring that is designed to support the weight of the vehicle in the event of a flat tire.
- A special tire that is designed to operate without air. ● **SEE FIGURE 109–21.**

The PAX tire design has a unique sizing, such as:

P245/680R 460A 102V

P	= passenger
245	= the cross-section width in millimeters (mm)
680	= the tire diameter in mm (26.77 inches)
R	= radial ply construction
460	= the wheel, diameter in mm (18.1 inches)
A	= asymmetric wheel, meaning that one bead is smaller than the other bead by 10 mm (0.040 in.)
102	= the load index
V	= the speed rating

FIGURE 109–21 The PAX run-flat tire system is composed of three unique components—a special asymmetrical wheel, a urethane support ring, and special tire.

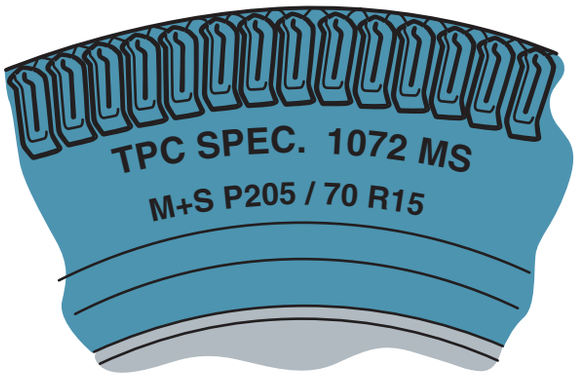

FIGURE 109–22 The Tire Performance Criteria (TPC) specification number is imprinted on the sidewall of all tires used on General Motors vehicles from the factory.

SERVICING A PAX WHEEL/TIRE ASSEMBLY If a flat tire occurs or when a PAX tire becomes worn and requires replacement, special care should be taken to properly remove the tire from the wheel. Because the urethane support ring prevents the tire bead from entering the dropped center section of the wheel, the outside bead should be broken from the wheel, and then the support ring removed before the tire can be removed from the wheel.

GENERAL MOTORS TPC RATING

All General Motors original equipment (OE) tires have a rating that identifies the size as well as the tread design, wear, traction, and heat resistance factors. All of these factors are combined in a set of numbers and letters that is imprinted in the tire mold. This is referred to as the **Tire Performance Criteria (TPC)** rating of the tire. If a customer wants to have the same tire performance in a replacement tire, then replace the tire with any brand of tire that has the same TPC identification. ● **SEE FIGURE 109–22.**

TIRE SELECTION CONSIDERATIONS

Selecting the proper tire is very important for the proper handling and safety of any vehicle. Do not select a tire by styling or looks alone. For best value and highest satisfaction, follow these guidelines:

Purchasing Suggestions	Reason Why
1. Purchase the same type of tire that came on your vehicle when new.	1. Chassis and tire engineers spend hundreds of hours testing and evaluating the best tire to use for each vehicle.
2. Purchase the same size as the original tire. The width of the tire should be within 10 mm of the width of the original tire. For example, a stock 195/75 × 14 tire's acceptable replacement *could be* 185/75 × 14 or 205/75 × 14.	2. The size of the tire is critical to the handling of any vehicle. Tire width, size, and aspect ratio affect the following: a. Braking effectiveness b. Headlight aiming c. Vehicle height d. Acceleration potential e. Speedometer calibration

? FREQUENTLY ASKED QUESTION

What Is a Low-Rolling-Resistance Tire?

Low-rolling-resistance (LRR) tires reduce rolling resistance, which is the power-robbing friction between the tire and crown. The **E-metric tire,** designated for use on electric or hybrid vehicles, operates at higher inflation pressures, reduced load percentages, and lower rolling resistance. These tires were first used on the GM EV1 electric vehicle.

To soften the ride of tires pumped with additional air, a new tire profile was developed. Narrower rim width and rounder sidewalls make the tire more shock absorbent.

To make the tires roll more freely, low-rolling-resistant tread compounds are molded into smaller tread elements that flex easily and with less friction when they touch the road. LRR tires are available from most major tire manufacturers, including Michelin the Energy MXV4 Plus and Goodyear VIVA 2. According to tire engineers, the basic tradeoff of low rolling resistance is poor wet traction performance. To improve wet road performance and traction requires the use of more silica in the tread, which increases the cost of the tire. Neither a technician nor a vehicle owner can determine the relative rolling resistance unless the tires are compared using a coast-down test from highway speed to zero or a laboratory testing machine.

Purchasing Suggestions	Reason Why
3. Purchase tires with the same speed rating as the original.	3. When any vehicle is manufactured, it is optimized for its designed use. High-performance tires are generally stiffer and have a speed rating as well. If you purchase non-high-performance tires, the carcass is not as stiff and the suspension is not designed to work with softer tires. Therefore, the cornering and handling, especially fast evasive maneuvers, could be dangerous. The vehicle may be capable of far more speed than the tires are designed to handle.
4. Purchase four of the same type of tire. Most vehicle manufacturers recommend against installing snow tires or all-season tires on just the drive wheels.	4. Every vehicle is designed to function best with four tires of the same size, construction, and tread design, unless the vehicle is specifically designed for different sizes of tires at the front and rear. Different tire styles and tread compounds have different slip angles. It is these different slip angles that can cause a vehicle to handle "funny" or cause the vehicle to get out of control in the event of a sudden maneuver.
5. Purchase the same *brand* of tire for both front and/or both rear wheels.	5. The sizes of tires are nominal and vary according to exact size (and shape) of the mold as well as tire design and construction. The same size of tire from two different manufacturers can often differ in diameter and width. While the differences should be slight, many vehicles are extremely sensitive to these small differences, and poor vehicle handling, torque steer, and pulling could result if different brands of tires are used.
6. Purchase fresh tires. Tires that are older may have been stored in a hot warehouse, where oxygen can attack rubber and cause deterioration.	6. Look at the tire build date code (the last three numbers of the DOT code). TRY to purchase four tires with the same or similar date codes.

CAUTION: If changing tire sizes or styles beyond the recommendations as stated here, consult a knowledgeable tire store representative for help in matching wheel and tire combinations to your vehicle.

NOTE: Some tires may be five or more years old when purchased. Always check the date code!

FIGURE 109–23 The size of the wheel is usually cast or stamped into the wheel. This wheel is 7 inches wide. The letter "J" refers to the contour of the bead seat area of the wheel.

WHEELS

TERMINOLOGY

The concept of a wheel has not changed in the last 5,000 years, but the style and materials used have changed a lot. Early automotive wheels were constructed from wood with a steel band as the tire.

Today's wheels are constructed of steel or aluminum alloy. The center section of the wheel that attaches to the hub is called the **center section** or **spider** because early wheels used wooden spokes that resembled a spider's web. The rubber tire attaches to the rim of the wheel. The rim has two *bead flanges* where the bead of the tire is held against the wheel when the tire is inflated. The shape of this flange is very important and is designated by Tire and Rim Association letters. For example, a wheel designated 14 × 6JJ means that the diameter of the wheel is 14 in. and the wheel is 6 in. wide measured from inside to inside of the flanges. The letters JJ indicate the *exact* shape of the flange area. ● **SEE FIGURE 109–23.** This flange area shape and the angle that the rim drops down from the flange are important because of the following:

- They permit a good seal between the rim and the tire.
- They help retain the tire on the rim in the event of loss of air. This is the reason why modern wheels are called "safety rim wheels." ● **SEE FIGURE 109–24.**
- Run-flat tires (tires that are designed to operate without air for a limited distance without damage) often require a specific wheel rim shape.

WHEEL OFFSET

Offset is a very important variable in wheel design. If the center section (spider) is centered on the outer rim, the offset is zero. Wheel offset is often referred to as ET, which stands for *Einpress Tieffe* in German. ● **SEE FIGURE 109–25.**

POSITIVE OFFSET

The wheel has a positive offset if the center section is outward from the wheel centerline. Front-wheel-drive vehicles commonly use positive-offset wheels to improve the loading on the front wheels and to help provide for a favorable scrub radius.

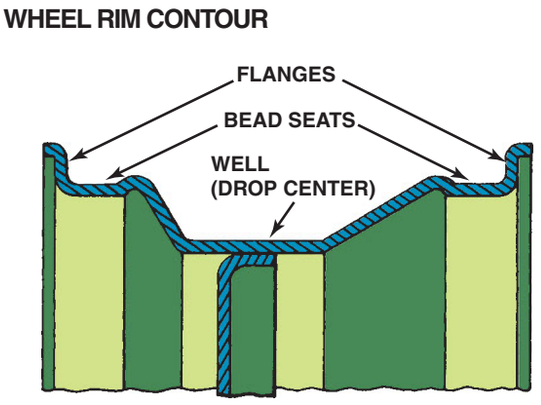

FIGURE 109–24 The wheel rim well provides a space for the tire to fit during mounting; the bead seat provides a tire-to-wheel sealing surface; the flange holds the beads in place.

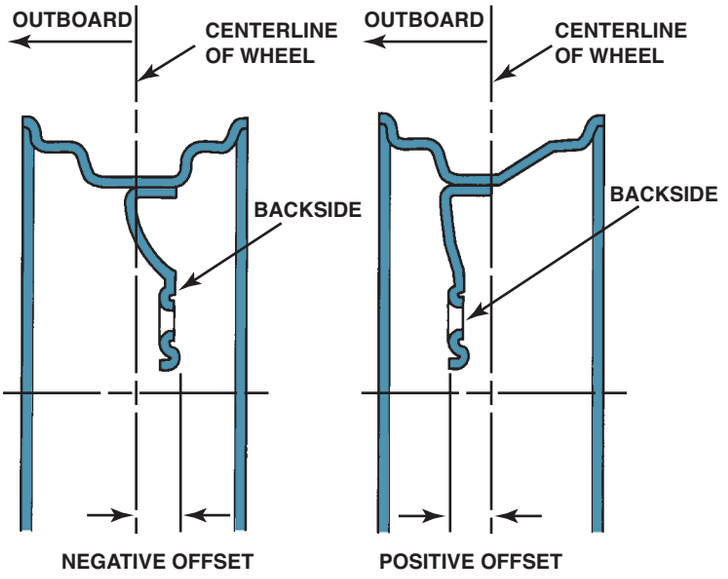

FIGURE 109–26 Offset is the distance between the centerline of the wheel and the wheel mounting surface.

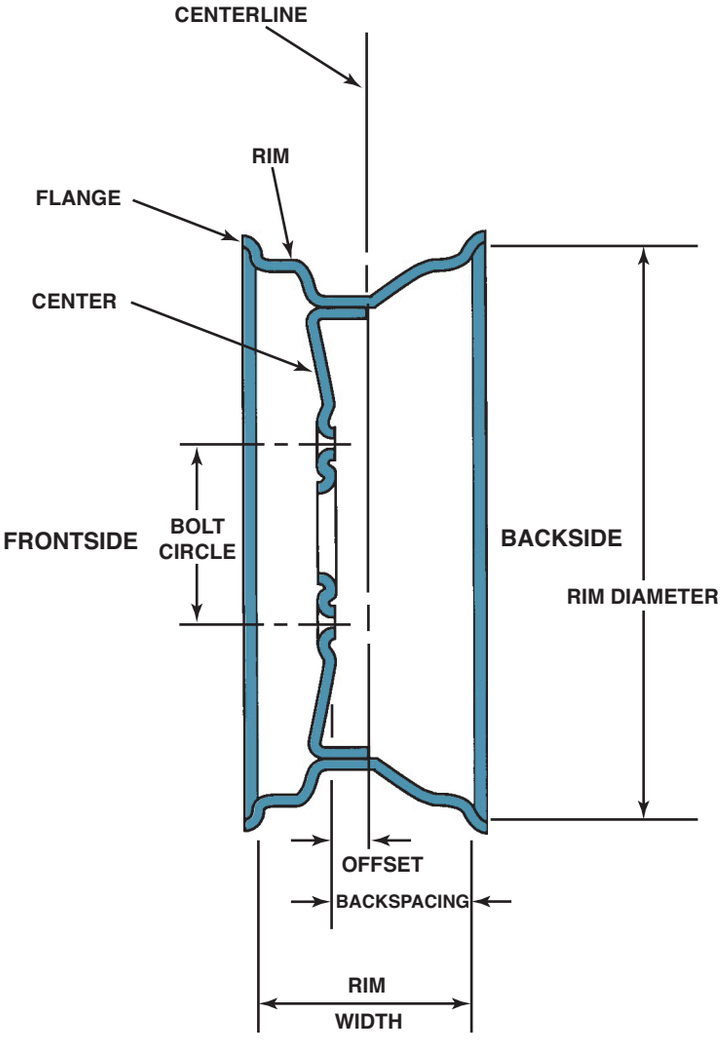

FIGURE 109–25 A cross section of a wheel showing part designations.

NEGATIVE OFFSET

The wheel has a negative offset if the center section is inboard (or "dished") from the wheel centerline. ● **SEE FIGURE 109–26.** Avoid using replacement wheels that differ from the original offset.

BACK SPACING

Back spacing, also called *rear spacing* or *backside setting,* is the distance between the back rim edge and the wheel center section mounting pad. **This is not the same as offset.** Back spacing can be measured directly with a ruler, as shown in ● **FIGURE 109–27.**

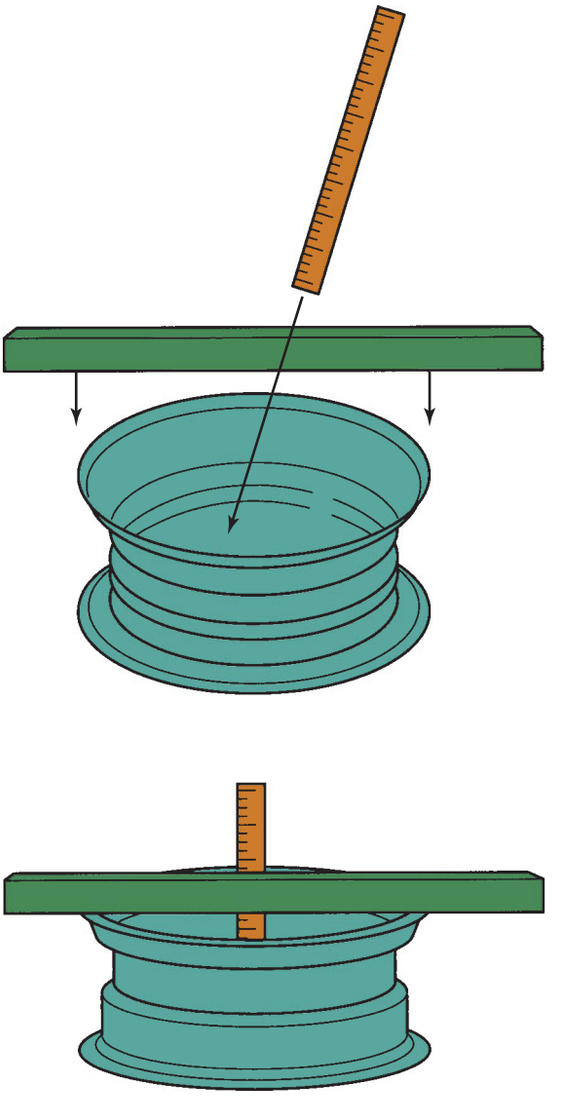

FIGURE 109–27 Back spacing (rear spacing) is the distance from the mounting pad to the edge of the rim. Most custom wheels use this measurement method to indicate the location of the mounting pad in relation to the rim.

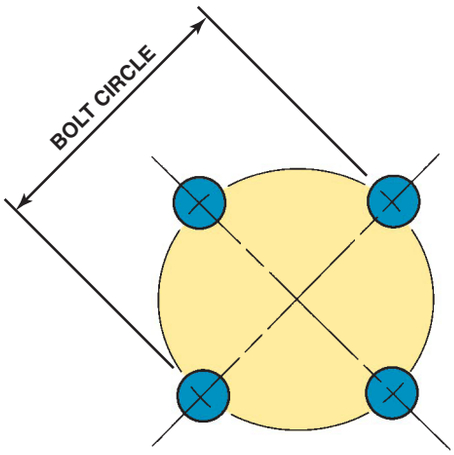

FIGURE 109–28 Bolt circle is the diameter of a circle that can be drawn through the center of each lug hole or stud. The bolt circle is sometimes referred to as PCD for pitch circle diameter.

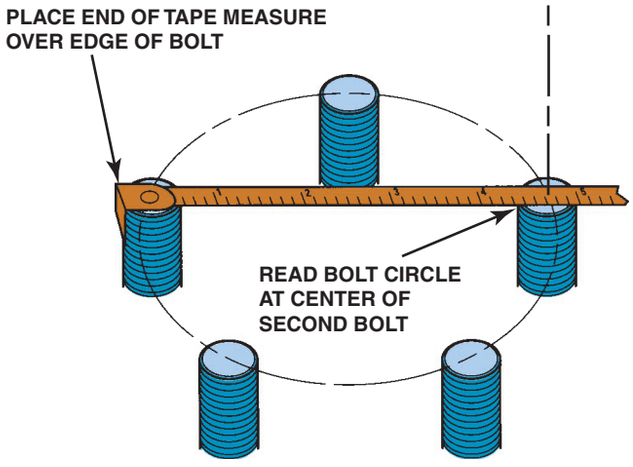

FIGURE 109–29 Measuring the bolt circle on a five lug wheel is difficult, but a quick and easy way includes measuring as shown to determine the approximate bolt circle of a five-lug wheel.

DETERMINING BOLT CIRCLE

On four-lug axles and wheels, the **bolt circle** measurement is simply taken from center to center on opposite studs or holes, as shown in ● **FIGURE 109–28.**

On five-lug axles and wheels, it is a little harder to determine bolt circle. One method is to measure from the far edge of one bolt hole to the center of the hole two over from the first, as shown in ● **FIGURE 109–29.** Another method for a five-lug wheel is to measure from center to center between two adjacent studs and convert this measurement into bolt circle diameter, as in the following chart. ● **SEE FIGURE 109–30.**

Center-to-Center Distance	Bolt Circle Diameter
2.645 in.	41/2-in. bolt circle
2.792 in.	43/4-in. bolt circle
2.939 in.	5-in. bolt circle
3.233 in.	51/2-in. bolt circle

STEEL WHEELS

Steel is the traditional wheel material. A steel wheel is very strong due to its designed shape and the fact that it is *work hardened* during manufacturing. In fact, most of the strength of a steel wheel is due to its work hardening. Painting and baking cycles also increase the strength of a steel wheel. Steel wheels are formed from welded hoops that are flared and joined to stamped spiders.

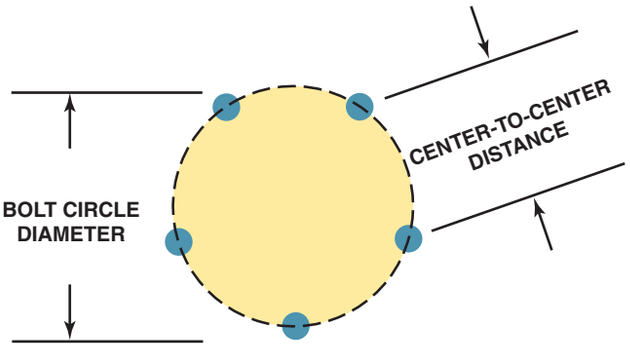

FIGURE 109–30 Measure center-to-center distance and compare the distance to the figures in the chart in the text to determine the diameter for a five-lug bolt circle.

? FREQUENTLY ASKED QUESTION

What Does This Mark in a Wheel Mean?

The symbol **JWL,** for the Japan Wheel Light Metal Standard Mark, means that the wheel meets the technical standards for passenger-car light-alloy wheels. See the mark in ● **FIGURE 109–31.**

The manufacturer is responsible for conducting the inspections set forth in the technical standard, and the JWL mark is displayed on those products that pass the inspection.

ALUMINUM WHEELS

Forged and cast aluminum wheels are commonly used on cars and trucks. *Forged* means that the aluminum is hammered or forged under pressure into shape. A forged aluminum wheel is much stronger than a *cast* aluminum wheel.

A cast aluminum wheel is constructed by pouring liquid (molten) aluminum into a mold. After the aluminum has cooled, the cast aluminum wheel is removed from the mold and machined. Aluminum wheels are usually thicker than steel wheels and require special wheel weights when balancing. Coated or covered wheel weights should be used when balancing aluminum wheels to prevent galvanic corrosion damage to the wheel. Most aluminum wheels use an alloy of aluminum. Aluminum can be combined (alloyed) with copper, manganese, silicon, or other elements to achieve the physical strength and characteristics for the exact product. Aluminum ally wheels are often called alloy wheels.

Some racing wheels are made from a lighter-weight metal called magnesium. These wheels are called *mag* wheels (an abbreviation for *magnesium*). True magnesium wheels are not practical for production wheels because their cost and corrosion are excessive compared with steel or aluminum alloy wheels. The term *mag wheel,* however, is still heard when referring to alloy (aluminum) wheels.

NOTE: If purchasing replacement aftermarket wheels, check that they are certified by the SFI. SFI is the Specialty Equipment Manufacturers Association (SEMA) Foundation, Incorporated. SEMA and SFI are nongovernment agencies that were formed by the manufacturers themselves to establish standards for safety.

FIGURE 109–31 A typical JWL symbol for the Japan Wheel Light Metal standard mark.

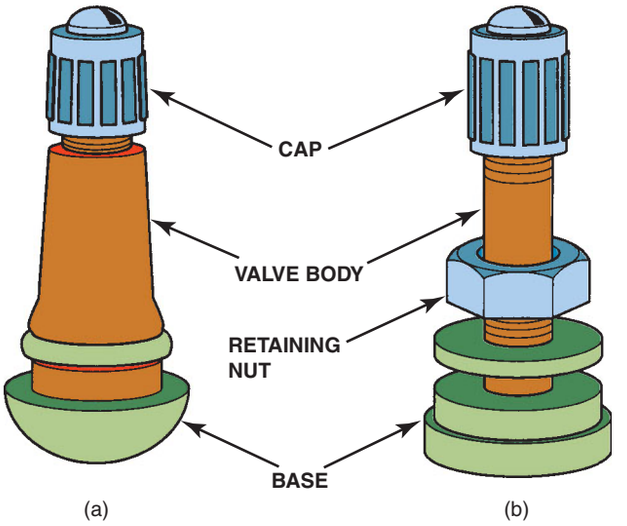

FIGURE 109–32 (a) A rubber snap-in style tire valve assembly. (b) A metal clamp-type tire valve assembly used on most high-pressure (over 60 PSI) tire applications such as is found on many trucks, RVs, and trailers. The internal Schrader valve threads into the valve itself and can be replaced individually, but most experts recommend replacing the entire valve assembly every time the tires are replaced to help prevent air loss.

TIRE VALVES

All tires use a tire valve, called a **Schrader valve,** to hold air in the tire. The Schrader valve was invented in New York in 1844 by August Schrader for the Goodyear Brothers: Charles, Henry, and Nelson. Today, Schrader valves are used not only as valves in tires but on fuel-injection systems, air-conditioning systems, and air shock (ride control) systems. Most tire experts agree that the valve stem (which includes the Schrader valve) should be replaced whenever tires are replaced–tires can last four or more years, and in that time the valve stem can become brittle and crack. A defective or leaking valve stem is a major cause of air loss. Low tire pressure can cause the tire to become overheated. Replacement valve stems are therefore a wise investment whenever purchasing new tires. Aluminum (alloy) wheels often require special metal valve stems that use a rubber washer and are actually bolted to the wheel. ● **SEE FIGURE 109–32.**

UNSPRUNG WEIGHT

The lighter the wheel and tire assembly, the faster it can react to bumps and dips in the road surface and thus the better the ride. The chassis and the body of any vehicle are supported by some sort of spring suspension system. It is the purpose of the suspension system to isolate the body of the vehicle from the road surface. Also, for best handling, all four tires must remain in contact with the road. After all, a tire cannot grip the road if it leaves the ground after hitting a bump. The wheel and tire are **unsprung weight** because they are not supported by the vehicle's springs. If heavy wheels or tires are used, every time the vehicle hits a bump, the wheel is forced upward. The heavy mass of the wheel and tire would transmit this force through the spring of the vehicle and eventually to the driver and passengers. Obviously, a much lighter wheel and tire assembly reacts faster to bumps and dips in the road surface. The end result is a smoother-riding vehicle with greater control.

An aluminum wheel is *generally* lighter than the same-size stamped steel wheel. This is not always the case, however, so before purchasing aluminum wheels, check their weight!

NOTE: Putting oversized tires on an off-road-type vehicle is extremely dangerous. The increased unsprung weight can cause the entire vehicle to leave the ground after hitting a bump in the road. The increased body height necessary to clear the larger tires seriously affects driveshaft angles and wheel alignment angles, making the vehicle very difficult to control.

LUG NUTS

PURPOSE AND FUNCTION **Lug nuts** are used to hold a wheel to the brake disc, brake drum, or wheel bearing assembly. Most manufacturers use a stud in the brake or bearing assembly with a lug nut to hold the wheel. Some models of VW, Audi, and Mazda use a lug *bolt* that is threaded into a hole in the brake drum or bearing assembly.

NOTE: Some aftermarket manufacturers offer a stud conversion kit to replace the lug bolt with a conventional stud and lug nut.

Typical lug nuts are tapered so that the wheel stud will center the wheel onto the vehicle. Another advantage of the taper of the lug nut and wheel is to provide a suitable surface to prevent the nuts from loosening. The taper, usually 60 degrees, forms a wedge that helps ensure that the lug nut will not loosen. Steel wheels are deformed slightly when the lug nut is torqued down against the wheel mounting flange; be certain that the taper is *toward* the vehicle.

TYPES Many alloy wheels use a *shank-nut*-type lug nut that has straight sides without a taper. This style of nut must be used with wheels designed for this nut type. If replacement wheels are used on any vehicle, check with the wheel manufacturer as to the proper

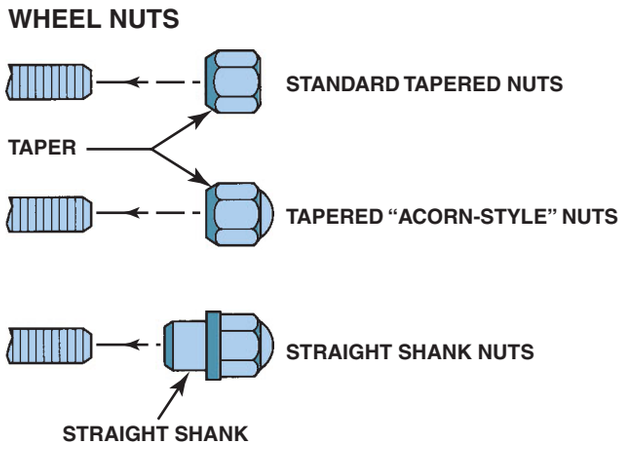

FIGURE 109–33 Various styles of lug nuts.

type and style of lug nut. ● **FIGURE 109–33** shows several of the many styles of lug nuts that are available.

SIZE Lug nuts are sized to the thread size of the stud onto which they screw. The diameter and the number of threads per inch are commonly stated. Since some vehicles use left-hand threads, RH and LH are commonly stated, indicating "right-hand" and "left-hand" threads. A typical size is 7/16-20RH, where the 7/16 indicates the diameter of the wheel stud and 20 indicates that there are 20 threads per inch. Another common fractional size is 1/2 × 20. Metric sizes such as M12 × 1.5 use a different sizing method.

M	metric
12	12-mm diameter of stud
1.5	1.5-mm distance from one thread peak to another

Other commonly used metric lug sizes include M12 × 1.25 and M14 × 1.5. Obviously, metric wheel studs require metric lug nuts.

LUG STUDS Lug studs are usually installed in hubs or drums using a press fit. Serrations on the shoulder of the stud provide support. Most studs are replaceable and should be replaced if the treads are damaged.

TIRE INSPECTION

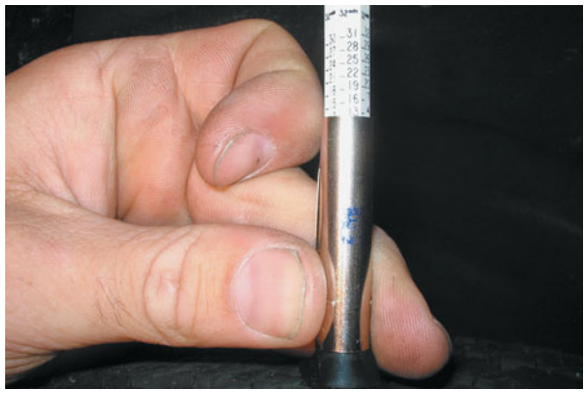
1 Check the tire information placard, usually located on the driver's door or door jamb, for the specified tire size and inflation pressure.

2 Visually check the tires for abnormal wear or damage.

3 Remove the tire valve cap and visually check the condition of the valve stem.

4 Check inflation pressure by pushing the tire pressure gauge straight onto the end of the tire valve. If a "hissing" sound is heard, then the reading will not be accurate.

5 Read the pressure and compare to specifications. Use an analog or digital gauge if possible which have been proven to be more accurate than a mechanical pencil-type gauge.



6 A typical tire tread depth gauge.

CONTINUED ▶

TIRE INSPECTION (CONTINUED)

7 The blade of the tire tread depth gauge is pushed down into the groove of the tire at the lowest part.

8 Remove the gauge from the tire and read the tread depth at the metal housing. Tread depth is usually measured in 1/32's of an inch.

9 If the top of Lincoln's head is visible, then the tread depth is lower than 2/32 in., the legal limit in many states.

REVIEW QUESTIONS

1. List the various parts of a tire and explain how a tire is constructed.
2. What is the aspect ratio?
3. List the factors that should be considered when purchasing tires.
4. Explain the three major areas of the Uniform Tire Quality Grading System.
5. How is the proper tire inflation pressure determined?

CHAPTER QUIZ

1. The part of the tire that is under just the tread of a radial tire is called the _____.
   - **a.** Bead
   - **b.** Body (carcass) ply
   - **c.** Belt
   - **d.** Inner liner
2. The aspect ratio of a tire means _____.
   - **a.** Its width to diameter of a wheel ratio
   - **b.** The ratio of height to width
   - **c.** The ratio of width to height
   - **d.** The ratio of rolling resistance

3. A tire is labeled 215/60R × 15 92T; the T indicates _____.
   a. Its speed rating
   b. Its tread wear rating
   c. Its load rating
   d. Its temperature resistance rating
4. The 92 in the tire designation in question 3 refers to the tire's _____.
   a. Speed rating
   b. Tread wear rating
   c. Load rating
   d. Temperature resistance rating
5. Radial tires can cause a vehicle to pull to one side while driving. This is called "radial tire pull" and is often due to _____.
   a. The angle of the body (carcass) plies
   b. Tire conicity
   c. Tread design
   d. Bead design
6. Tire inflation is very important to the safe and economical operation of any vehicle. Technician A says that the pressure should never exceed the maximum pressure imprinted on the sidewall of the tire. Technician B says to inflate the tires to the pressures recommended on the tire information decal or placard on the driver's door. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. When purchasing replacement tires, do not change tire width from the stock size by more than _____.
   a. 10 mm
   b. 15 mm
   c. 20 mm
   d. 25 mm
8. What do the letters JJ mean in a wheel designation size labeled 14 × 7JJ?
   a. The offset of the rim
   b. The bolt circle code
   c. The back spacing of the rim
   d. The shape of the flange area
9. Technician A says that a PAX run-flat tire uses a special wheel. Technician B says that a standard tire can be used to replace a PAX run-flat tire. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. Wheel back spacing is also called _____.
   a. Rear spacing
   b. Positive offset
   c. Negative offset
   d. Offset

chapter 110 TIRE PRESSURE MONITORING SYSTEMS

OBJECTIVES: **After studying Chapter 110, the reader will be able to:** • Explain why a tire-pressure monitoring system is used. • Describe how an indirect tire pressure monitoring system works. • Describe how a direct tire pressure monitoring system works. • Discuss the TREAD Act. • List the two types of TPMS sensors. • Describe how to program or relearn TPMS sensors. • List the tools needed to service a tire-pressure monitoring system.

KEY TERMS: Active mode 1265 • Alert mode 1265 • Cold placard inflation pressure 1262 • Delta pressure method 1267 • Initialization 1263 • Relearn 1263 • Sleep mode 1265 • Storage mode 1266 • Tire-pressure monitoring system (TPMS) 1261 • Transmitter ID 1267 • TREAD Act 1263

NEED FOR TIRE PRESSURE MONITORING

BACKGROUND A **tire-pressure monitoring system (TPMS)** is a system that detects a tire that has low inflation pressure and warns the driver. A tire-pressure monitoring system was first used when run-flat tires were introduced in the 1990s. A driver was often not aware that a tire had gone flat after a puncture. Because a run-flat tire is designed to be driven a limited distance and at limited speed after it loses air pressure, a method of alerting the driver had to be found. There were two systems used, indirect and direct, until the 2008 model year when the use of direct-reading pressure systems was required by law.

FIGURE 110–1 The tire pressure placard (sticker) on the driver's side door or door jamb indicates the specified tire pressure.

TEMPERATURE	TIRE PRESSURE (PSI)	CHANGE FROM COLD PLACARD INFLATION PRESSURE
120°F (49°C)	37	+5
110°F (43°C)	36	+4
100°F (38°C)	35	+3
90°F (32°C)	34	+2
80°F (27°C)	33	+1
70°F (21°C)	32	0
60°F (16°C)	31	−1
50°F (10°C)	30	−2
40°F (4°C)	29	−3
30°F (−1°C)	28	−4
20°F (−7°C)	27	−5
10°F (−12°C)	26	−6
0°F (−18°C)	25	−7
−10°F (−23°C)	24	−8
−20°F (−29°C)	23	−9

CHART 110–1

The effects of outside temperature on tire inflation, assuming a placard pressure of 32 PSI.

LOW TIRE PRESSURE EFFECTS

Low-tire inflation pressures have led to all of the following:

- Reduces fuel economy due to increased rolling resistance of the tires—3 PSI below specifications results in an increase of 1% in fuel consumption
- Reduces tire life—3 PSI below specifications results in a decrease of 10% of tire life
- Increases the number of roadside faults, which have been estimated to be 90% related to tire issues
- Reduces handling and braking efficiency
- Hundreds of deaths and thousands of personal injuries are due to problems associated with low-tire inflation pressure.

COLD PLACARD INFLATION PRESSURE

The term **cold placard inflation pressure** is used in service information to indicate the specified tire inflation pressure. The "placard" is the driver's side door jamb sticker that shows the tire size and the specified tire inflation pressure. The pressure stated is measured when the tires are cold or at room temperature, which is about 70°F (21°C). ● **SEE FIGURE 110–1.**

The tires become warmer while the vehicle is being driven, so tires should be checked before the vehicle has been driven or allowed to cool after being driven. Tire inflation pressure changes 1 PSI for every 10 degrees. ● **SEE CHART 110–1.**

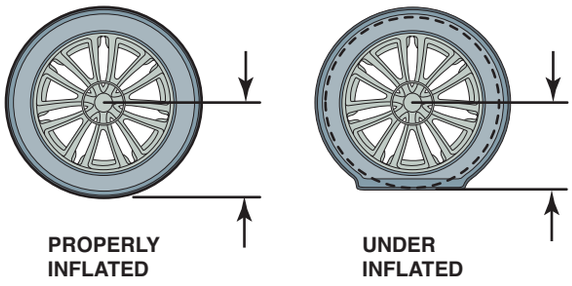


FIGURE 110–2 A tire with low inflation will have a shorter distance (radius) between the center of the wheel and the road and will therefore rotate faster than a tire that is properly inflated.

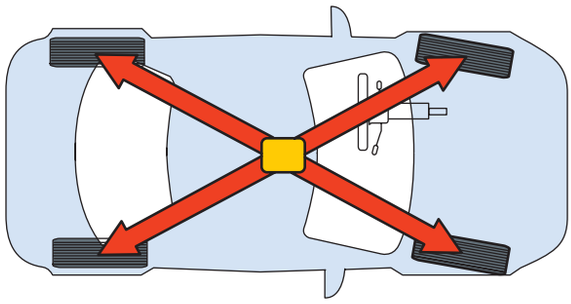

FIGURE 110–3 The speeds of the diagonally opposed wheels are added together and then compared to the other two wheels to check if one tire is rotating faster.

INDIRECT TPMS

PURPOSE AND FUNCTION

Indirect tire-pressure monitoring systems do not measure the actual tire pressure. Instead, the system uses the wheel speed sensors to detect differences in the speed of the wheels. The indirect system uses the wheel speed sensors to check the rolling speed of each of the tires. If a tire is underinflated, the following occurs:

- A tire that is underinflated will have a smaller diameter than a properly inflated tire. ● **SEE FIGURE 110–2.**
- An underinflated tire will rotate faster than a properly inflated tire.

COMPENSATION FOR CORNERING

When a vehicle turns a corner, the outside wheels rotate faster than the inside wheels. To compensate for this normal change in wheel rotation speed, the indirect tire-pressure monitoring system checks the diagonally opposed wheels. ● **SEE FIGURE 110–3.**

If the calculation of the diagonal wheel speed indicates that one of the wheels is rotating faster than the other, the TPMS warning light is illuminated.

ADVANTAGES Advantages for using the indirect system include:

- This system does not require additional components, such as tire-pressure sensors.
- This system is easily added to existing vehicles that were equipped with four-wheel speed sensors.
- It is low cost.

DISADVANTAGES Disadvantages for using the indirect system include:

- System cannot detect if all four tires are underinflated.
- Use of a space-saver spare tire may trigger the warning light.
- Cannot detect if more than one tire is low.
- Does not meet the Federal Highway Traffic Safety Standard (FMVSS) 138, which requires the system to be able to detect if any tire is underinflated by 25%.

DIAGNOSIS OF INDIRECT TPMS The diagnosis of an indirect tire-pressure monitoring system includes the following steps:

STEP 1 Verify the fault.
- If the TPMS warning light is on but not flashing, this indicates that the system has detected a tire with low inflation pressure.
- If the TPMS warning light flashes, this indicates that the system has detected a fault. Check service information for the specified steps to follow.

STEP 2 If the system has detected low tire pressure, check and adjust the tire pressure to that listed on the door pillar placard or factory specifications as stated in the owner's manual or service information.

STEP 3 Determine and correct the cause of the underinflated tire.

RELEARN (RESET) PROCEDURES After checking that all four tires are the same size and condition, the system may require resetting, also called **relearn** or **initialization.** Check service information for the exact steps to follow, which could include driving the vehicle over an extended period of time. The procedure usually includes the following:

- Inflate all four tires to the placard inflation pressure.
- Depress and hold the reset switch for 3 seconds. **SEE FIGURE 110–4.** The TPMS warning lamp should flash three times.
- Drive the vehicle so the ABS controller can learn the new "good" values. Typical driving times include:
  - Ford—20 minutes of driving
  - Toyota—30 to 60 minutes of driving
  - General Motors—60 minutes of driving

Check service information for the exact procedure to follow. Many service technicians ask the vehicle owner to drive the vehicle instead of taking the technician's time.

DIRECT TPMS

PURPOSE AND FUNCTION Direct tire pressure monitoring systems use a pressure sensor in each wheel that detects and transmits the tire pressure to a TPMS controller. This system means that the controller can notify the driver if any one or all of the tires are under-inflated. While some vehicles used the direct system for many years especially those vehicles equipped with run-flat tires such as the Chevrolet Corvettes, it was not until 2008 when all vehicles sold in the United States were required to be equipped with a direct tire pressure monitoring system.

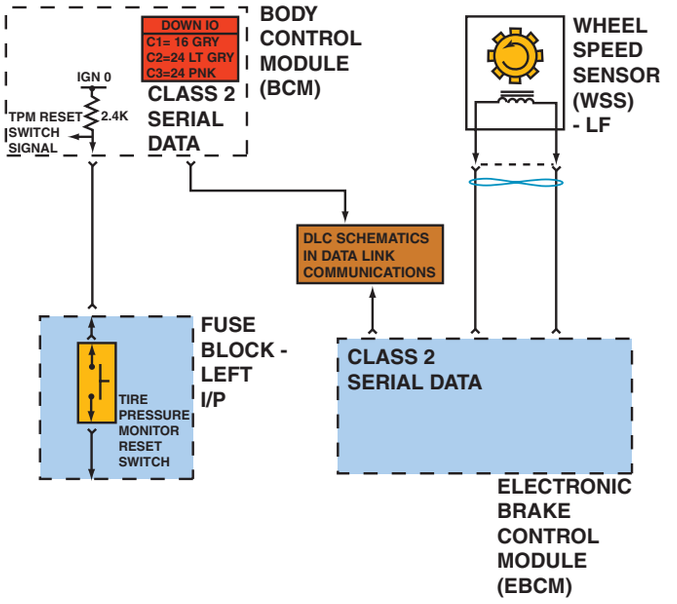

FIGURE 110–4 The indirect tire-pressure monitoring system has a reset switch that should be depressed after rotating or replacing tires.

TREAD ACT The **Transportation Recall Enhancement, Accountability and Documentation (TREAD) Act** requires that all vehicles be equipped with a tire-pressure monitoring system that will warn the driver in the event of an underinflated tire. This act was passed due to many accidents that were caused at least in part to underinflated tires. These accidents resulted in many deaths.

Congress passed the TREAD Act on November 1, 2000. The National Highway Traffic Safety Administration (NHTSA) requires the installation of tire-pressure monitoring systems (TPMSs) in passenger vehicles and light trucks manufactured after September 1, 2007 (2008 model year).

The NHTSA ruling is part one of a two-part final ruling.

- Part one establishes a new Federal Motor Vehicle Safety Standard (FMVSS) 138 that requires tire-pressure monitoring systems be installed in passenger vehicles and light trucks to warn the driver when a tire is 25% below the cold placard pressure.
- Part two includes the requirement to equip vehicles with a tire-pressure monitoring system that was phased-in starting in 2004. The phase-in included:
  - 20% from October 5, 2005 to August 31, 2006
  - 70% from September 1, 2006 to August 31, 2007
  - 100% from September 1, 2007 (2008 model year vehicles)

FMVSS 138 requires all cars, trucks, and vans with a gross vehicle weight rating (GVWR) of 10,000 pounds or less to illuminate a warning lamp within 10 minutes when the inflation pressure drops 25% or more from the vehicle manufacturer's specified cold tire inflation pressure as printed on the door placard.

WARNING LAMP The FMVSS 138 specifies that the driver must be warned of a low-tire inflation pressure by turning on an amber warning lamp. The warning lamp must also come on during a bulb check. The spare tire is not required to be monitored, but many vehicle manufacturers do equip full-size spare tires with a pressure sensor.

COLD PLACARD INFLATION PRESSURE (PSI)	WARNING LIGHT PRESSURE (−25%)	PSI LOW
40	30.0	10.0
39	29.3	9.7
38	28.5	9.5
37	27.8	9.2
36	27.0	9.0
35	26.3	8.7
34	25.5	8.5
33	24.8	8.2
32	**24**	**8.0**
31	23.3	7.7
30	22.5	7.5
29	21.8	7.2
28	21	7.0

CHART 110–2

Placard inflation pressure compared with the pressure when the TPMS triggers a warning light.

FIGURE 110–5 A clear plastic valve-stem tire-pressure monitoring sensor, showing the round battery on the right and the electronic sensor and transistor circuits on the left.

TECH TIP

Check Tire Pressure and Do Not Rely on the Warning Light

Industry experts think that 25% is too low and that this generally means that a tire has to be lower by about 8 PSI to trigger a warning light. All experts agree that tire pressure should be checked at least every month and kept at the specified cold placard inflation pressure.

- If the TPMS warning lamp is on at start-up, the system has detected a tire with low inflation pressure.
- If the TPMS warning lamp is flashing for 60 to 90 seconds, a system fault has been detected.

TWENTY-FIVE PERCENT RULE The TREAD Act specifies that the driver be warned if any tire inflation pressure drops by 25% or more from the cold placard pressure. ● **SEE CHART 110–2.**

IDENTIFYING A VEHICLE WITH TPMS

All vehicles sold in the United States since the 2008 model year must be equipped with a tire-pressure sensor. If the tire/wheel assembly has a tire-pressure monitoring system (TPMS) valve-type sensor, it can usually be identified by the threaded portion of the valve stem. ● **SEE FIGURE 110–5.**

RUBBER TIRE VALVE STEMS Some TPMS sensors are black rubber like a conventional valve core but it uses a tapered brass section and a longer cap. ● **SEE FIGURE 110–6.** If the cap is short then it does not have a stem-mounted tire-pressure sensor. However, the wheel may be equipped with a wheel-mounted sensor, so care should still be taken to avoid damaging the sensor during service.

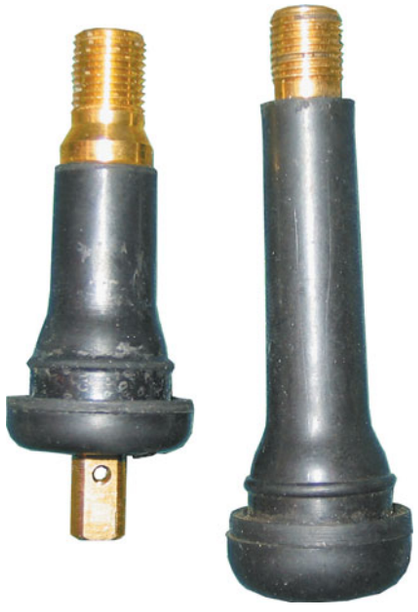

FIGURE 110–6 A conventional valve stem is on the right compared with a rubber TPMS sensor stem on the left. Notice the tapered and larger brass stem. The rubber TPMS sensor also uses a longer cap that makes it easy for a technician to spot that this is not a conventional rubber valve stem.

ALUMINUM TIRE VALVE STEMS If the vehicle has an aluminum tire valve stem, it is equipped with a direct tire-pressure monitoring system. The valve stem itself is the antenna for the sensor.

TPMS PRESSURE SENSORS

TYPES All direct TPMS sensors transmit tire inflation pressure to a module using a radio frequency (RF) signal. There are two basic designs used in direct pressure-sensing systems.

FIGURE 110–7 The three styles of TPMS sensors most commonly found include the two stem-mounted (rubber and aluminum, left and top), and the banded style (right).

FIGURE 110–8 A typical tire-pressure monitoring system tester. The unit should be held near the tire and opposite the valve stem if equipped with a wheel-mounted sensor, and near the valve stem if equipped with a valve-stem-type sensor.

TECH TIP

Use TPMS-Friendly Replacement Tires

Some replacement tires use steel body plies and could therefore block the low-level radio frequency signal sent from the tire-pressure sensor. Before installing replacement tires, check that the tires are safe and recommended for use on vehicles equipped with a direct-type tire-pressure monitoring system.

These sensors are manufactured by a variety of manufacturers, including:

- Beru
- Lear
- Pacific
- Schrader
- Siemens
- TRW

Each sensor uses a 3-volt lithium ion battery that has a service life of 7 to 10 years.

1. **Valve stem-mounted sensor**—This type of sensor uses the valve stem as the transmitter. The correct (nickel plated) valve core *must* be used in the aluminum valve stem. If a conventional brass valve is used, moisture in the air will cause corrosion between the two different metals.
2. **Banded sensor**—Banded sensors are installed in the drop well of the wheel and banded or clamped to keep them secure. Early banded sensors, such as those used in Corvettes equipped with run-flat tires, were piezoelectric and did not require a battery. All newer banded sensors include a battery.

   ● **SEE FIGURE 110–7.**

MODES OF OPERATION Tire-pressure sensors operate in three modes of operation:

1. **Active mode**—When the sensor inside detects that the vehicle is traveling above 20 mph (32 km/h), the sensor transmits once every minute.

TECH TIP

Check the TPMS Sensors Before and After Service

It is wise to check that all of the tire-pressure monitoring system sensors are working before beginning service work. For example, if the tires need to be rotated, the sensors will have to be reprogrammed for their new location. If a tire-pressure monitoring sensor is defective, the procedure cannot be performed. Use an aftermarket or original equipment tire-pressure monitoring sensor tester, as shown in ● **FIGURE 110–8.**

Then the tire-pressure sensors should be checked again after the service to make sure that they are working correctly before returning the vehicle to the customer.

2. **Sleep mode**—When the vehicle is stopped, the sensor "goes to sleep" to help improve battery life. In this mode, the transmitter still will broadcast tire inflation information every hour or every 6 hours, depending on the sensor.
3. **Alert mode**—Alert mode is triggered if a rapid change in inflation pressure is detected. In alert (or rapid mode), the tire inflation pressure is sent about every second (every 800 milliseconds on some sensors).

TPMS SENSOR OPERATION

Depending on the type and manufacturer, tire-pressure monitoring sensors can be any of several different designs. The TREAD Act does not specify the type or operation of the pressure sensors, only that the system must be capable of measuring tire inflation pressure and light the TPMS warning lamp. The types of sensors include:

- **Continuous-wave-type sensor**—designed to signal a tester when exposed to 5 to 7 seconds of continuous 125 KHz wave signal.

FIGURE 110–9 Some vehicles display the actual measured tire pressure for each tire on a driver information display.

FREQUENTLY ASKED QUESTION

Does a TPMS Sensor Work before Being Installed?

No. New tire-pressure warning sensors (transmitters) are shipped in **storage mode.** This mode prevents the battery from becoming discharged while in storage. When the transmitter is installed in a wheel/tire assembly and the tire is inflated to more than 14 PSI (97 kPa), the transmitter automatically cancels storage mode. Once a transmitter has canceled storage mode, it cannot enter this mode again. Therefore, once a sensor has been installed and the tire inflated above 14 PSI, the clock is ticking on battery life.

- **Magnetically-triggered-type sensor**—designed to trigger a tester if exposed to a powerful magnetic force.
- **Pulse-width-modulated-type sensor**—designed to be triggered when exposed to modulated wave 125 KHz signal.

The sensor also can vary according to the frequency at which it transmits tire-pressure information to the receiver in the vehicle. The two most commonly used frequencies are:

- 315 MHz
- 433.92 MHz (commonly listed as 434 MHz)

TPMS RECEIVER

The wireless TPMS receiver is housed in one of the following locations, depending on the vehicle:

- Remote keyless entry (RKE) receiver
- Body control module (BCM)
- Door module
- Individual antennas near each wheel well. These individual antennas then transmit tire-pressure information to the driver information center. ● **SEE FIGURE 110–9.**

DIRECT TPMS DIAGNOSIS

WARNING LIGHT ON If the TPMS warning light is on and not flashing, the system has detected a tire that has low inflation pressure. ● **SEE FIGURE 110–10.**

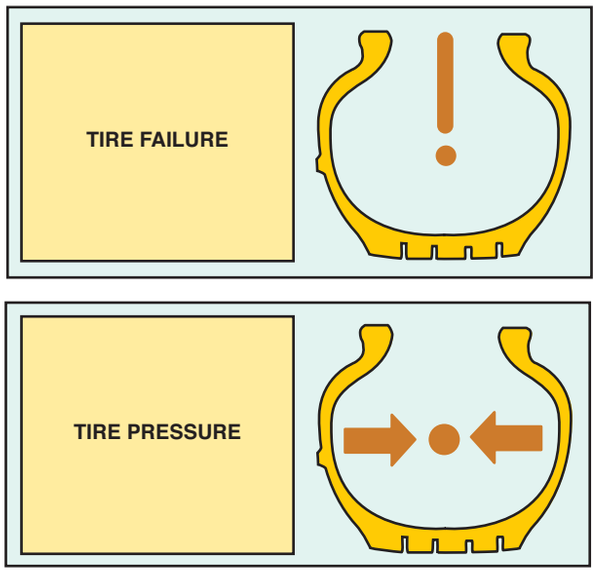

FIGURE 110–10 A tire-pressure warning light can vary depending on the vehicle, but includes a tire symbol.

If the TPMS light is on, perform the following steps:

STEP 1 Check the door placard for the specified tire inflation pressure.

STEP 2 Check all tires using a known-accurate tire-pressure gauge.

STEP 3 Inflate all tires to the specified pressure.

NOTE: Some systems will trigger the TPMS warning light if a tire is overinflated. An overinflated tire is also a safety-related problem.

WARNING LIGHT FLASHING If the TPMS warning lamp is flashing on and off, the system has detected a fault in the system. Faults could include:

- Defective wheel sensors, such as a sensor with a dead battery.
- A fault in the receiver, such as in the remote keyless entry module.

Check service information for the exact procedure to follow if the TPMS warning lamp is flashing. Always follow the specified diagnostic and service procedures.

INSTALLING A NEW PRESSURE SENSOR

When installing a new pressure sensor either because it failed or was damaged, the new sensor has to be relearned. This process is usually done with either:

- A scan tool
- A TPMS tester

The identification number on each sensor must be recorded before being installed, so it can register to a specific location on the vehicle. All four sensor identification numbers usually have to be entered into the tool within 300 seconds (5 minutes). On some vehicles, all four sensors must be relearned even if only one sensor is replaced.

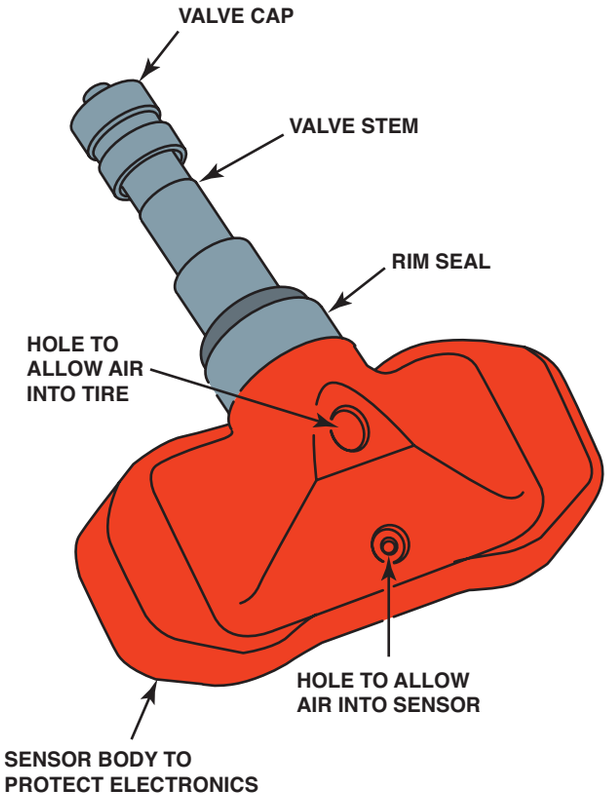

FIGURE 110–11 The parts of a typical stem-mounted TPMS sensor. Notice the small hole used to monitor the inflation pressure. The use of stop-leak can easily clog this small hole.

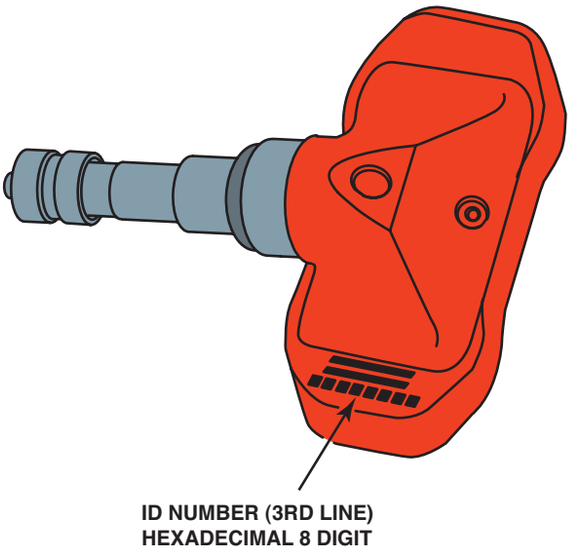

FIGURE 110–12 When replacing a TPMS sensor, be sure to record the sensor ID because this needs to be entered into the system through the use of a tester or scan tool.

FIGURE 110–13 A magnet is placed around the valve stem to reprogram some stem-mounted tire-pressure sensors.

TECH TIP

Check the Spare Tire

Many vehicles equipped with a full-size spare tire also have a TPMS sensor. If the inflation pressure decreases enough, the system will trigger the TPMS warning light. This is confusing to many vehicle owners who have checked all four tires and found them to be properly inflated. This fault often occurs during cold weather when the tire inflation pressure drops due to the temperature change. Most 2008 and newer vehicles equipped with a full size spare tire will come equipped with a TPMS sensor in the spare.

TPMS DIAGNOSTIC TOOLS

SCAN TOOLS Scan tools can be used for TPMS service if the scan tool is an original equipment tool for the vehicle make or if an aftermarket scan tool has original equipment-compatible software to access the chassis or body functions of the vehicle. A scan tool is used to perform the following functions:

1. **Register TPMS sensors**—A replacement TPMS transmitter has an 8-digit number, called the **transmitter ID,** on each valve/transmitter assembly. ● **SEE FIGURE 110–11.**
2. **Perform initialization**—This step assigns a transmitter ID to the correct position on the vehicle, such as right front (RF). ● **SEE FIGURE 110–12.**
3. **Monitor sensor values**—TPMS transmitters send information to the controller including:
   - Sensor identification
   - Tire inflation pressure
   - Tire air temperature (some sensors)
   - Sensor battery voltage (some sensors)

TPMS SENSOR ACTIVATIONS

ACTIVATING THE SENSOR A tire-pressure monitoring system sensor needs to be activated to verify that the sensor actually works. This should be performed before any tire or wheel service is performed. There are three methods used to activate a TPMS sensor to cause it to send a signal that can be captured to verify proper operation. These activation methods include:

1. **Using a magnet** (aluminum wheels and stem-mounted sensors only) ● **SEE FIGURE 110–13.**
2. **Changing inflation pressure** (usually requires lowering the inflation pressure by 5 to 10 PSI) This method is called the **delta pressure method.** The term *delta* refers to a change and is named for the Greek letter delta (Δ).

FIGURE 110–14 Always use an accurate, known-good tire-pressure gauge. Digital gauges are usually more accurate than mechanical gauges.

3. **Triggered by a handheld TPMS tester** that transmits a signal to wake up the sensor. There are two formats used, depending on the sensor. They include:
   - 125 KHz constant or continuous pulse
   - 125 KHz pulse-width-modulated pulse

HANDHELD TESTERS Several manufacturers produce handheld testers to reset the sensors. These tools are used to perform the following functions:

- TPMS sensor activation
- TPMS sensor relearn
- To program a new TPMS sensor

Tools are available from the following companies:

- OTC (http://www.otctools.com)
- Bartec (http://www.bartecusa.com)
- Snap-on (http://www.snapon.com)

TPMS RELEARN PROCEDURE

The following procedure will allow the service technician to reprogram the TPMS after tire rotation on a General Motors vehicle without using a scan tool.

1. With KOEO (key on, engine off), the "lock" and "unlock" buttons on the key fob should be simultaneously pressed and held. The horn will chirp within 10 seconds, indicating the receiver is in programming mode. The programming procedure must now be completed within five minutes, with no more than one minute between programming.

   NOTE: If the horn does not chirp at the start of this procedure, the TPMS option has not been enabled. A scan tool is needed to enable the system.

2. At the left front wheel, the special magnet tool must be held over the valve stem to force the sensor to transmit its code. The horn will chirp once, indicating the system has recognized the sensor. The next sensor must be programmed within one minute.
3. The remaining sensors should be programmed in the following order: RF, RR, LR. The horn will chirp once when each sensor has been detected. It will chirp twice to indicate completion of the programming process.

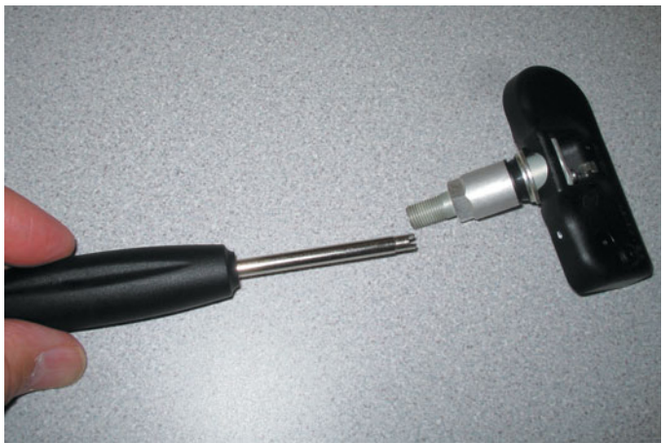

FIGURE 110–15 A clicker-type valve core tool ensures that the valve core is tightened to factory specifications.

TECH TIP

All TPMS Sensors Will Fail

All TPMS pressure sensors will fail because they contain a battery that has a service life of 7 to 10 years. What does this mean to the service technician? This means that if new tires are being installed on a 5- or 6-year-old vehicle equipped with tire-pressure sensors, then the customer should be notified that the TPMS sensors could fail almost anytime.

TPMS SENSOR SERVICE TOOLS

ITEMS NEEDED Whenever servicing a tire/wheel assembly that has a direct TPMS system, certain items are needed. When a stem-mounted sensor is removed, the following items are needed:

1. **Information**—Check service information for the exact procedure to follow for the vehicle being serviced. Vehicles and sensors are different for different vehicles.
2. **Digital tire-pressure gauge**—Many mechanical tire-pressure gauges are not accurate. An old mechanical gauge may be used to ensure that all tires are inflated to the same pressure, but the pressure may not be accurate. ● **SEE FIGURE 110–14.**
3. **Tire valve core torque wrench**—This calibrated tool ensures that the valve core is tightened enough to prevent air loss, but not too tight to cause harm. The recommended torque is 3 to 5 inch-pounds (0.34 to 0.56 N.m). ● **SEE FIGURE 110–15.**
4. **Tire valve nut torque wrench**—Most are 11 or 12 mm in size and the torque ranges from 30 to 90 in.-lb (4.25 to 10.0 N.m).
5. **Sensor service kit**—If a pressure sensor is going to be reused, the following service parts must be replaced:
   - Cap
   - Valve core (nickel plated only)
   - Nut
   - Grommet

   These parts are usually available individually or in an assortment package. Pressure sensor and kit information can be found at the following websites:

- http://www.schrader-bridgeport.com
- http://www.myerstiresupply.com
- http://www.rubber-inc.com

● **SEE FIGURE 110–16.**

? **FREQUENTLY ASKED QUESTION**

Can TPMS sensors be switched to new wheels?

Maybe. It depends on the style of the new or replacement wheels as to whether the sensors will fit or not. Some vehicles are designed to allow for a second set of sensors such as for winter tires. Many Lexus vehicles can be programmed to use set #1 or set #2. It is best to check before purchasing new wheels. Another set of TPMS sensors could be a major added expense.

FIGURE 110–16 An assortment of service parts that include all of the parts needed to service a stem-mounted TPMS sensor being installed after removal for a tire replacement or repair.

REVIEW QUESTIONS

1. How does the use of wheel speed sensors detect a tire with low inflation pressure?
2. What is the difference between faults when the TPMS warning lamp is on compared with when it is flashing?
3. What is the percentage of vehicles that each vehicle manufacturer must equip with TPMS?
4. TPMS pressure sensors can be made by what manufacturer?
5. What are the three modes of sensor operation?
6. What information is sent to the TPMS controller from the sensor?
7. After removing a stem-type pressure sensor to replace a tire or perform a tire repair, what should be replaced?

CHAPTER QUIZ

1. A tire with lower than specified inflation pressure could lead to what condition?
   a. Reduced fuel economy
   b. Reduced tire life
   c. Increased chances of roadside faults or accidents
   d. All of the above
2. Which tire inflation information should be checked to determine the proper tire inflation pressure?
   a. Cold placard inflation pressure
   b. The maximum pressure as stated on the sidewall of the tire
   c. 32 PSI in all tires
   d. Any of the above
3. Two technicians are discussing tire pressure and temperature. Technician A says that tire pressure will drop 1 PSI for every 10-degree drop in temperature. Technician B says that the tire pressure will increase as the vehicle is being driven. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. Two technicians are discussing the indirect tire-pressure monitoring system. Technician A says that it was used by some vehicle manufacturers on vehicles before the 2008 model year. Technician B says that it uses the speeds of the RF and LR tires and compares the rotating speeds of the LF and RR tires to detect a low tire. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. The FMVSS 138 law requires that the driver be notified if the tire inflation pressure drops how much?
   a. 30% **c.** 20%
   b. 25% **d.** 15%
6. The two basic types of direct TPMS sensors include _____.
   a. Rubber stem and aluminum stem
   b. Beru and Schrader
   c. Stem-mounted and banded
   d. Indirect and direct
7. What mode does a direct pressure sensor enter when the vehicle is stopped?
   a. Sleep mode **c.** Alert mode
   b. Storage mode **d.** Active mode
8. To activate or learn a direct pressure sensor, what does the service technician need to do?
   a. Enter learn mode and use a magnet
   b. Enter learn mode and decrease inflation pressure
   c. Use a handheld tester
   d. Any of the above depending on the vehicle and system
9. What does the “delta pressure method” mean?
   a. Change the inflation pressure
   b. Activate the sensor so it broadcasts the pressure to the scan tool
   c. Inflating the tire to the specified pressure
   d. Using a handheld tester to read the pressure as reported by the sensor
10. What type of valve core is used in stem-mounted sensors?
    a. Brass **c.** Steel
    b. Nickel plated **d.** Aluminum

chapter 111

TIRE AND WHEEL SERVICE

OBJECTIVES: After studying Chapter 111, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "E" (Wheel and Tire Diagnosis and Repair). • Discuss the need for proper inflation pressure. • Explain the purpose of nitrogen inflation. • Discuss proper tire mounting procedures. • Describe recommended tire rotation methods. • Discuss how to properly balance a tire. • Describe tire repair procedures. • Explain wheel and tire safety precautions.

KEY TERMS: Dynamic balance 1278 • Lateral runout 1277 • Match mounting 1272 • Modified X 1275 • Radial force variation 1277 • Radial runout 1276 • Shimmy 1277 • Static balance 1278 • Tire rotation 1274 • Tramp 1276 • Wheel mounting torque 1273

INTRODUCTION

Proper tire service is extremely important for the safe operation of any vehicle. Premature wear can often be avoided by checking and performing routine service, such as frequent rotation and monthly inflation checks. Avoid overloading the vehicle and have any leaks repaired as soon as possible. ● **SEE FIGURE 111–1.**

TIRE INFLATION

Tires should always be inflated to the pressure indicated on the driver's door or pillar sticker. Tires should be checked when cold, before the vehicle has been driven, because driving on tires increases the temperature and therefore the pressure of the tires. Proper tire inflation is important for the following reasons:

- **Inflation pressure carries the load of the vehicle.** If the pressure is low, the load capacity of the tire is decreased. ● **SEE FIGURE 111–2.**

FIGURE 111–1 Using soapy water from a spray bottle is an easy method to find the location of an air leak from a tire.

- **Inflation pressure varies with temperature.** Tires lose 1 PSI for every 10-degree drop in temperature. This means that as the sensors change and the temperature changes, so does the inflation pressure inside the tires. For example, if tires were inflated to 35 PSI on the first day of summer (June 21) when the temperature was 90°F (32°C), then the following pressures would occur, assuming no air loss at all:

  Summer (June 21) 90°F—35 PSI

  Fall (September 21) 80°F—34 PSI

  Winter (December 21) 30°F—29 PSI

  Therefore, it is very important to check and correct inflation pressures regularly.
- **Tire inflation affects fuel economy.** A drop in inflation pressure from 30 PSI to 23 PSI can result in a drop of fuel economy from 20 miles per gallon to 18 miles per gallon. ● **SEE FIGURE 111–3.**
- **Tire inflation affects tire life.** Even a slight drop in air pressure can have a major effect on the life of a tire. If, for example, the inflation pressure dropped 10 PSI, the life of the tire would be reduced by 40%. ● **SEE FIGURE 111–4.**
- **The TREAD Act specifies that the driver be notified if the inflation of a tire drops by 25%.** However, 25% represents a loss of air pressure of about 8 PSI. A drop of 8 PSI means an approximate 2-mpg decrease in fuel economy as well as about a 25% reduction in tread wear.

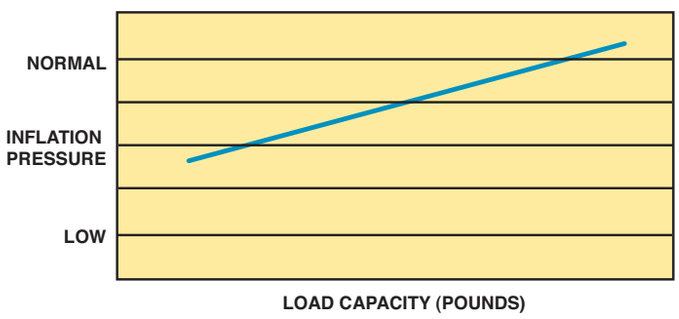

FIGURE 111–2 This chart shows the relationship between tire inflation pressure and load capacity of the tire.

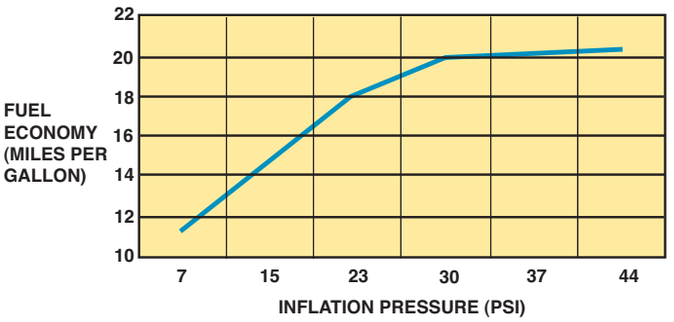

FIGURE 111–3 This chart shows that a drop in inflation pressure has a major effect on fuel economy.

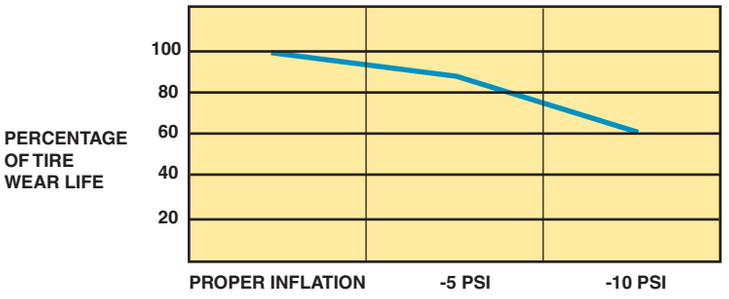

FIGURE 111–4 Notice that if a tire is underinflated by 10 PSI, the life expectancy is reduced by 40%.

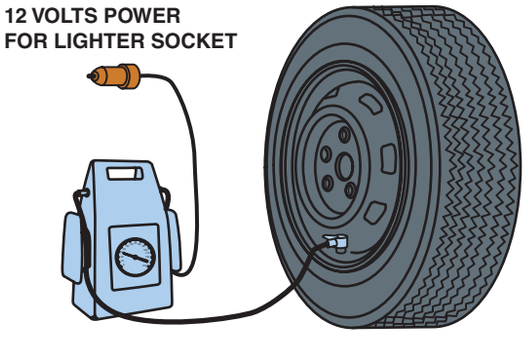

FIGURE 111–5 A temporary inflation pump that uses 12 volts from the cigarette lighter to inflate the tire.

FREQUENTLY ASKED QUESTION

What Is a "Temporary Mobility Kit"?

A temporary mobility kit is a system to inflate a flat tire supplied by the vehicle manufacturer instead of a spare tire. A temporary mobility kit can include:

- A compressor powered by the cigarette lighter. ● **SEE FIGURE 111–5.**
- An aerosol spray can that provides inflation and sealer. ● **SEE FIGURE 111–6.**

Either type can be found in many vehicles because such devices save weight, increase trunk space, and cost less than a conventional spare tire and jack. However, these kits are designed to be a temporary repair only because the cause of the low tire was never determined. If the tire appears to be fixed, many vehicle owners may think that the tire has been repaired. However, the tire should be carefully inspected inside and out for damage and properly repaired.

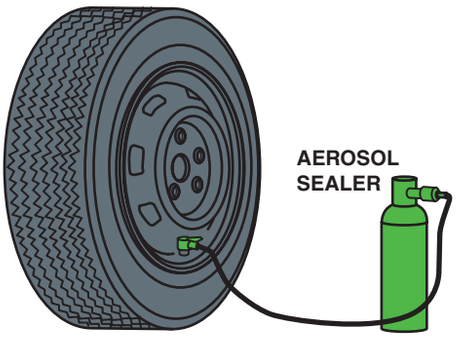

FIGURE 111–6 Many vehicle manufacturers include an aerosol can of sealer on vehicles that are not equipped with a conventional spare tire.

FIGURE 111–7 Most shops that use nitrogen inflation install a green tire value cap to let others know that nitrogen, rather than air has been used to inflate the tire.

NITROGEN INFLATION

PURPOSE Some shops recommend and inflate tires using nitrogen instead of using compressed air. Compressed air contains about 78% nitrogen, 21% oxygen, and 1% other gases. If air already contains mostly nitrogen, why use pure nitrogen? There are several reasons, including:

- The nitrogen molecule is slightly larger than the oxygen molecule so the tire will lose pressure faster if air is used instead of nitrogen.
- Compressed nitrogen contains less moisture than compressed air. When the tire heats up, moisture in the tire vaporizes and expands, causing the pressure inside the tire to increase. Even small changes in tire pressure can noticeably affect the handling of the vehicle.
- Race teams use nitrogen because they already come to the track with a cylinder of nitrogen to power the air tools.
- Race teams also have more control over how much the pressure will increase when the tires heat up, because nitrogen has less tendency to change pressure with temperature change.
- Some oxygen in the tires could, over a long period of time, cause the oxidation of the inner liner of the tire and the corrosion of the wheel. ● **SEE FIGURE 111–7.**

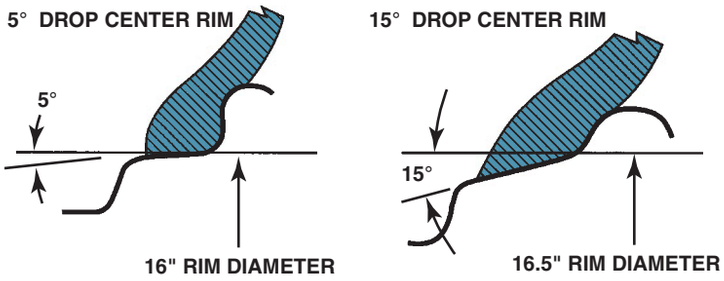

FIGURE 111–8 Note the difference in the shape of the rim contour of the 16-in. and 16 1/2-in. diameter wheels. While it is possible to mount a 16-in. tire on a 16 1/2-in. rim; it cannot be inflated enough to seat against the rim flange. If an attempt is made to seat the tire bead by overinflating (over 40 PSI), the tire bead can break, resulting in an explosive force that could cause serious injury or death.

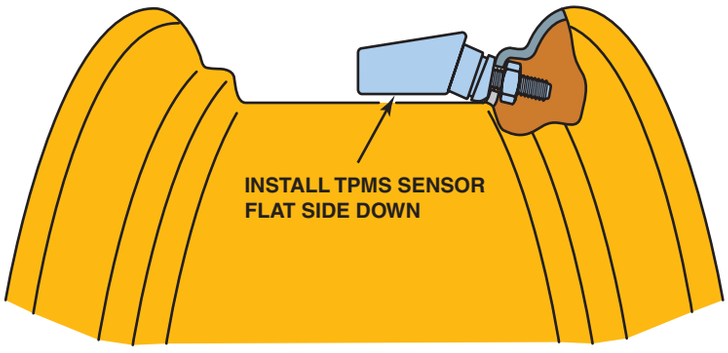

FIGURE 111–9 When installing a tire-pressure monitoring system sensor, be sure that the flat part of the sensor is parallel to the center section of the rim.

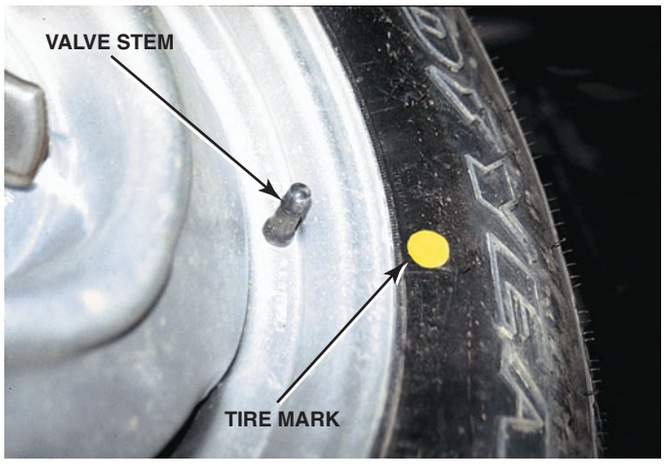
TIRE MOUNTING RECOMMENDATIONS

1. When removing a wheel from a vehicle for service, mark the location of the wheel and lug stud to ensure that the wheel can be replaced in exactly the same location. This ensures that tire balance will be maintained if the tire/wheel assembly was balanced on the vehicle.
2. Make certain that the wheel has a good, clean metal-to-metal contact with the brake drum or rotor. Rust, grease, oil, or dirt between these two surfaces could cause the wheel lug nuts to loosen while driving.
3. Always check the rim size. For example, simply by looking it is hard to distinguish a 16-in. wheel from a 16.5-in. wheel used on some trucks. ● **SEE FIGURE 111–8.** The rim size is marked on the sidewall of the tire, and the rim's diameter and width are stamped somewhere on the wheel.
4. Remove the tire from the rim following the instructions of the tire change machine adhering to all safety precautions.
5. Install a new tire valve or the tire-pressure monitoring system (as shown in ● **FIGURE 111–9**).



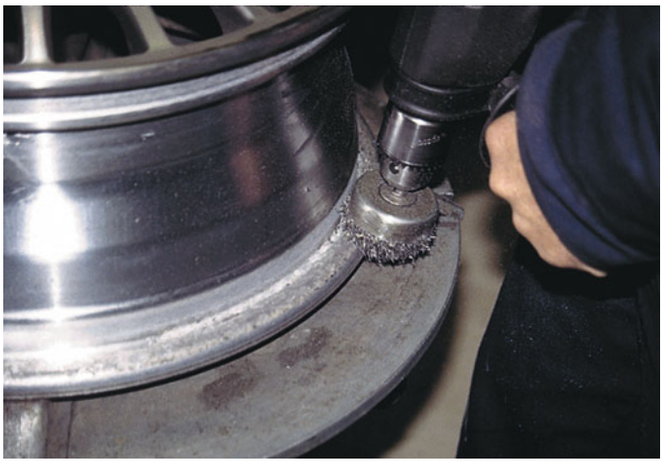


FIGURE 111–10 This tire on a new vehicle has been match mounted at the factory. The yellow sticker is placed at the largest diameter of the tire. The valve core hole in the wheel is usually drilled at the smallest diameter of the wheel. The best way to make sure the assembly is as round as possible and to reduce the number of wheel weights needed to balance the tire is to align the sticker with the valve core.

6. Many tires have been marked with a paint dot or sticker, as shown in ● **FIGURE 111–10.** This mark represents the largest diameter (high point) and/or stiffest portion of the tire. This variation is due to the overlapping of carcass and belt fabric layers, as well as tread and sidewall rubber splices. The tire should be mounted to the rim with this mark lined up with the valve stem. The valve stem hole is typically drilled at the smallest diameter (low point) of the wheel. Mount the tires on the rim with the valve stem matched to (lined up next to) the mark on the tire. This is called **match mounting.**
7. Never use more than 40 PSI (275 kPa) to seat a tire bead.
8. Rim flanges must be free of rust, dirt, scale, or loose or flaked rubber build-up prior to mounting the tire. ● **SEE FIGURE 111–11.**
9. When mounting new tires, do *not* use silicone lubricant on the tire bead. Use special lubricant such as rendered (odorless) animal fat or rubber lubricant to help prevent tire rotation on the rim. This rubber lube is a water-based soap product that is slippery when wet (coefficient of friction when less than 0.3) and acts almost as an adhesive when dry (coefficient of friction when dry of over 0.5 for natural products and over 1.0 for synthetic products). ● **SEE FIGURE 111–12.** If the wrong lubricant is used, the rubber in the bead area of the tire can be softened or weakened. Also, most other lubricants do not increase in friction when they dry like rubber lubricant does. The result can be the rotation of the tire on the rim (wheel), especially during rapid acceleration or braking.

NOTE: Many experts recommend that when a new tire is installed the vehicle should be driven at less than 50 mph (80 km/h) for the first 50 miles (80 km) to allow the tires to adhere to the rim. During this break-in period, the rubber lube used to mount the tire is drying and the tire is becoming fully seated on the rim. By avoiding high speeds, rapid acceleration, and fast braking, the driver is helping to prevent the tire from rotating on the rim.

(a)

(b)

FIGURE 111–11 (a) Cleaning the bead area of an aluminum (alloy) wheel using a handheld wire brush. The technician is using the tire changer itself to rotate the wheel as the brush is used to remove any remnants of the old tire. (b) Using an electric or air-powered wire brush speeds the process, but care should be exercised not to remove any of the aluminum itself. (Remember, steel is harder than aluminum and a steel wire brush could cause recesses to be worn into the aluminum wheel, which would prevent the tire from proper seating in the bead area.) The bead seat area on steel wheels should also be cleaned to prevent air leaks at the rim.

TECH TIP

Spin the Tires

When performing a vehicle inspection and the vehicle has been hoisted on a frame-type lift, check the tires by rotating them by hand. The tires on the nondrive wheels should spin freely.

- On front-wheel-drive vehicles, rear wheels should rotate easily.
- On rear-wheel-drive vehicles, front wheels should rotate easily.
- On all-wheel-drive vehicles, all four wheels may require effort to rotate.

What to Look For:

- When rotating the wheels, look at the tires from the front or rear and check that the tread of the tires does not change or look as if the tread is moving inward or outward. If the tread is moving, this indicates an internal fault with the tire and it should be replaced. This type of fault can cause a vibration even though the tire/wheel assembly has been correctly balanced.
- Look from the side of the vehicle as the wheel/tire assembly is being rotated. Look carefully at the tread of the tire and see if the tire is round. If the tire is out-of-round, the tread will appear to move up and down as the tire is being rotated.

WHEEL MOUNTING TORQUE

For **wheel mounting torque,** make certain that the wheel studs are clean and dry, and torqued to the manufacturer's specifications.

CAUTION: Most manufacturers warn that the wheel studs should not be oiled or lubricated with grease; this can cause the wheel lug nuts to loosen while driving. Always follow the vehicle manufacturers' recommended service procedures.

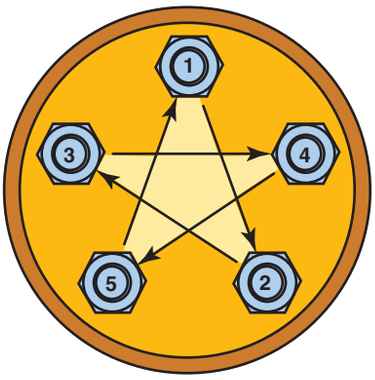

FIGURE 111–12 Rendered (odorless) animal fat is recommended by some manufacturers of tire changing equipment for use as a rubber lubricant.

Always tighten lug nuts gradually in the proper sequence—star pattern (tighten one nut, skip one, and tighten the next nut). This helps prevent warping the brake drums or rotors, or bending a wheel. ● **SEE FIGURE 111–13.**

Tire lug nuts should always be torqued to factory specifications. If the exact torque value is not available, use the following chart as a guide for the usual value based on the size (diameter) of the lug studs.

Stud Diameter	Torque (lb-ft)
3/8 in.	35–45
7/16 in.	55–65
1/2 in.	75–85
9/16 in.	95–115
5/8 in. (usually only trucks)	125–150
12 mm	70–80
14 mm	85–95

TORQUE SEQUENCE

FIGURE 111–13 Always tighten wheel lug nuts (or studs) in a star pattern to ensure even pressure on the axle flange, brake rotors or drums, and the wheel itself.

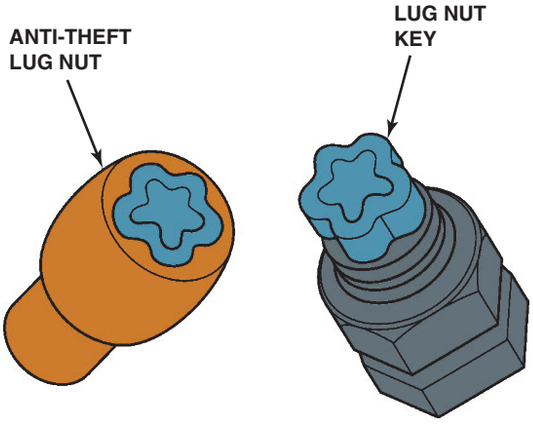

FIGURE 111–14 Most manufacturers recommend using hand tools rather than an air impact wrench to remove and install lock-type lug nuts to prevent damage. If either the key or the nut is damaged, the nut may be very difficult to remove.

Many factory-installed and aftermarket wheels use anti-theft wheel lug nuts, as shown in ● **FIGURE 111–14,** usually on only one wheel stud. When removing or installing a locked lug nut, be sure the key is held square to the lug nut to prevent damaging either the nut or the key.

Whenever you install a brand new set of aluminum wheels, re-torque the wheels after the first 25 miles. The soft aluminum often compresses slightly, loosening the torque on the wheels.

NOTE: The use of torque-absorbing adapters (torque-limiting shank sockets or torque sticks) on lug nuts with an air impact wrench properly set has proved to give satisfactory results. ● SEE FIGURE 111–15 for a photo of a torque-absorbing adapter.

TIRE ROTATION

To ensure long life and even tire wear, **tire rotation** is essential. It is important to rotate each tire to another location. Some rear-wheel-drive vehicles, for example, may show premature tire wear

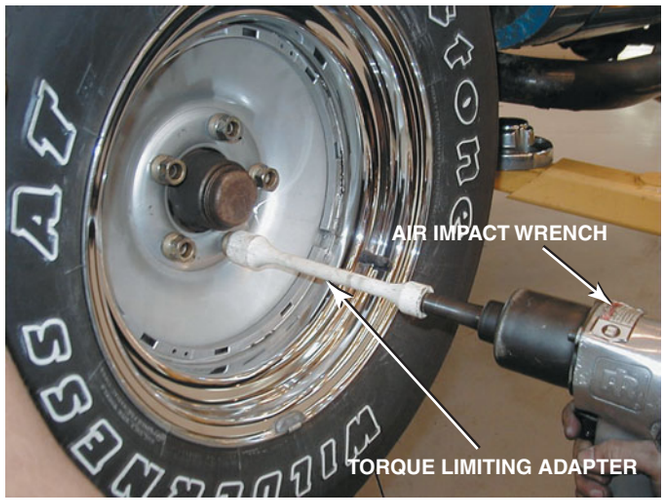

FIGURE 111–15 A torque-limiting adapter (torque stick) for use with an air impact wrench still requires care to prevent overtightening. The air pressure to the air impact should be limited to 125 PSI (860 kPa) in most cases, and the proper adapter must be selected for the vehicle being serviced. The torque adapter absorbs any torque beyond its designed rating. Most adapters are color coded for easy identification as to the size of lug nut and torque value.

TECH TIP

Fine-Tune Handling with Tire-Pressure Changes

The handling of a vehicle can be changed by changing tire pressures between the front and rear tires.

Understeer—A term used to describe how a vehicle handles when cornering where additional steering input is needed to maintain the corner, or resisting turning into a corner. This is normal handling for most vehicles.

Oversteer—A term used to describe handling where correction while cornering is often necessary because the rear tires lose traction before the front tires.

Tire Pressure	To Decrease Understeer	To Decrease Oversteer
Front tire inflation pressure	Increase	Decrease
Rear tire inflation pressure	Decrease	Increase

CAUTION: Do not exceed the maximum inflation pressure as imprinted on the tire sidewall.

REAL WORLD FIX

I Thought the Lug Nuts Were Tight!

Proper wheel nut torque is critical, as one technician discovered when a customer returned complaining of a lot of noise from the right rear wheel. ● **SEE FIGURE 111–16** for a photo of what the technician discovered. The lug (wheel) nuts had loosened and ruined the wheel.

CAUTION: Most vehicle manufacturers also specify that the wheel studs/nuts should not be lubricated with oil or grease. The use of a lubricant on the threads could cause the lug nuts to loosen.

FIGURE 111–16 This wheel was damaged because the lug nuts were not properly torqued.

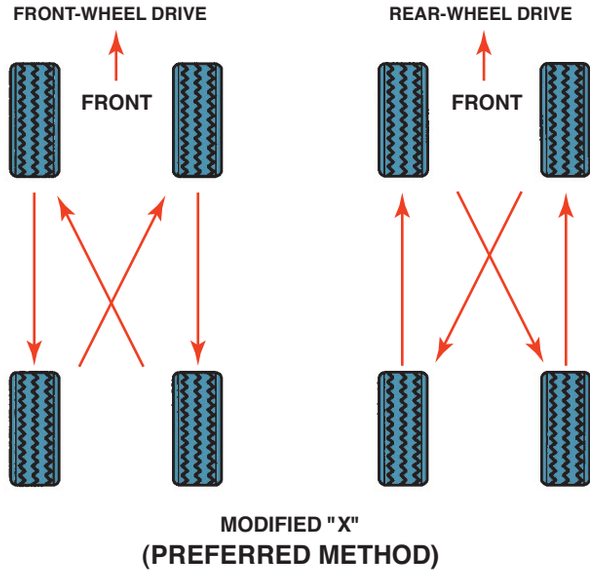

FIGURE 111–17 The method most often recommended is the modified X method. Using this method, each tire eventually is used at each of the four wheel locations. An easy way to remember the sequence, whether front wheel drive or rear wheel drive, is to say to yourself, "Drive wheels straight, cross the nondrive wheels."

TECH TIP

Tire Rotation

Tire rotation should be done at every *other* oil change. Most manufacturers recommend changing the engine oil every 6,000 miles (9,500 km) or every six months so this means that a tire rotation is recommended every year or every 12,000 miles (19,000 km).

on the front tires. The wear usually starts on the outer tread row. This wear usually appears as a front-to-back (high and low) wear pattern on individual tread blocks. These *blocks of tread* rubber are deformed during cornering, stopping, and turning. This type of tread block wear can cause tire noise and/or tire roughness. While some shoulder wear on front tires is normal, it can be reduced by proper inflation, alignment, and tire rotation. For best results, tires should be rotated every 6,000 miles or every six months. ● **SEE FIGURE 111–17** for suggested methods of rotation, such as the **modified X.**

NOTE: Radial tires can cause a radial pull due to their construction. If wheel alignment is correct, attempt to correct a pull by rotating the tires front to rear or, if necessary, side to side.

Some tire manufacturers do not recommend rotating the tires on front-wheel-drive vehicles because the front tires often wear three times as fast as the rear. They recommend replacing just front tires, because the rear tires often last over 90,000 miles (145,000 km).

CAUTION: General Motors also warns that the wheels on many vehicles such as the Pontiac Trans Am and the newer Grand Prix cannot be rotated front to rear because the wheels and tires are different sizes. Always check service information as to the specified tire rotation procedure to follow on the vehicle being serviced.

TECH TIP

All-Wheel-Drive Tire Concerns

It is very important that all-wheel-drive vehicles be equipped with tires that are all the same outside diameter. If, for example, the vehicle has 20,000 miles and the tires are half worn, all of the tires should be replaced in the event of a problem requiring replacement of only one tire.

Most vehicle manufacturers specify that all tires must be within 2/32 in. of tread depth without causing a constant strain on the drive train.

FIGURE 111–18 Tire showing excessive shoulder wear resulting from underinflation and/or high-speed cornering.

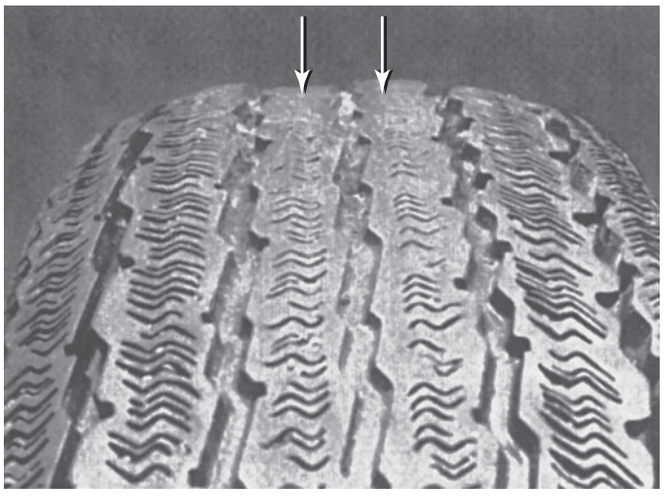

FIGURE 111–19 Tire showing excessive wear in the center, indicating overinflation or heavy acceleration on a drive wheel.

TIRE INSPECTION

All tires should be carefully inspected for faults in the tire itself or for signs that something may be wrong with the steering or suspension systems of the vehicle. ● **SEE FIGURES 111–18 THROUGH 111–20** for examples of common problems.

RADIAL RUNOUT

Even though a tire has no visible faults, it can be the cause of vibration. If vibration is felt above 45 mph, regardless of the engine load, the cause is usually an out-of-balance or a defective out-of-round tire. Both of these problems cause a **tramp** or *up-and-down*-type vibration. If the vibration is seen in the hood of the vehicle or felt in the steering wheel, then the problem is usually the *front* tires. If the vibration is felt throughout the entire vehicle or in the seat of your pants, then the rear tires (or drive shaft, in rear-wheel-drive vehicles) are the problem. This can be checked by using a runout gauge and checking for **radial runout.** ● **SEE FIGURES 111–21** and **111–22.**

FIGURE 111–20 Wear on the outside shoulder only is an indication of an alignment problem.

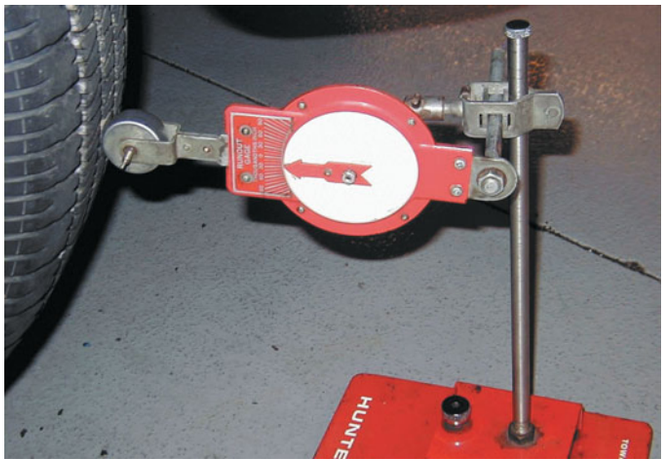

FIGURE 111–21 A tire runout gauge being used to measure the radial runout of a tire.

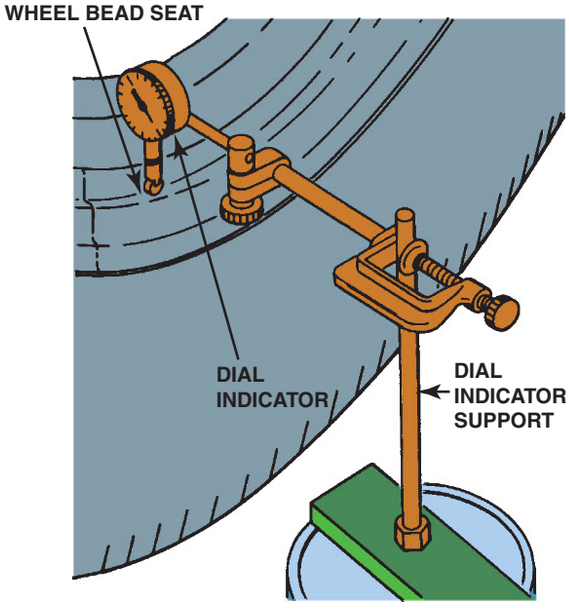

FIGURE 111–22 To check wheel radial runout, the dial indicator plunger tip rides on a horizontal surface of the wheel, such as the bead seat.

FREQUENTLY ASKED QUESTION

I Thought Radial Tires Couldn't Be Rotated!

When radial tires were first introduced by American tire manufacturers in the 1970s, rotating tires side-to-side was *not* recommended because of concerns about belt or tread separation. Since the late 1980s, most tire manufacturers throughout the world, including the United States, have used tire-building equipment specifically designed for radial-ply tires. These newer radial tires are constructed so that the tires can now be rotated from one side of the vehicle to the other without fear of causing a separation by the resulting reversal of the direction of rotation.

To check radial runout (checking for out-of-round) and lateral runout (checking for side-to-side movement), follow these steps:

1. Raise the vehicle so that the tires are off the ground approximately 2 in. (5 cm).
2. Place the runout gauge against the tread of the tire in the center of the tread and, while rotating the tire, observe the gauge reading.
3. Note that maximum radial runout should be less than 0.060 in. (1.5 mm). Little, if any, tramp will be noticed with less than 0.030 in. (0.8 mm) runout. If the reading is over 0.125 in. (3.2 mm), replacement of the tire is required.
4. Check all four tires.

CORRECTING RADIAL RUNOUT Excessive radial runout may be corrected by one of several methods:

1. Try relocating the wheel on the mounting studs. Mark one stud and remount the wheel two studs away from its original position. Excessive wheel hole and/or stud tolerance may be the cause. If the radial runout is now satisfactory, re-mark the stud and wheel to prevent a future occurrence of the problem.
2. Remount the tire on the wheel 180 degrees from its original location. This can solve a runout problem, especially if the tire was not match mounted to the wheel originally.
3. If runout is still excessive, remove the tire from the wheel and check the runout of the *wheel.* If the wheel is within 0.035 in. (0.9 mm), yet the runout of the tire/wheel assembly is excessive, the problem has to be a defective tire and it should be replaced.

Sometimes a problem within the tire itself can cause a vibration, and yet not show up as being out-of-round when tested for radial runout. A condition called **radial force variation** can cause a vibration even if correctly balanced.

NOTE: Some tire balancers are equipped with a roller that is pressed against the tread of the tire to measure radial force variations. Follow the instructions as shown on the balancer display to correct for excessive radial force variations.

LATERAL RUNOUT

Another possible problem that tires can cause is a type of vibration called **shimmy.** This *rapid back-and-forth motion* can be transmitted through the steering linkage to the steering wheel.

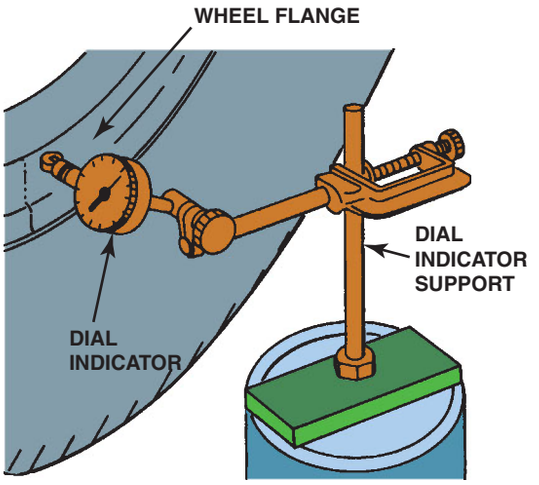

FIGURE 111–23 To check lateral runout, the dial indicator plunger tip rides on a vertical surface of the wheel, such as the wheel flange.

FREQUENTLY ASKED QUESTION

Is the Age of a Tire Important?

Yes. The National Highway Traffic Safety Administration (NHTSA) recommends that any tire six years old or older should be replaced regardless of tread depth. This means that tires that look almost like new but are six years old or older should be replaced because the NHTSA determined that age, not tread depth, was a major factor in tire failures.

Excessive runout is usually noticeable by the driver of the vehicle as a side-to-side vibration, especially at low speeds between 5 and 45 mph (8 and 72 km/h). Shimmy can be caused by an internal defect of the tire or a bent wheel. This can be checked using a runout gauge on the side of the tire or wheel to check for **lateral runout.**

Place the runout gauge against the side of the tire and rotate the wheel. Observe the readings. The maximum allowable reading is 0.045 in. (1.1 mm). If close to or above 0.045 in. (1.1 mm), check on the edge of the wheel to see if the cause of the lateral runout is due to a bent wheel, as shown in ● **FIGURE 111–23.**

Most manufacturers specify a maximum lateral runout of 0.035 in. (0.9 mm) for alloy wheels and 0.045 in. (1.1 mm) for steel wheels. ● **SEE FIGURE 111–24.**

CORRECTING LATERAL RUNOUT Excessive lateral runout may be corrected by one of several methods:

1. Re-torque the wheel in the proper star pattern to the specified torque. Unequal or uneven wheel torque can cause excessive lateral runout.
2. Remove the wheel and inspect the wheel mounting flange for corrosion or any other reason that could prevent the wheel from seating flat against the brake rotor or drum surface.
3. Check the condition of the wheel or axle bearings. Looseness in the bearings can cause the wheel to wobble.

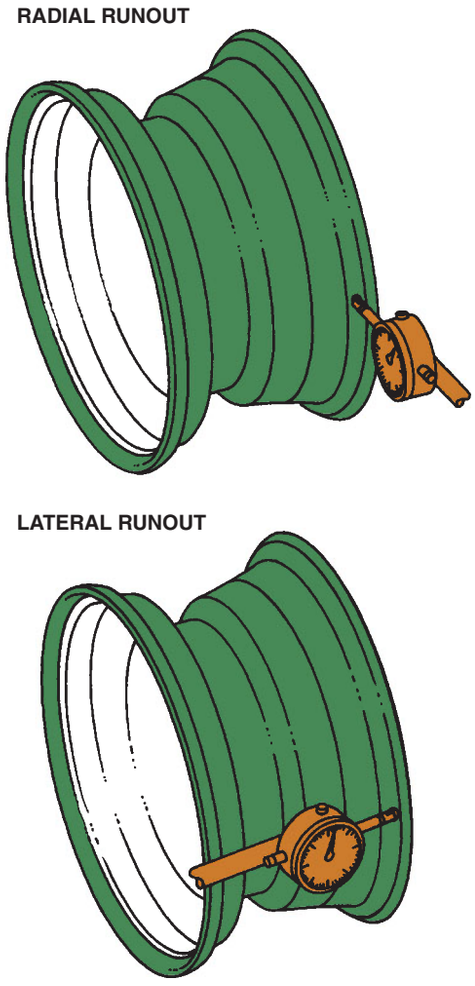

FIGURE 111–24 The most accurate method of measuring wheel runout is to dismantle the tire and take dial indicator readings on the inside of the wheel rim.

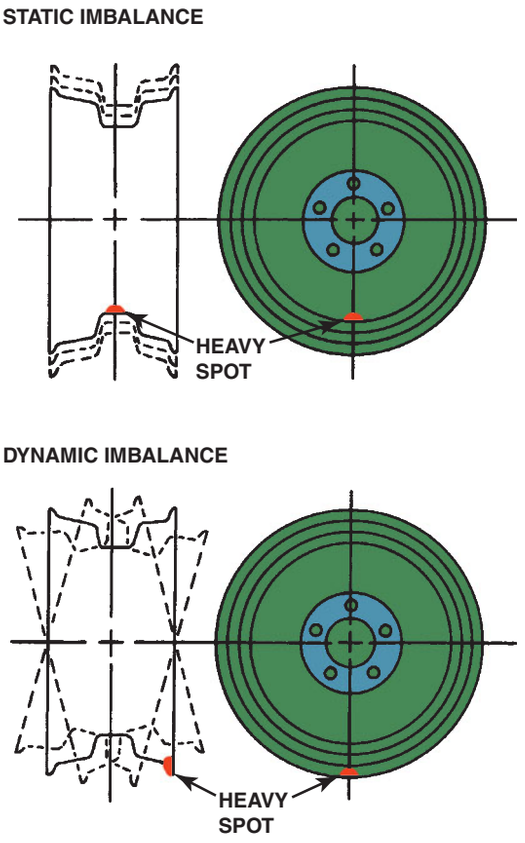

FIGURE 111–25 A wheel balancer detects heavy spots on the wheel and tire, and indicate where to place weight to offset both static and dynamic imbalance.

REAL WORLD FIX

The Greased Wheel Causes a Vibration

Shortly after an oil change and a chassis lubrication, a customer complained of a vibration at highway speed. The tires were checked for excessive radial runout to be certain the cause of the vibration was not due to a defective out-of-round tire. After removing the wheel assembly from the vehicle, excessive grease was found on the inside of the rim. Obviously, the technician who greased the lower ball joints had dropped grease on the rim. After cleaning the wheel, it was checked for proper balance on a dynamic computer balancer and found to be properly balanced. A test-drive confirmed that the problem was solved.

TIRE BALANCING

Proper tire balance is important for tire life, ride comfort, and safety. Tire balancing is needed because of the lack of uniform weight and stiffness (due to splices) and a combination of wheel runout and tire runout. Balancing a tire can compensate for most of these conditions. However, if a tire or wheel is excessively out of round or bent, then replacement of the wheel or tire is required.

STATIC BALANCE The term **static balance** means that the weight mass is evenly distributed around the axis of rotation.

1. For example, if a wheel is spun and stops at different places with each spin, then the tire is statically balanced.
2. **If the static balance is not correct, wheel tramp-type (vertical shake) vibration and uneven tire wear can result.**
3. Static balance can be tested with the tire stationary or while being spun to determine the heavy spot (sometimes called *kinetic balance*).

DYNAMIC BALANCE The term **dynamic balance** means that the centerline of weight mass is in the same plane as the centerline of the wheel. ● **SEE FIGURE 111–25.**

1. Dynamic balance must be checked while the tire and the wheel are rotated, to determine side-to-side as well as up-and-down out of balance.
2. **Incorrect dynamic balance causes shimmy.** Shimmy-type vibration causes the steering wheel to shake from side to side.

PREBALANCE CHECKS Before attempting to balance any tire, the following should be checked and corrected to ensure good tire balance:

1. Check the wheel bearing adjustment for looseness or wear.
2. Check the radial runout.
3. Check the lateral runout.

FIGURE 111–26 An assortment of wheel weights designed to fit different shaped rims.

FIGURE 111–27 Liquid tire stop leak was found in all four tires. This liquid caused the tires to be out of balance.

4. Remove stones from the tread.
5. Remove grease or dirt buildup on the inside of the wheel.
6. Check for dragging or misadjusted brakes.
7. Check for loose or backward lug nuts.
8. Check for proper tire pressures.
9. Remove all of the old weights.
10. Check for bent or damaged wheel covers.

WHEEL WEIGHTS A weight equal to and placed 180 degrees opposite from the heavy spot of the tire/wheel assembly is used for static balancing. In other words, tire balancing is actually counter-balancing a heavy spot with a weight. For dynamic balancing, the tire balancing machine calculates how far out and 180 degrees opposite the heavy spot from centerline of the out-of-balance section. Wheel weights are available in a variety of styles and types, including the following:

1. Clip-on lead weights for standard steel rims.
2. Clip-on weights for alloy (aluminum) wheels. ● **SEE FIGURE 111–26.**
   a. Uncoated—generally *not* recommended by wheel or vehicle manufacturers because corrosion often occurs where the lead weight contacts the alloy wheel surface.
   b. Coated—lead weights that are painted or coated in a plastic material are usually the *recommended* type of weight to use on alloy wheels.

   Weights are usually coated with a nylon or polyester-type material that often matches the color of the aluminum wheels.
3. Steel or zinc wheel weights are being sold to replace weights made from lead. Some states have outlawed lead weights due to environmental concerns of lead on the ground from lost wheel weights.
4. Adhesive (stick on) wheel weights are used on the inside of the rim where they do not show. Stick-on weights come with an adhesive backing that is most often used on alloy wheels. ● **SEE FIGURE 111–28.**

FIGURE 111–28 Stick-on weights are used from the factory to balance the alloy wheels of this Prowler.

REAL WORLD FIX

The Vibrating Ford Van

A technician was asked to solve a vibration problem on a rear-wheel-drive Ford van. During a test-drive, the vibration was felt everywhere—the dash, the steering wheel, the front seat, the shoulder belts; everything was vibrating! The technician balanced all four tires on a computer balancer. Even though wheel weights were put on all four wheels and tires, the vibration was even worse than before. The technician rebalanced all four wheels time after time, but the vibration was still present. The shop supervisor then took over the job of solving the mystery of the vibrating van. The supervisor balanced one wheel/tire assembly and then tested it again after installing the weights. The balance was way off! The supervisor broke the tire down and found about 1 quart (1 liter) of liquid in the tire! Liquid was found in all four tires. No wonder the tires couldn't be balanced! Every time the tire stopped, the liquid would settle in another location.

The customer later admitted to using a tire stop-leak liquid in all four tires. Besides stop leak, another common source of liquid in tires is water that accumulates in the storage tank of air compressors, which often gets pumped into tires when air is being added. All air compressor storage tanks should be drained of water regularly to prevent this from happening. ● **SEE FIGURE 111–27.**

FIGURE 111–29 Wheel weight pliers are specially designed to remove and install wheel weights.

TECH TIP

Stop Leak Can Damage TPMS Sensors

Stop leak should never be used in a tire that is equipped with the TPMS sensor because the sensor can be damaged.

FREQUENTLY ASKED QUESTION

How Much Is Too Much Weight?

Whenever balancing a tire, it is wise to use as little amount of weight as possible. For most standard-size passenger vehicle tires, most experts recommend that no more than 5.5 oz of weight be added to correct an imbalance condition. If more than 5.5 oz total weight is needed, remove the tire from the wheel (rim) and carefully inspect for damage to the tire or the wheel. If the tire still requires more than 5.5 oz and the wheel is not bent or damaged, replace the tire.

Most wheel weights come in 1/4 ounce (0.25-oz) increment (oz × 28 = grams).

0.25 oz = 7 gm	1.75 oz = 49 gm
0.50 oz = 14 gm	2.00 oz = 56 gm
0.75 oz = 21 gm	2.25 oz = 63 gm
1.00 oz = 28 gm	2.50 oz = 70 gm
1.25 oz = 35 gm	2.75 oz = 77 gm
1.50 oz = 42 gm	3.00 oz = 84 gm

Use a wheel weight pliers to help ensure proper installation and removal of wheel weights. ● **SEE FIGURE 111–29.**

BUBBLE BALANCER This type of static balancer is commonly used and is accurate, if calibrated and used correctly. A bubble balancer is portable and can be easily stored away when not in use. It is also easy to use and is relatively inexpensive.

COMPUTER BALANCER The most popular type of tire balancer is the computer dynamic balancer. Most computer balancers are designed to balance wheels and tires off the vehicle. Computer dynamic balancers spin the tire at a relatively slow speed (approximately 20 mph). Sensors attached to the spindle of the balancer determine the amount and location of weights necessary to balance the tire dynamically. All computer balancers must be programmed with the actual rim size and tire location for the electronic circuits to calibrate the required weight locations. Some computer balancers can perform loaded radial force and lateral force variation testing on the tire/wheel assembly and display corrective actions. ● **SEE FIGURE 111–30.**

FIGURE 111–30 A tire balancer that can also detect radial and lateral force variation and instruct the operator where to rotate the tire to achieve the best ride, or indicate a bent wheel.

FREQUENTLY ASKED QUESTION

Are the Brake Drums and Rotors Balanced?

Whenever an off-the-vehicle computer balancer is used, a question often asked by beginning technicians is, "What about the balance of the brake drums and rotors?" Brake drums and rotors are balanced at the factory, usually to within 0.5 oz-in. Imbalance measured in oz-in. means that any imbalance force is measured in ounces, then multiplied by the distance from the center measured in inches. This means that at a distance of 1 in. from the center of the drum or rotor, it is within 0.5 ounce of being perfectly balanced. Being within 0.5 ounce-inch also means that at 5 inches from the center, the imbalance is only 0.1 ounce.

What this means to the technician is that most drums and rotors are balanced well enough not to be a problem when using off-the-vehicle balancers. However, the smart technician should look for evidence that weights have been removed from brake drums to permit aluminum wheels to fit, or other cases where the factory balance of the drums and rotors has been changed.

Most computer balancers will be accurate to within 1/4 oz (0.25 oz), while some are accurate to within 1/8 oz (0.125 oz). (Most drivers can feel an out-of-balance of 1 oz or more, but few can feel a vibration caused by just 1/4 oz.) For sensitive drivers or vehicles used for high speeds, such as racing, most computer balancers can be programmed to balance within 1/8 oz (0.125 oz). Refer to the manufacturer's instructions for the exact capabilities and procedures for your computer balancer.

Most vehicle manufacturers specify that no more than 5.5 oz (150 gm) be used to balance any tire, with no more than 3.5 oz (100 gm) used per side of each wheel.

REPLACEMENT WHEELS

Whenever a replacement wheel is required, the same offset should be maintained. If wider or larger-diameter wheels are to be used, consult a knowledgeable wheel or tire salesperson to determine the correct wheel for your application.

CAUTION: Never remove the weights that are welded to the surface of the brake drum facing the wheel. ● **SEE FIGURE 111–31.** **If replacement wheels do not fit without removing these weights, either replace the brake drum (one without a weight) or select another brand or style of wheel. Removing the weights from a brake drum can cause severe vibration at highway speeds.**

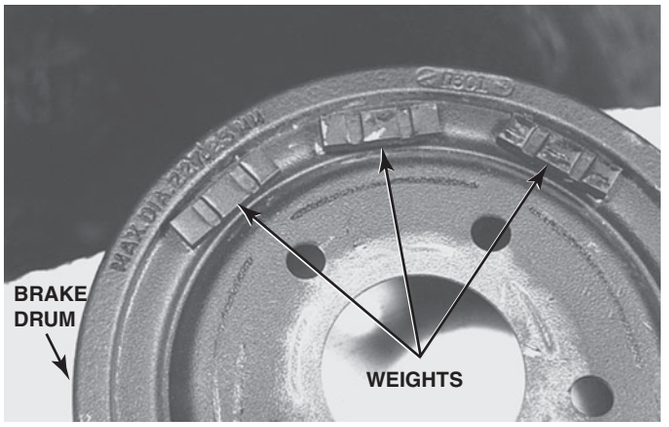

FIGURE 111–31 Most brake drums do not have this much attached weight.

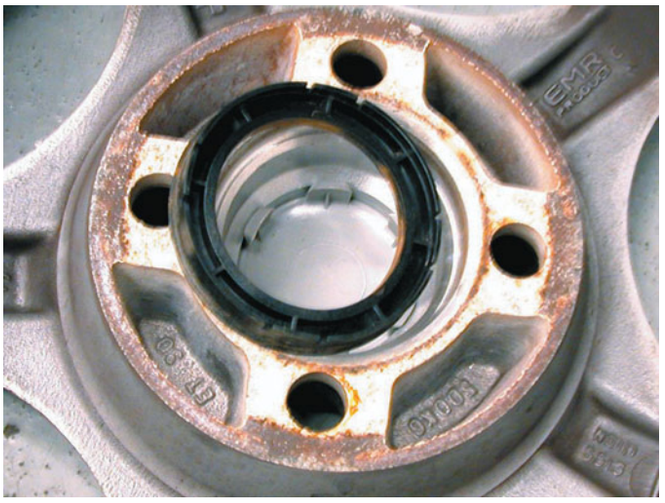
REAL WORLD FIX

It Happened to Me—It Could Happen to You

During routine service, I rotated the tires on a Pontiac Trans Am. Everything went well and I even used a torque wrench to properly torque all of the lug nuts. Then, when I went to drive the car out of the service stall, I heard a horrible grinding sound. When I hoisted the car to investigate, I discovered that the front wheels were hitting the outer tie rod ends. ● **SEE FIGURE 111–32.** The 16-in. wheels had a different back spacing front and rear, and therefore these wheels could not be rotated. Always check replacement or aftermarket wheels for proper fit before driving the vehicle.

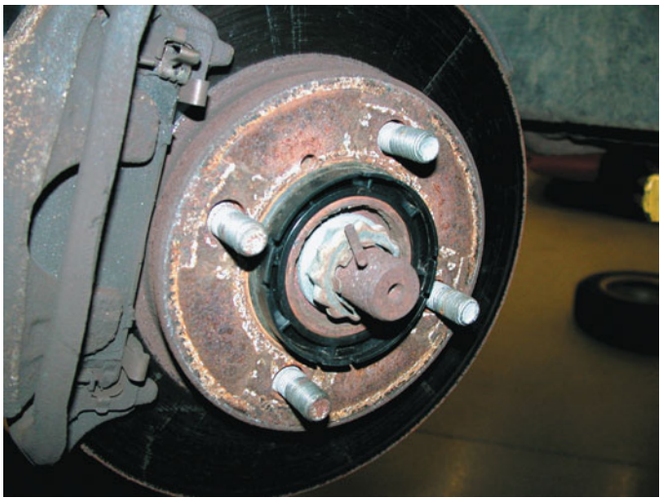
FREQUENTLY ASKED QUESTION

What Are Hubcentric Wheels?



Most wheels are designed to fit over and be supported by the axle hub. This type of wheel is called a hubcentric type wheel. Some wheels use an enlarged center hub section and rely on the wheel studs for support and to keep the wheel centered on the axle. Some aftermarket wheels may be designed to fit several different vehicles. As a result, the wheel manufacturers use plastic hubcentric adapter rings. ● **SEE FIGURE 111–33.**

TIRE REPAIR



Tread punctures, nail holes, or cuts up to 1/4 in. (2.6 mm) can be repaired. Repairs should be done from the inside of the tire using plugs or patches. The tire should be removed from the rim to make the

FIGURE 111–32 Notice that the rim touches the tie rod end.

(a)

(b)

FIGURE 111–33 (a) A hubcentric plastic ring partially removed from an aftermarket wheel. (b) A hubcentric plastic ring left on the hub when removing a wheel.

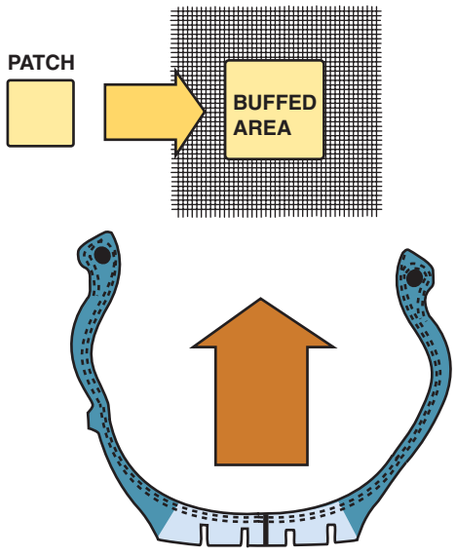


FIGURE 111–34 The area of the repair should be buffed slightly larger than the patch to be applied.

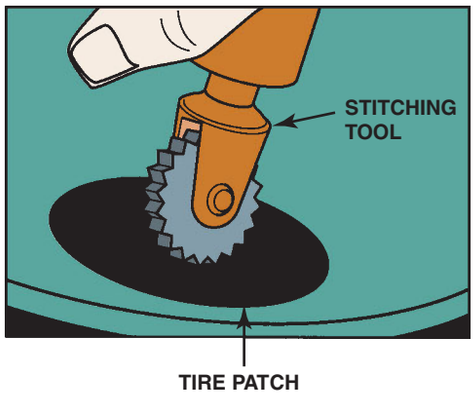

FIGURE 111–35 A stitching tool being used to force any trapped air out from under the patch.

repair. With the tire off the wheel, inspect the wheel and the tire for hidden damage. The proper steps to follow for a tire repair are as follows:

1. Mark the location of the tire on the wheel.
2. Dismount the tire; inspect and clean the punctured area with a prebuff cleaner. DO NOT USE GASOLINE!
3. Buff the cleaned area with sandpaper or a tire-buffing tool until the rubber surface has a smooth, velvet finish. ● **SEE FIGURE 111–34.**
4. Ream the puncture with a fine reamer from the inside. Cut and remove any loose wire material from the steel belts.
5. Fill the puncture with contour filling material, and cut or buff the material flush with the inner liner of the tire.
6. Vacuum and clean the area. Then apply chemical vulcanizing cement and allow to dry.
7. Apply the patch and use a stitching tool from the center toward the outside of the patch to work any air out from between the patch and the tire. ● **SEE FIGURE 111–35.** Another excellent tire repair procedure uses a rubber plug. Pull the stem through the hole in the tire, as shown in ● **FIGURE 111–36.**
8. Remount the tire on the rim, aligning the marks made in step 1. Inflate to the recommended pressure and check for air leaks.

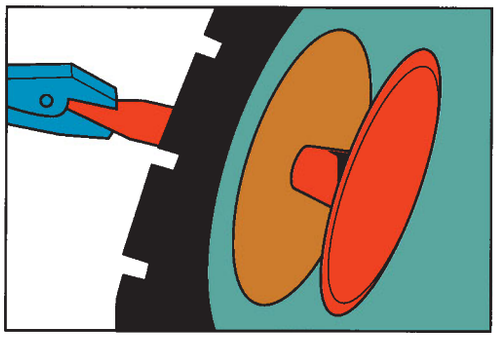

FIGURE 111–36 A rubber plug being pulled through a hole in the tire. The stem is then cut off flush with the surface of the tire tread.

TECH TIP

Dispose of Old Tires Properly

Old tires cannot be thrown out in the trash. They must be disposed of properly. Tires cannot be buried because they tend to come to the surface. They also trap and hold water, which can be a breeding ground for mosquitoes. Used tires should be sent to a local or regional recycling center where the tires will be ground up and used in asphalt paving or other industrial uses. Because there is often a charge to dispose of old tires, it is best to warn the customer of the disposal fee.

WARNING

Most experts agree that tire repairs should be done from the inside. Many technicians have been injured and a few killed when the tire they were repairing exploded as a steel reamer tool was inserted into the tire. The reamer can easily create a spark as it is pushed through the steel wires of a steel-belted tire. This spark can ignite a combustible mixture of gases inside the tire caused by using stop leak or inflator cans. Since there is no way a technician can know if a tire has been inflated with a product that uses a combustible gas, always treat a tire as if it could explode.

TECH TIP

Open-End Wrenches Make It Easier

Tire repair is made easier if two open-end wrenches are used to hold the beads of the tire apart. See step 4 in the tire repair photo sequence.

NOTE: Most vulcanizing (rubber) cement is highly flammable. Use out of the area of an open flame. Do not smoke when making a tire repair.

There are many tire repair products on the market. Always follow the installation and repair procedures exactly per the manufacturer's instructions.

1 A typical tire-changing machine showing the revolving table and movable arm used to remove a tire from the wheel.

2 The foot-pedal controls allow the service technician to break the tire bead, damp the wheel (rim) to the machine, rotate the tire/wheel assembly, and still have both hands free.

3 Using a tire valve removal tool, unscrew the valve core using extreme caution and wear eye protection because the valve is under pressure and can be forced outward and cause personal injury.

4 The valve core removed from the tire valve. Allow all of the air in the tire to escape.

5 A bead breaker is being used to separate the tire from the bead seat of the wheel. Repeat as needed to break the bead on both sides of the wheel.

6 After breaking the beads from both sides of the tire, install the wheel/tire assembly flat onto the machine and, using the foot-pedal control, lock the wheel to the changer.

CONTINUED ▶

7 To remove the tire from the wheel, position the arm of the changer against the rim of the wheel and lock in position.

8 The tire tool (flat bar) is placed between the bead of the tire and the wheel. Using tire lubricant can help prevent damage to the tire.

9 The foot pedal that causes the table to rotate is depressed and the tire is removed from the wheel.

10 Reposition the tire tool to remove the lower bead of the tire from the wheel.

11 As the table of the tire changer is rotated, the tire is released from the wheel and can be lifted off the wheel.

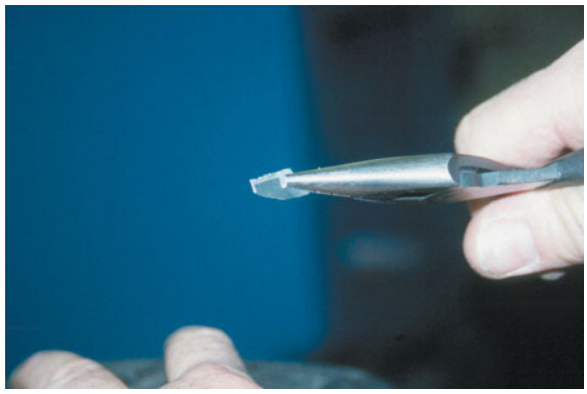
12 Before installing a tire, inspect and clean the bead seat.

13 Before installing a new tire, most experts recommend replacing the tire valve, being installed here, using a tool that pulls the valve through the hole in the wheel.

14 Apply tire soap or rubber lubricant to both beads of the tire.

15 Rotate the tire on the wheel and position the arm so that the tire will be guided onto the rim as the wheel is rotated.

16 Repeat for the upper bead.



17 Inflate the tire, being careful to not exceed 40 PSI. Experts suggest that a tire be in a cage during the initial bead seating inflation to help prevent personal injury if the wheel or tire fails.

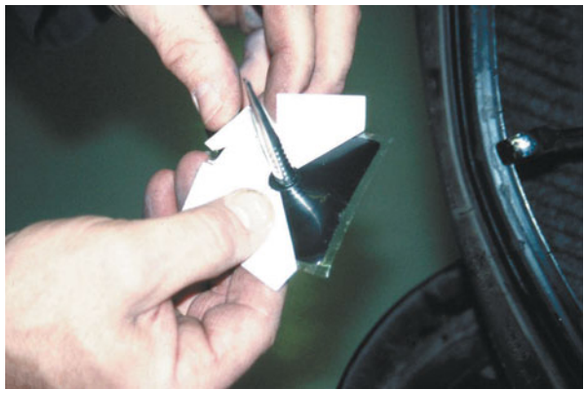
18 Install the tire valve core and inflate the tire to specifications.

1 The source of the leak was detected by spraying soapy water on the inflated tire. Needle-nose pliers are being used to remove the object that caused the flat tire.

2 A part of a razor blade was found to be the cause of the flat tire.

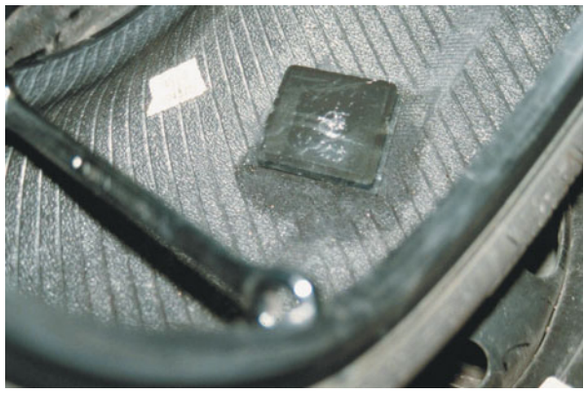
3 A reamer is being used to clean the puncture hole.

4 This technician is using two open-end wrenches to hold the tire beads apart if a tire bead spreader is not available.



5 The surrounding area is being buffed using an air-powered die grinder equipped with a special buffing tool specifically designed for this process.

6 After using a vacuum on all debris and rubber after buffing, apply rubber cement to the area.



7 The brush included with the rubber cement makes the job easy. Be sure to cover the entire area around the puncture.

8 Peel off the paper from the adhesive on the patch. Insert the tip of the patch through the puncture from the inside of the tire.

9 Use a pair of pliers to pull the plug of the patch through the puncture.

10 This view of the patch is from the inside of the tire.

11 To be assured of an airtight patch, the adhesive of the patch should be “stitched” to the inside of the tire using a serrated roller called a stitching tool.

12 A view of the plug from the outside of the tire after metal covering used to pierce the puncture is removed from the patch plug. The plug can be trimmed to the level of the tread using side cutters or a knife.

REVIEW QUESTIONS

1. List the precautions and recommendations regarding tire selection and maintenance.
2. Determine the proper wheel mounting torque for your vehicle from the guidelines provided.
3. Describe how to check for lateral and radial runout of the wheels and tires.
4. Describe the difference between static and dynamic balance.

CHAPTER QUIZ

1. A tire is worn excessively on both edges. The most likely cause of this type of tire wear is _____.
   a. Overinflation **c.** Excessive radial runout
   b. Underinflation **d.** Excessive lateral runout
2. When seating a bead of a tire, never exceed _____ PSI.
   a. 30 **c.** 50
   b. 40 **d.** 60
3. For best tire life, most vehicle and tire manufacturers recommend tire rotation every _____.
   a. 3,000 miles **c.** 9,000 miles
   b. 6,000 miles **d.** 12,000 miles
4. What lubricant should be used when mounting a tire?
   a. Silicone spray **c.** Water-based soap
   b. Grease **d.** SAE 10W-30 engine oil
5. Using the modified X-method of tire rotation on a front-wheel-drive vehicle, where should the left front wheel be placed?_____
   a. Right front **c.** Left rear
   b. Right rear **d.** Kept at the left front
6. Which statement is *false?*
   a. Excessive radial runout can cause a tramp-type vibration.
   b. Excessive lateral runout can cause a tramp-type vibration.
   c. A tire out of balance dynamically can cause a shimmy-type vibration.
   d. A tire out of balance statically can cause a tramp-type vibration.
7. The recommended type of wheel weight to use on aluminum (alloy) wheels is _____.
   a. Lead with plated spring steel clips
   b. Coated (painted) or stick-on lead weights
   c. Lead weights with longer-than-normal clips
   d. Aluminum weights
8. Most vehicle and tire manufacturers recommend that no more than _____ ounces of balance weight be added to a wheel/tire assembly.
   a. 2.5 **c.** 4.5
   b. 3.5 **d.** 5.5
9. A vehicle vibrates at highway speed. Technician A says that water in the tire(s) could be the cause. Technician B says that an out-of-round tire could be the cause. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. Proper tire inflation pressure information is found _____.
    a. On the driver's door or post **c.** On the sidewall of the tire
    b. In the owner's manual **d.** Both a and b

chapter 112

SUSPENSION SYSTEM PRINCIPLES AND COMPONENTS

OBJECTIVES: **After studying Chapter 112, the reader will be able to:** • Prepare for ASE Suspension and Steering (A4) certification test content area "B" (Suspension System Diagnosis and Repair). • List various types of suspensions and their component parts. • Explain how coil, leaf, and torsion bar springs work. • Describe how suspension components function to allow wheel movement up and down and provide for turning. • Describe how shock absorbers control spring forces.

KEY TERMS: Air spring 1306 • Anti-dive 1299 • Anti-squat 1299 • Ball joints 1300 • Bulkhead 1290 • Bump stop 1308 • Center bolt 1295 • Coil springs 1291 • Composite leaf spring 1296 • Control arms 1299 • Cradle 1289 • Full frame 1289 • GVW 1290 • Hooke's Law 1291 • Independent suspension 1290 • Insulators 1294 • Kingpin 1299 • Ladder frame 1289 • Lateral links 1298 • Leaf springs 1295 • Load-carrying ball joint 1300 • Mono leaf 1296 • Non-load-carrying ball joint 1300 • Perimeter frame 1289 • Platforms 1290 • Rebound clips 1296 • Shackles 1296 • Shock absorbers 1302 • Space frame 1290 • Spring pocket 1294 • Spring rate 1291 • Springs 1291 • Sprung weight 1290 • Stabilizer bars 1301 • Steering knuckles 1299 • Stress riser 1295 • Strut rod 1301 • Struts 1306 • Stub-type frame 1289 • Torsion bar 1297 • Unit-body 1290 • Unsprung weight 1290 • Wheel rate 1294

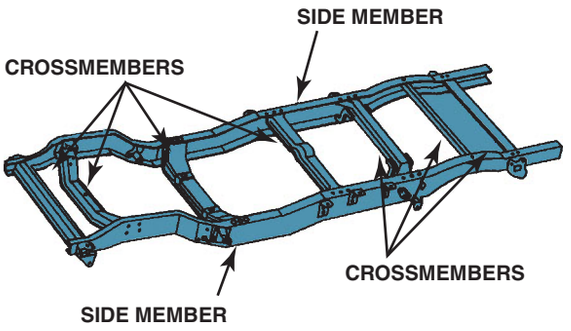


FIGURE 112–1 A typical truck frame is an excellent example of a ladder-type frame. The two side members are connected by a crossmember.

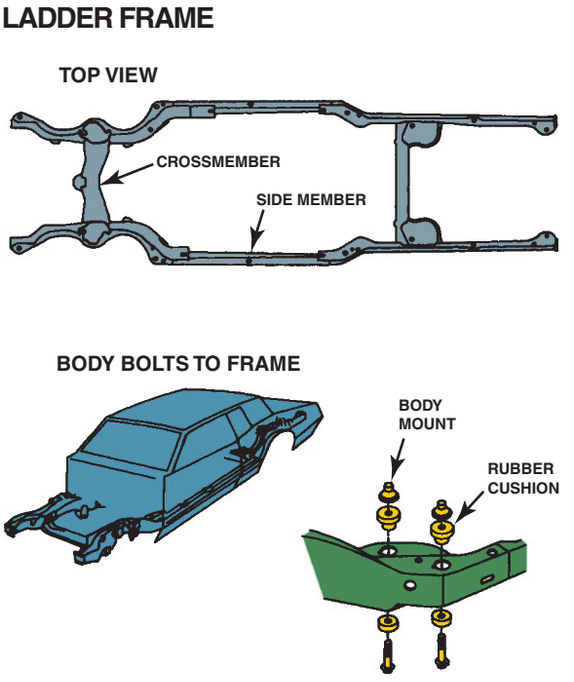

FIGURE 112–2 Rubber cushions used in body or frame construction isolate noise and vibration from traveling to the passenger compartment.

INTRODUCTION

PURPOSE AND FUNCTION Street-driven cars and trucks use a suspension system to keep the tires on the road and to provide acceptable riding comfort. A vehicle with a solid suspension, or no suspension, would bounce off the ground when the tires hit a bump. If the tires are off the ground, even for a fraction of a second, loss of control is possible. The purpose of the suspension is to provide the vehicle with the following:

1. A smooth ride
2. Accurate steering
3. Responsive handling
4. Support for the weight of the vehicle
5. Maintenance of acceptable tire wear

FRAME CONSTRUCTION

TERMINOLOGY Frame construction usually consists of channel-shaped steel beams welded and/or fastened together. The frame of a vehicle supports all the "running gear" of the vehicle, including the engine, transmission, rear axle assembly (if rear-wheel drive), and all suspension components.

This frame construction, referred to as **full frame,** is so complete that most vehicles can usually be driven without the body. Most trucks and larger rear-wheel-drive cars use a full frame.

LADDER FRAME A **ladder frame** is a common name for a type of perimeter frame where the transverse (lateral) connecting members are straight across. ● **SEE FIGURES 112–1 AND 112–2.** When viewed with the body removed, the frame resembles a ladder. Most pickup trucks are constructed with a ladder-type frame.

PERIMETER FRAME A **perimeter frame** consists of welded or riveted frame members around the entire perimeter of the body. This means that the frame members provide support underneath the sides as well as for the suspension and suspension components.

STUB-TYPE FRAMES A **stub-type frame** is a partial frame often used on unit-body vehicles to support the power train and suspension components. It is also called a **cradle** on many front-wheel-drive vehicles. ● **SEE FIGURE 112–3.**

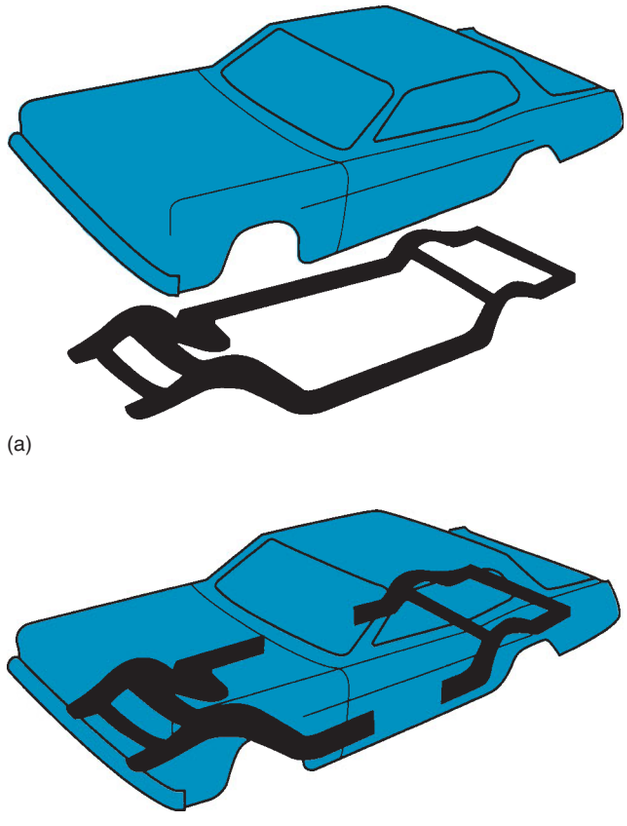

FIGURE 112–3 (a) Separate body and frame construction; (b) unitized construction: the small frame members are for support of the engine and suspension components. Many vehicles attach the suspension components directly to the reinforced sections of the body and do not require the rear frame section.

UNIT-BODY CONSTRUCTION

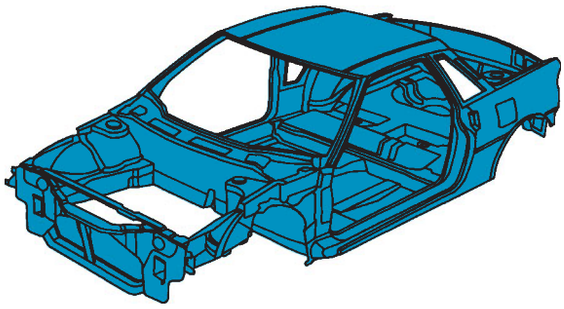

FIGURE 112–4 Welded metal sections create a platform that combines the body with the frame using unit-body construction.

UNIT-BODY CONSTRUCTION

Unit-body construction (sometimes called *unibody*) is a design that combines the body with the structure of the frame. The body supports the engine and drive line components, as well as the suspension and steering components. The body is composed of many individual stamped-steel panels welded together.

The strength of this type of construction lies in the *shape* of the assembly. The typical vehicle uses 300 separate and different stamped steel panels that are spot-welded to form a vehicle's body. ● **SEE FIGURE 112–4.**

NOTE: A typical vehicle contains about 10,0000 individual parts.

SPACE FRAME CONSTRUCTION

Space frame construction consists of formed sheet steel used to construct a framework for the entire vehicle. The vehicle is drivable without the body, which uses plastic or steel panels to cover the steel framework.

PLATFORMS

TERMINOLOGY

The **platform** of any vehicle is its basic size and shape. Various vehicles of different makes can share the same platform, and therefore many of the same drive train (engine, transmission, and final drive components) and suspension and steering components.

A platform of a unit-body vehicle includes all major sheet-metal components that form the load-bearing structure of the vehicle, including the front suspension and engine-supporting sections. The area separating the engine compartment from the passenger compartment is called the **bulkhead.** The height and location of this bulkhead panel to a large degree determines the shape of the rest of the vehicle.

TRACK AND WHEELBASE

Other components of vehicle platform design that affect handling and ride are the track and wheelbase of the vehicle. *The track of a vehicle is the distance between the wheels, as viewed from the front or rear.* A wide-track vehicle is a vehicle with a wide wheel stance; this increases the stability of the vehicle, especially when cornering. *The wheelbase of a vehicle is the distance between the center of the front wheel and the center of the rear wheel, as viewed from the side.* A vehicle with a long wheelbase tends to ride smoother than a vehicle with a short one.

Examples of common platforms include the following:

1. Chevrolet Impala and Pontiac Grand Prix
2. Toyota Camry and Lexus ES 350
3. Buick Lucerne and Cadillac DTS

? FREQUENTLY ASKED QUESTION

What Does GVW Mean?

GVW, gross vehicle weight, is the weight of the vehicle plus the weight of all passengers the vehicle is designed to carry (× 150 lb [68 kg] each), plus the maximum allowable payload or luggage load. *Curb weight* is the weight of a vehicle when *wet,* meaning with a full tank of fuel and all fluids filled, but without passengers or cargo (luggage). *Model weight* is the weight of a vehicle wet and with passengers.

The GVW is found stamped on a plate fastened to the doorjamb of most vehicles. A high GVW rating does not mean that the vehicle itself weighs a lot more than other vehicles. For example, a light truck with a GVW of 6,000 lbs (2,700 kg) will not ride like an old 6,000-lb luxury car. In fact, a high GVW rating usually requires stiff springs to support the payload; these stiff springs result in a harsh ride. Often technicians are asked to correct a harsh-riding truck that has a high GVW rating. The technician can only check that everything in the suspension is satisfactory and then try to convince the owner that a harsher-than-normal ride is the result of a higher GVW rating.

UNSPRUNG WEIGHT

A suspension system has to be designed to allow the wheels to move up and down quickly over bumps and dips without affecting the entire weight of the car or truck. In fact, the lighter the total weight of the components that move up and down, the better the handling and ride. This weight is called **unsprung weight.** The idea of very light weight resulted in magnesium wheels for racing cars, which are very light yet strong. Aftermarket wheels that resemble racing car wheels are often referred to as *mag* wheels. For best handling and ride, the unsprung weight should be kept as low as possible.

Sprung weight is the term used to identify the weight of the car or truck that does *not* move up and down and is supported or *sprung* by the suspension.

TYPES OF SUSPENSIONS

Early suspension systems on old horse wagons, buggies, and older vehicles used a solid axle for front and rear wheels. ● **SEE FIGURE 112–5.** If one wheel hit a bump, the other wheel was affected, as shown in ● **FIGURE 112–6.**

Most vehicles today use a separate control-arm-type of suspension for each front wheel, which allows for movement of one front wheel without affecting the other front wheel. This type of front suspension is called **independent suspension.** ● **SEE FIGURE 112–7.**

Many rear suspensions also use independent-type suspension systems. Regardless of the design type of suspension, all suspensions use springs in one form or another.

SPRINGS A suspension **spring** serves two purposes. First, it acts as a buffer between the suspension and frame to absorb vertical wheel and suspension movement without passing it on to the frame. Second, each spring transfers part of the vehicle weight to the suspension component it rests on, which transfers it to the wheels.

The basic method by which springs absorb road shocks varies according to the type of spring. Simply stated, leaf springs flatten, coil springs and air springs compress, and torsion bars twist. What all springs have in common is that they somehow give way to absorb the vertical force of the moving wheel during jounce, then release that force during rebound as they return to their original shape and position.

SPRING MATERIALS. Most springs are made of a tempered steel alloy known as spring steel, consisting of chrome silicon or chrome-vanadium alloy. Tempering is a process of heating and cooling metal under controlled conditions, which increases the resilience of the metal. Resilience is the ability of the metal to return to, or spring back to, its original shape after being twisted or compressed.

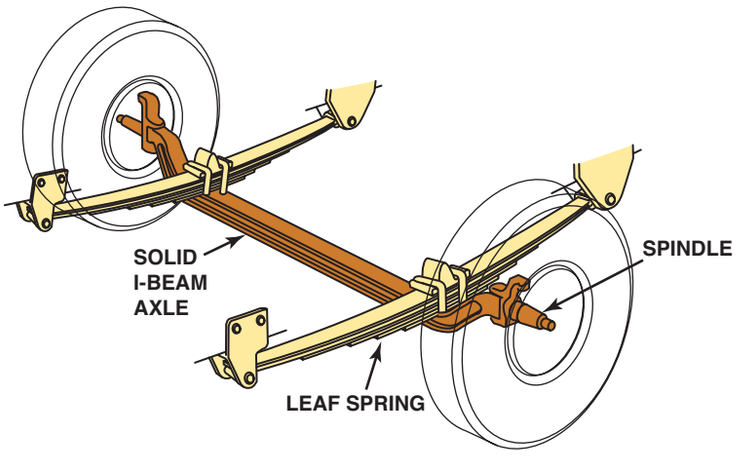

FIGURE 112–5 Solid I-beam axle with leaf springs.

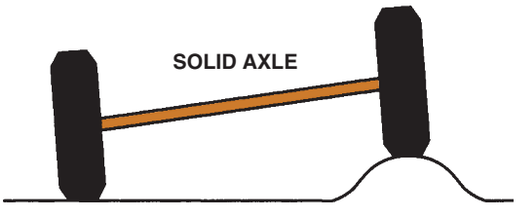

FIGURE 112–6 When one wheel hits a bump or drops into a hole, both left and right wheels are moved. Because both wheels are affected, the ride is often harsh and feels stiff.

HOOKE'S LAW

Regardless of type, all suspensions use springs that share a common characteristic described by **Hooke's Law.** Robert Hooke (1635–1703), an English physicist, discovered the force characteristics of springs: *The deflection (movement or deformation) of a spring is directly proportional to the applied force.*

What this means is that when a coil spring (for example) is depressed 1 in., it pushes back with a certain force (in pounds), such as 400 pounds. If the spring is depressed another inch, the force exerted by the spring is increased by another 400 pounds. The **spring rate** or force constant for this spring is therefore "400 lb per inch," usually symbolized by the letter K. Since the force constant is the force per unit of displacement (movement), it is a measure of the stiffness of the spring. The higher the spring rate (K), the stiffer the spring. ● **SEE FIGURE 112–8.**

COIL SPRINGS

Coil springs are made of special round spring steel wrapped in a helix shape. The strength and handling characteristics of a coil spring depend on the following:

1. Coil diameter
2. Number of coils

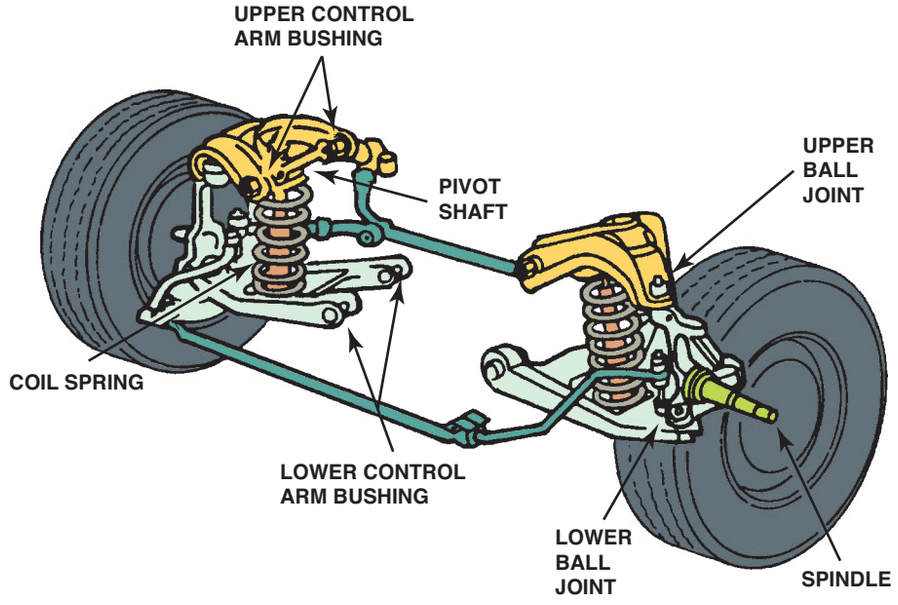

FIGURE 112–7 A typical independent front suspension used on a rear-wheel-drive vehicle. Each wheel can hit a bump or hole in the road independently without affecting the opposite wheel.

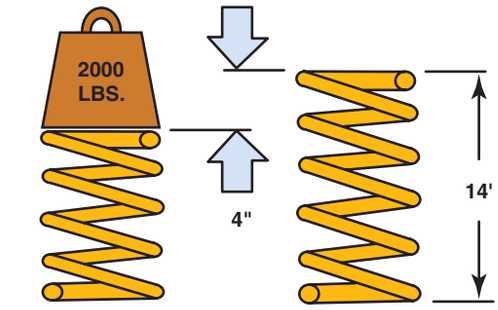

FIGURE 112–8 This spring was depressed 4 inches due to a weight of 2,000 lb. This means that this spring has a spring rate (K) of 500 lb per inch (2000 ÷ 4 in. = 500 lb./in.).

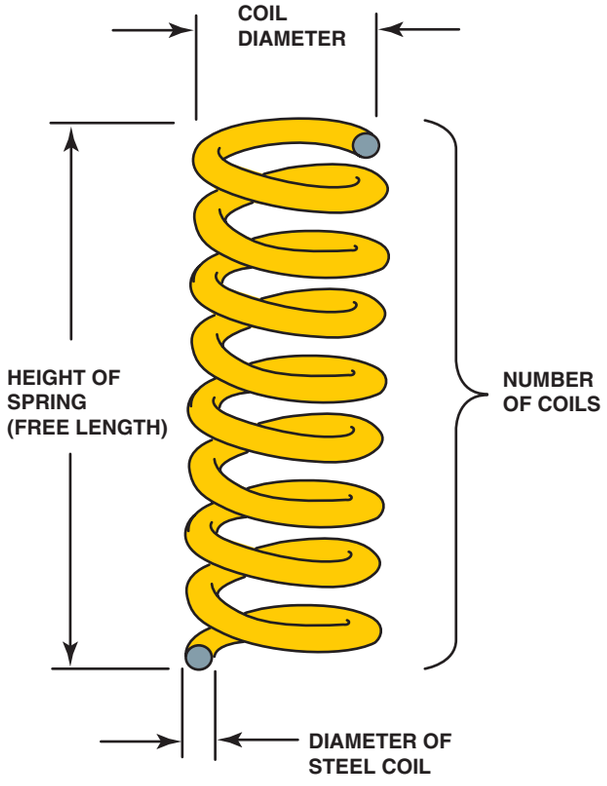

FIGURE 112–9 The spring rate of a coil spring is determined by the diameter of the spring and the diameter of the steel used in its construction plus the number of coils and the free length (height).

3. Height of spring
4. Diameter of the steel coil that forms the spring. ● **SEE FIGURE 112–9**.

The spring rate (K) for coil springs is expressed by the formula:

$$K = \frac{Gd4}{8ND3}$$

where

G = 11,250,000 (constant for steel)
d = diameter of wire
N = number of coils
D = diameter of the coil

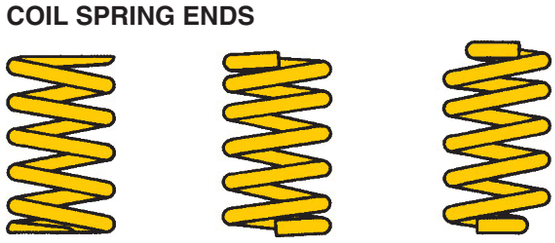

FIGURE 112–10 Coil spring ends are shaped to fit the needs of a variety of suspension designs.

Coil springs are used in front and/or rear suspensions.

- The larger the diameter of the steel, the "stiffer" the spring.
- The shorter the height of the spring, the stiffer the spring.
- The fewer the coils, the stiffer the spring.

Springs are designed to provide desired ride and handling and come in a variety of spring ends, as shown in ● **FIGURE 112–10.**

CAUTION: The use of spacers between the coils of a coil spring is *not* recommended because the force exerted by the spacers on the springs can cause spring breakage. When a spacer is installed between the coils, the number of coils is reduced and the spring becomes stiffer. The force exerted on the coil spring at the contact points of the spacer can cause the spring to break.

SPRING RATE

Spring rate, also called *deflection rate,* is a value that reflects how much weight it takes to compress a spring a certain amount. Generally, spring rate is specified in pounds per inch, which is the weight in pounds it takes to compress the spring 1 inch. In other words, if a 100-pound weight causes a spring to compress 1 inch, the spring has a spring rate of 100 pounds.

A constant-rate spring continues to compress at the same rate throughout its complete range of deflection. For example, if a constant-rate spring compresses 1 inch under a 100-pound load, it will compress 2 inches under a 200-pound load, and so on. ● **SEE FIGURE 112–11.** Many automotive suspension springs, both coil and leaf, compress at a variable rate. That is, they become stiffer and exert more force the farther they compress. For example, a variable-rate spring may compress 1 inch under a 100-pound load, but only compress an additional 1/2 inch under a 200-pound load. Variable-rate springs offer a soft, comfortable ride under normal circumstances but will not bottom out as quickly when adverse road conditions compress them farther. ● **SEE FIGURE 112–12.**

Before a spring is installed on a vehicle or any load is placed on it, it is at its uncompressed length, or free length. Once installed, the weight of the corner of the vehicle resting on the spring is called its *static load.* The static load constantly compresses the spring. Therefore, the uncompressed length and the spring rate must be such that the spring has room to compress and keep the vehicle at the correct ride height *after* the static load is applied. ● **SEE FIGURE 112–13.**

Typical Front-Wheel-Drive Sedan Springs

	Force @ Height	Spring Rate
LF	1,343 lbs. @ 7.6 in.	256 lb. in.
RF	1,300 lbs. @ 7.6 in.	254 lb. in.
LR	638 lbs. @ 9.38 in.	200 lb. in.
RR	610 lbs. @ 9.38 in.	195 lb. in.

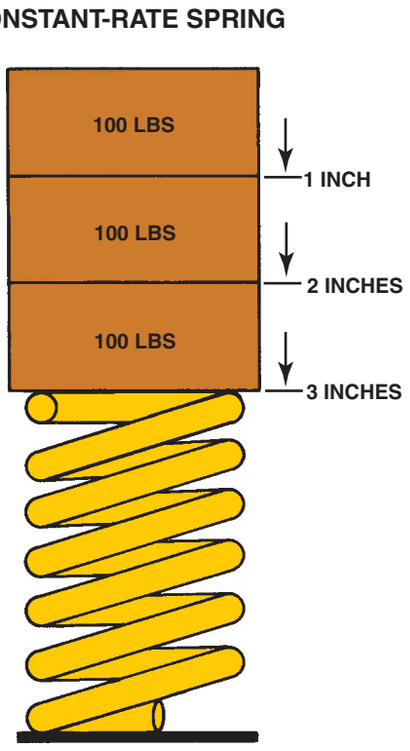

FIGURE 112–11 A constant-rate spring compresses at the same rate regardless of the amount of weight that is applied.

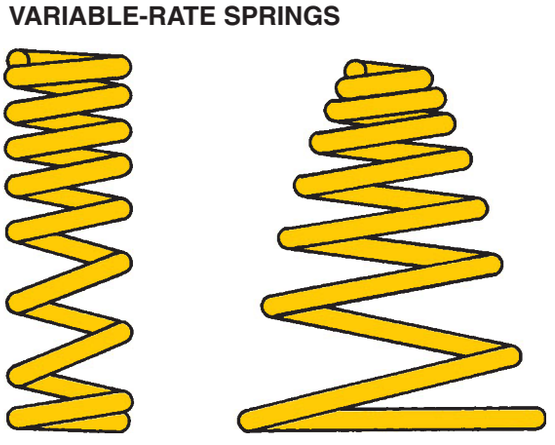

FIGURE 112–12 Variable-rate springs come in a variety of shapes and compress more slowly as weight is applied.

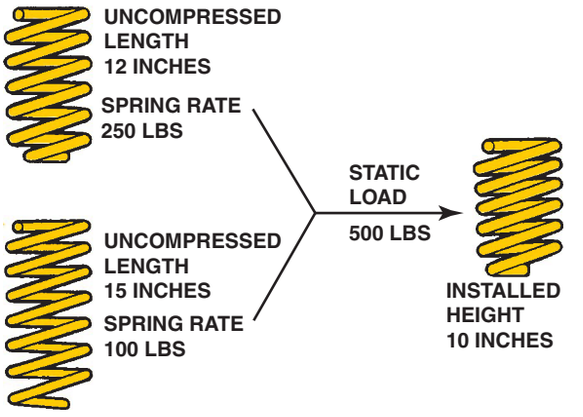

FIGURE 112–13 Two springs, each with a different spring rate and length, can provide the same ride height even though the higher-rate spring will give a stiffer ride.

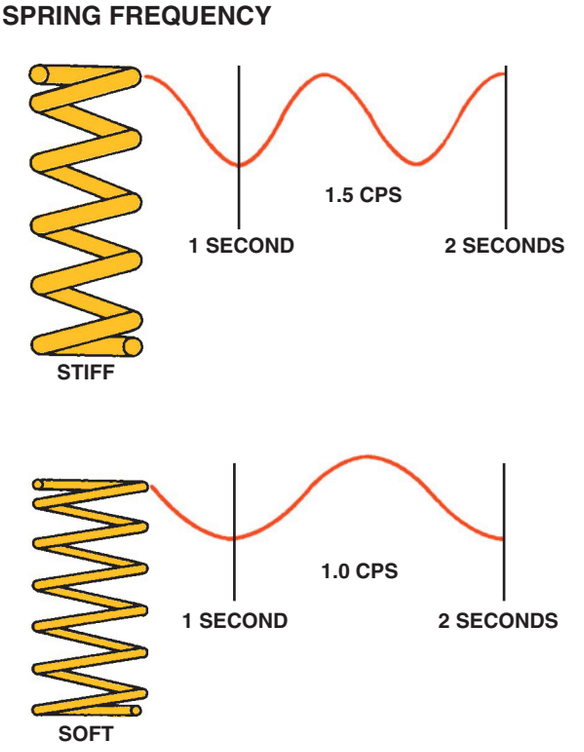

FIGURE 112–14 Stiffer springs bounce at a higher frequency than softer springs.

Notice that each of the four coil springs used on this vehicle is unique. The higher spring rate on the left is used to help support the weight of the driver. Because each spring is designed for each location on the vehicle, they should be marked if they are removed from a vehicle during service.

SPRING FREQUENCY Spring frequency is a value that reflects the speed at which a spring oscillates, or bounces, after it is released from compression or extension. Frequency is typically measured in cycles per second (CPS) or hertz (Hz). ● **SEE FIGURE 112–14.** There is a direct correlation between spring rate and spring frequency: the higher the spring rate, the higher the spring frequency. This means that stiffer springs bounce at a higher frequency, while softer springs bounce more slowly.

? FREQUENTLY ASKED QUESTION

Does the Spring Rate Change as the Vehicle Gets Older?

No, the spring rate of a spring does not change, but the spring load can change due to fatigue. The spring rate is the amount of force it takes to compress the spring 1 inch. The spring load is the amount of weight that a spring can support at any given compressed height. When a spring fatigues, the spring's load capacity decreases and the vehicle will sag.

WHEEL RATE Depending on the suspension design, springs are installed a certain distance away from the wheel, which determines the ratio of wheel travel to spring travel, or **wheel rate.** ● **SEE FIGURE 112–15.** For example, if a coil spring is mounted on the midpoint of a control arm, or halfway between the center of the wheel and the arm pivot points, it compresses approximately 1 inch when the wheel travels vertically 2 inches. On a strut-type suspension, the coil spring has a more direct ratio because it is closer to the wheel, so when the wheel of a strut travels vertically 2 inches, the spring also compresses 2 inches. This means that a coil spring used on a strut-type suspension is less than half the spring rate of a coil spring used on suspensions that use control arms.

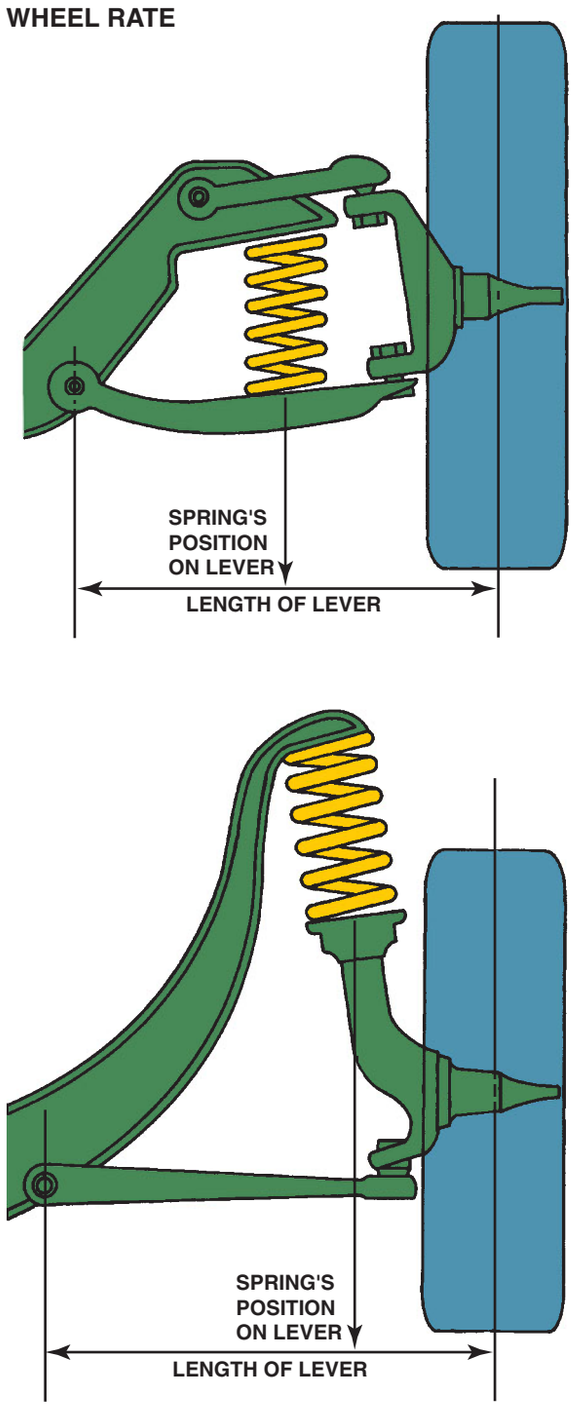

FIGURE 112–15 The wheel and arm act as a lever to compress the spring. The spring used on the top picture must be stiffer than the spring used on the strut-type suspension shown on the bottom because the length of the lever arm is shorter.

COIL SPRING MOUNTING Coil springs are usually installed in a **spring pocket** or spring seat. Hard rubber or plastic cushions or **insulators** are usually mounted between the coil spring and the spring seat. ● **SEE FIGURE 112–16.** The purpose of these insulators is to isolate and dampen road noise and vibration from the

TECH TIP

Don't Cut Those Coil Springs!

Chassis service technicians are often asked to lower a vehicle. One method is to remove the coil springs and cut off half or more coils from the spring. While this *will* lower the vehicle, this method is generally *not* recommended for the following reasons:

1. A coil spring could be damaged during the cutting-off procedure, especially if a torch is used to do the cutting.
2. The spring will get stiffer when shortened, often resulting in a very harsh ride.
3. The amount the vehicle is lowered is *less* than the amount cut off from the spring. This is because as the spring is shortened, it becomes stiffer. The stiffer spring will compress less than the original.

Instead of cutting springs to lower a vehicle, several preferable methods are available if the vehicle *must* be lowered:

1. There are replacement springs designed specifically to lower that model vehicle. A change in shock absorbers may be necessary because the shorter springs change the operating height of the stock (original) shock absorbers. Consult spring manufacturers for exact installation instructions and recommendations. ● **SEE FIGURE 112–17.**
2. There are replacement spindles designed to *raise* the location of the wheel spindle, thereby lowering the body in relation to the ground. Except for ground clearance problems, this is the method recommended by many chassis service technicians. Replacement spindles keep the same springs, shock absorbers, and ride, while lowering the vehicle without serious problems.

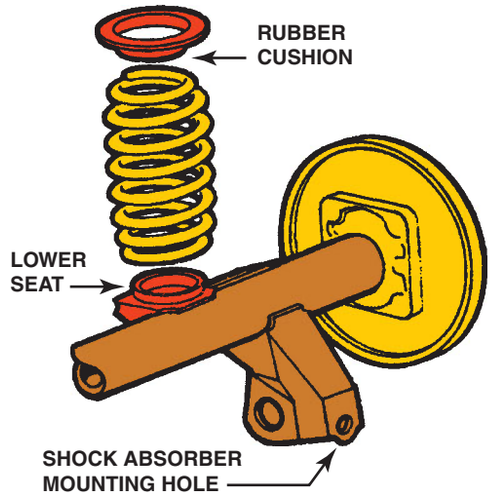

FIGURE 112–16 The spring cushion helps isolate noise and vibration from being transferred to the passenger compartment. *(Courtesy of Cooper Automotive Company)*

FIGURE 112–17 This replacement coil spring is coated to prevent rust and corrosion and colored to help identify the spring and/or spring manufacturer.

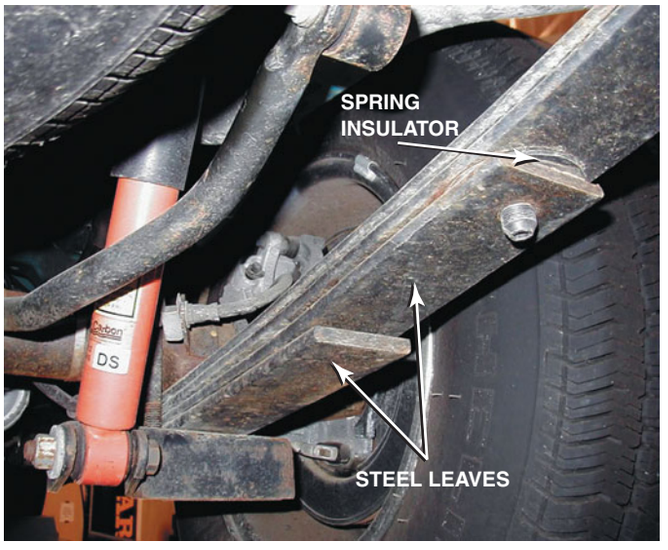

FIGURE 112–18 A typical leaf spring used on the rear of a pickup truck showing the plastic insulator between the leaves, which allows the spring to move without creating wear or noise.

vehicle body. The type of end on the coil spring also varies and determines the style of the spring mount.

SPRING COATINGS All springs are painted or coated with epoxy to help prevent breakage. A scratch, nick, or pit caused by corrosion can cause a **stress riser** that can lead to spring failure. The service technician should be careful not to remove any of the protective coating. Whenever a service operation requires the spring to be compressed, always use a tool that will not scratch or nick the surface of the spring.

LEAF SPRINGS

Leaf springs are constructed of one or more strips of long, narrow spring steel. These metal strips, called leaves, are assembled with plastic or synthetic rubber insulators between the leaves, allowing for freedom of movement during spring operation. ● **SEE FIGURE 112–18.**

The ends of the longest spring leaf are rolled or looped to form eyes. Rubber bushings are installed in the eyes of the spring and act as noise and vibration insulators. ● **SEE FIGURE 112–19.**

The leaves are held together by a **center bolt,** also called a *centering pin.* ● **SEE FIGURE 112–20.**

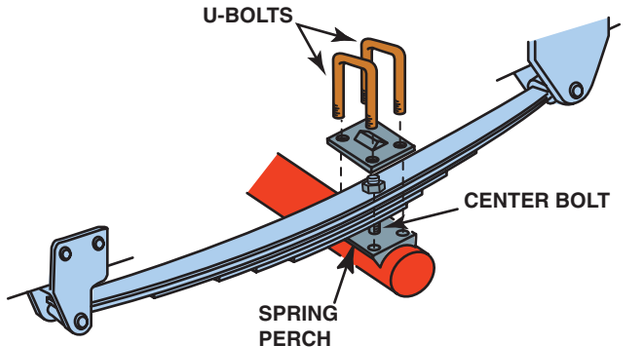

FIGURE 112–20 All multileaf springs use a center bolt to not only hold the leaves together but also help retain the leaf spring in the center of the spring perch.

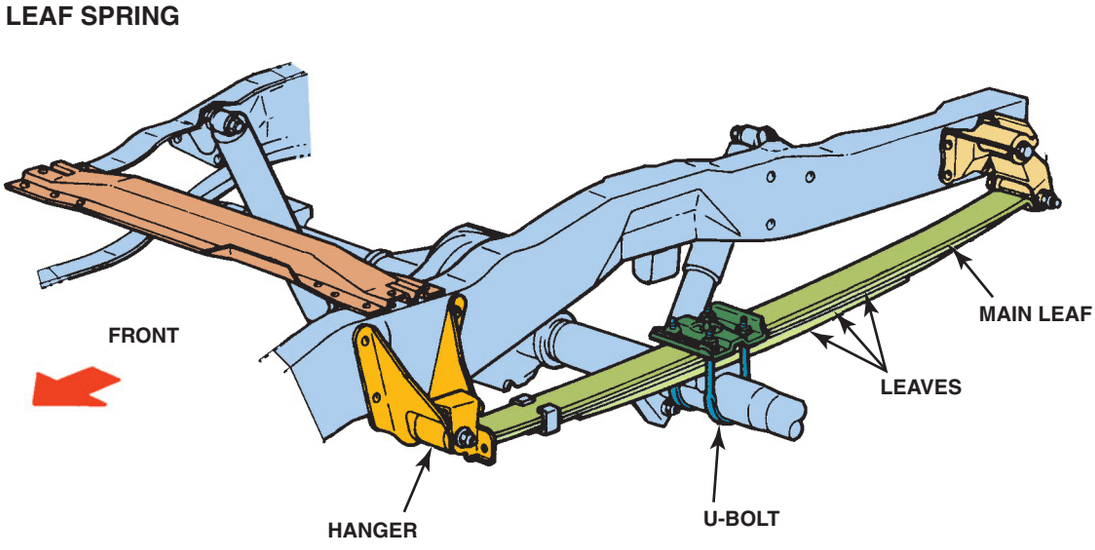

FIGURE 112–19 A typical leaf spring installation. The longest leaf, called the *main leaf,* attaches to the frame through a shackle and a hanger.

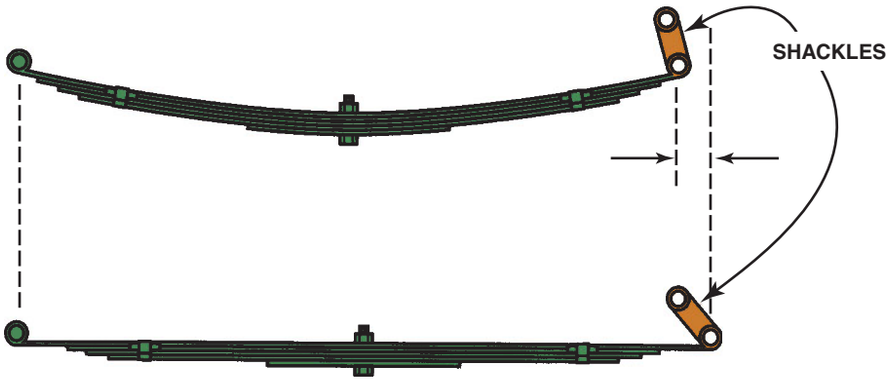

FIGURE 112–21 When a leaf spring is compressed, the spring flattens and becomes longer. The shackles allow for this lengthening. Rubber bushings are used in the ends of the spring and shackles to help isolate road noise from traveling into the passenger compartment.

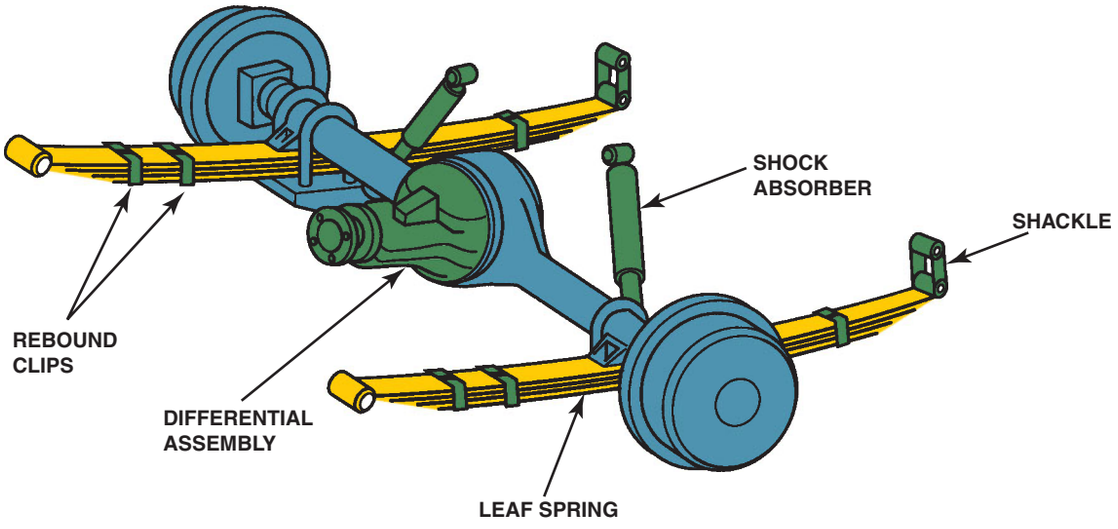

FIGURE 112–22 Typical rear leaf-spring suspension of a rear-wheel-drive vehicle.

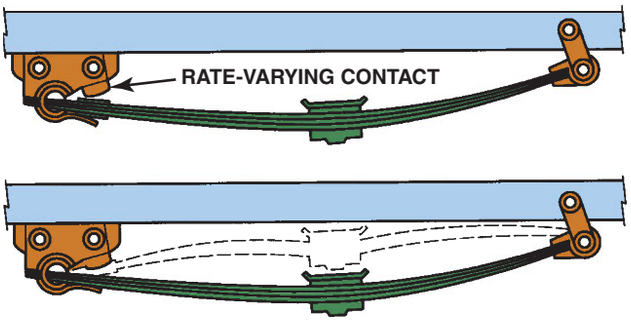

FIGURE 112–23 As the vehicle is loaded, the leaf spring contacts a section of the frame. This shortens the effective length of the spring, which makes it stiffer.

One end of a leaf spring is mounted to a hanger with a bolt and rubber bushings directly attached to the frame. The other end of the leaf spring is attached to the frame with movable mounting hangers called **shackles.** ● **SEE FIGURE 112–21.**

The shackles are necessary because as the spring hits a bump, the slightly curved spring (semi-elliptical) becomes longer and straighter, and the shackles allow for this rearward movement. **Rebound clips,** or spring alignment clips, help prevent the leaves from separating whenever the leaf spring is rebounding from hitting a bump or rise in the roadway. ● **SEE FIGURE 112–22**.

Single leaf steel springs, called **mono leaf,** are used on some vehicles. A single or mono leaf spring is usually tapered to produce a variable spring rate. Leaf springs are used for rear suspensions on cars and many light trucks. A variable rate can be accomplished with a leaf spring suspension by providing contacts on the mount that effectively shorten the spring once it is compressed to a certain point. This provides a smoother ride when the load is light and still provides a stiffer spring when the load is heavy. ● **SEE FIGURE 112–23**.

To provide additional load-carrying capacity, especially on trucks and vans, auxiliary or *helper* leaves are commonly used. This extra leaf becomes effective only when the vehicle is heavily loaded. ● **SEE FIGURE 112–24** on page 1297.

Leaf springs are used on the front suspension of many four-wheel-drive trucks, especially medium and heavy trucks.

COMPOSITE LEAF SPRINGS Since the early 1980s, fiberglass-reinforced epoxy plastic **composite leaf springs** have been used on production vehicles. They save weight: An 8-pound spring can replace a conventional 40-pound steel leaf spring. The secret to making a strong plastic leaf spring is the glass fibers

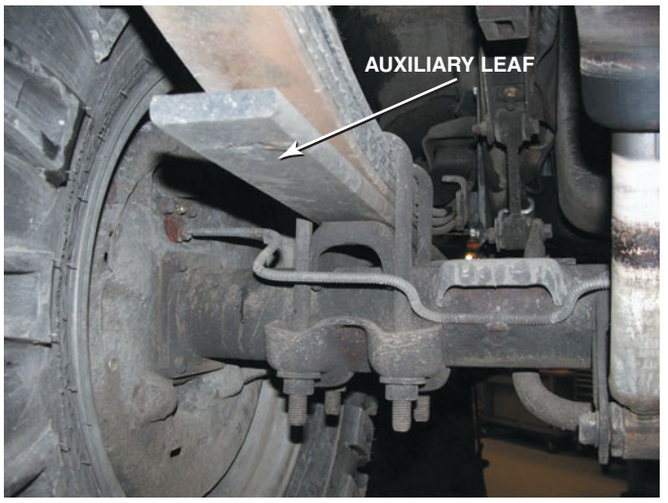

FIGURE 112–24 Many pickup trucks, vans, and sport utility vehicles (SUVs) use auxiliary leaf springs that contact the other leaves when the load is increased.

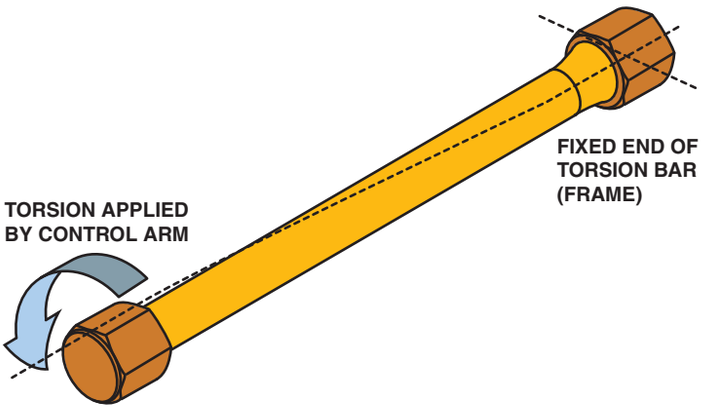

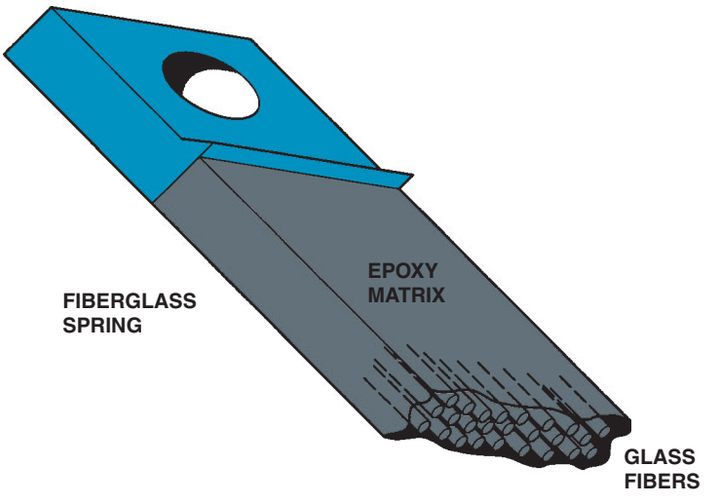

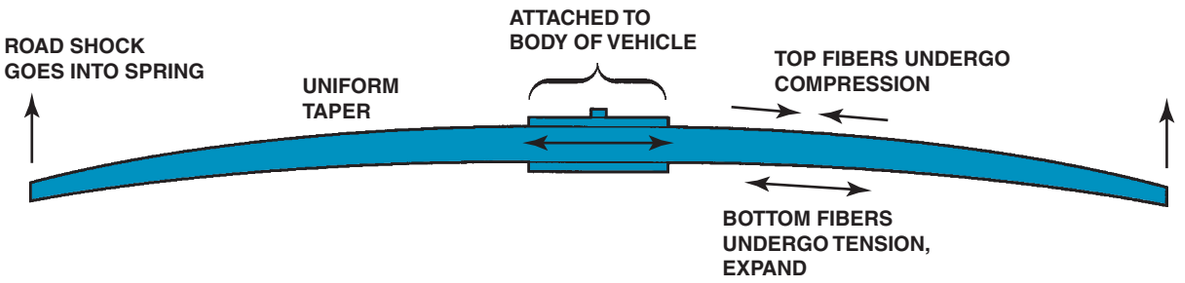

FIGURE 112–26 A torsion bar resists twisting and is used as a spring on some cars and many four-wheel-drive pickup trucks and sport utility vehicles. The larger the diameter, or the shorter the torsion bar, the stiffer the bar. A torsion bar twists very little during normal operation and about a 1/16 of a revolution during a major suspension travel event.

FIGURE 112–25 (a) A fiberglass spring is composed of long fibers locked together in an epoxy (resin) matrix. (b) When the spring compresses, the bottom of the spring expands and the top compresses. Composite leaf springs are used and mounted transversely (side-to-side) on Chevrolet Corvettes and at the rear on some other General Motors vehicles.

(a)

(b)

running continuously from one end of the spring to the other, and the use of 70% fiberglass with 30% epoxy composite. The single-leaf composite spring helps isolate road noise and vibrations. It is more efficient than a multileaf spring because it eliminates the interleaf friction of the steel leaves and requires less space. ● **SEE FIGURE 112–25**.

Leaf spring rate increases when the thickness increases, and decreases as the length increases.

TORSION BARS

A **torsion bar** is a spring that is a long, *round,* hardened steel bar similar to a coil spring except that it is a *straight* bar. ● **SEE FIGURE 112–26**.

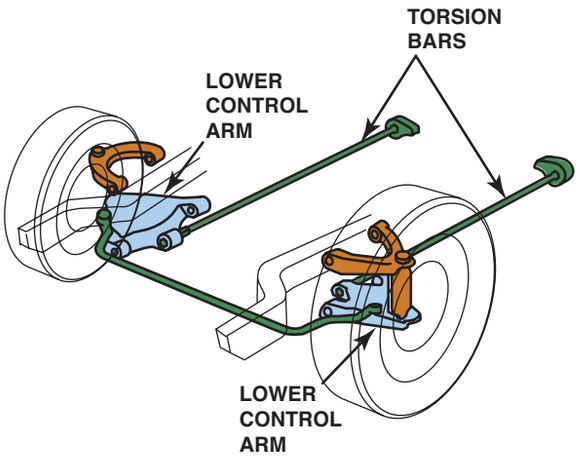

FIGURE 112–27 Longitudinal torsion bars attach at the lower control arm at the front and at the frame at the rear of the bar.

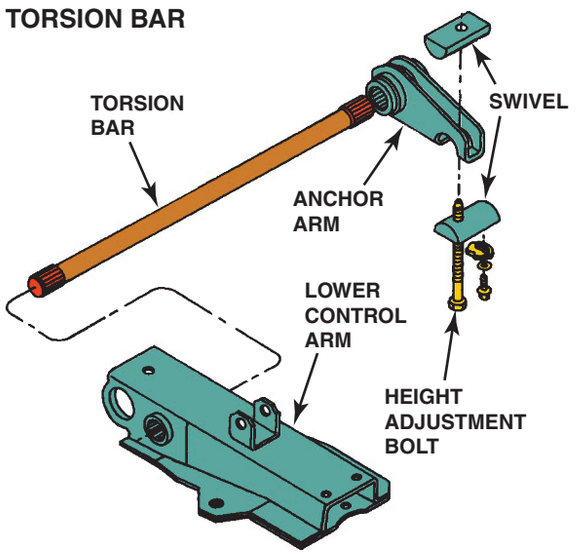

FIGURE 112–28 One end of the torsion bar attaches to the lower control arm and the other to an anchor arm that is adjustable.

One end is attached to the lower control arm of a front suspension and the other end to the frame. When the wheels hit a bump, the bar twists and then untwists. General Motors pickup trucks use torsion-bar front suspension longitudinally. ● **SEE FIGURE 112–27**.

Many manufacturers of pickup trucks currently use torsion-bar-type suspensions, especially on their four-wheel-drive models. Torsion bars allow room for the front drive axle and constant velocity joint and still provide for strong suspension.

As with all automotive springs, spring action is controlled by the shock absorbers. Unlike other types of springs, torsion bars may be adjustable for correct ride height. ● **SEE FIGURE 112–28.**

Most torsion bars are labeled *left* or *right,* usually stamped into the end of the bars. The purpose of this designation is to make sure that the correct bar is installed on the original side of the vehicle. Torsion bars are manufactured without any built-in direction or preload. However, after being in a vehicle, the bar takes a set; reversing the side the torsion bar is used on causes the bar to be twisted in the opposite direction. Even though the bars are usually interchangeable, proper ride height can be accomplished even if the bars were installed on the side opposite from the original. But because the bar is being "worked" in the opposite direction, it can weaken and break. If a torsion bar breaks, the entire suspension collapses; this can cause severe vehicle damage, as well as a serious accident.

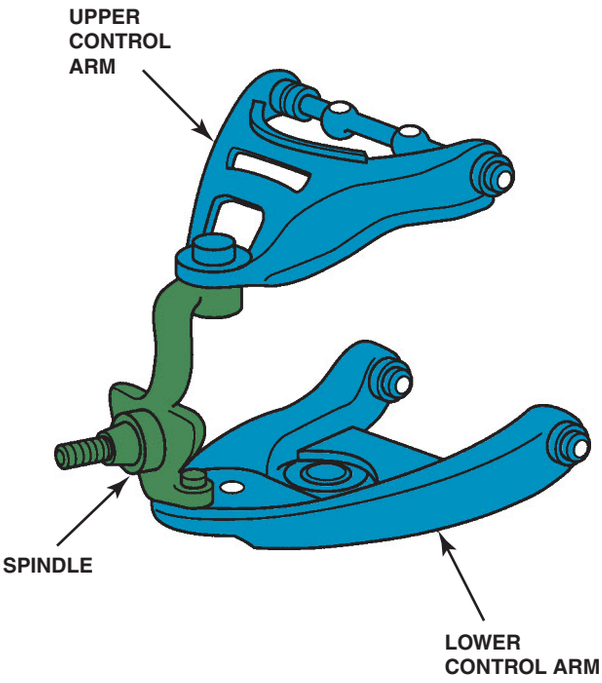

FIGURE 112–29 The spindle supports the wheels and attaches to the control arm with ball-and-socket joints called ball joints. The control arm attaches to the frame of the vehicle through rubber bushings to help isolate noise and vibration between the road and the body. (*Courtesy of Cooper Automotive Company*)

SUSPENSION PRINCIPLES

Suspensions use various links, arms, and joints to allow the wheels to move freely up and down; front suspensions also have to allow the front wheels to turn. All suspensions must provide for the following supports:

1. **Transverse (or side-to-side) wheel support.** As the wheels of the vehicle move up and down, the suspension must accommodate this movement and still keep the wheel from moving away from the vehicle or inward toward the center of the vehicle. ● **SEE FIGURE 112–29**. The control arm pivots on the vehicle frame. The wheels attach to a spindle that attaches to the ball joint at the end of the control arm. Transverse links are also called **lateral links.**
2. **Longitudinal (front-to-back) wheel support.** As the wheels of the vehicle move up and down, the suspension must allow for this movement and still keep the wheels from moving backward whenever a bump is hit. Note in ● **FIGURE 112–29** how the separation of the pivot points, where the control arm meets the frame, provides support to prevent front-to-back wheel movement.

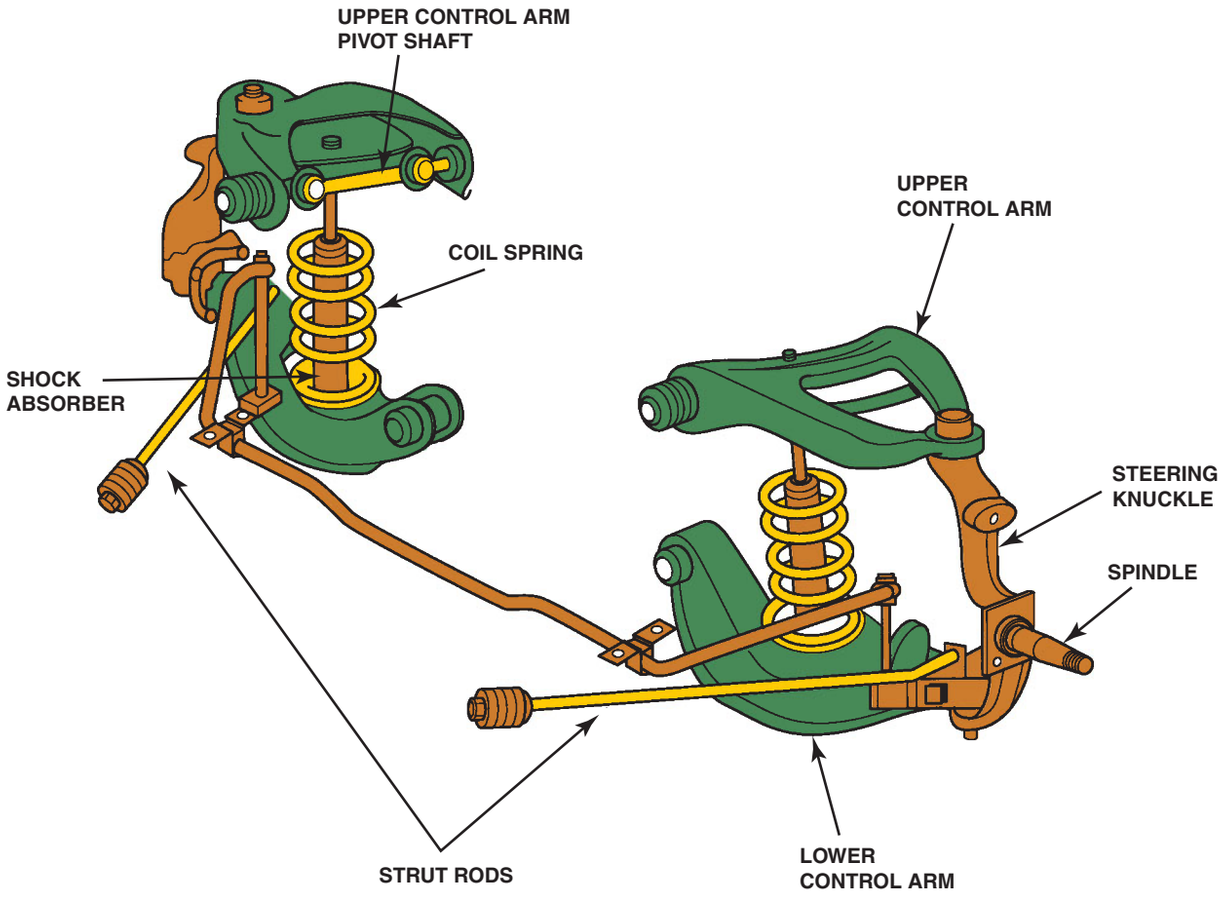

FIGURE 112–30 The strut rods provide longitudinal support to the suspension to prevent forward or rearward movement of the control arms.

At least two suspension links or arms are required in order to provide for freedom of movement up or down, and to *prevent* any in–out or forward–back movement. Some suspension designs use an additional member to control forward–back movement. ● **SEE FIGURE 112–30.**

The design of the suspension and the location of the suspension mounting points on the frame or body are critical to proper vehicle handling. Two very important design factors are called **anti-squat** and **anti-dive.**

1. **Anti-squat.** Anti-squat refers to the reaction of the body of a vehicle during acceleration. It is normal in most designs for the vehicle to squat down at the rear while accelerating. Most drivers feel comfortable feeling this reaction, even on front-wheel-drive vehicles. Anti-squat refers to the degree to which this normal force is neutralized. If 100% anti-squat were designed into the suspension system, the vehicle would remain level while accelerating.
2. **Anti-dive.** Anti-dive refers to the force that causes the front of the vehicle to drop down while braking. Some front-nose dive feels normal to most drivers. If 100% anti-dive were designed into a vehicle, it would remain perfectly level while braking.

The service technician cannot, and should not, attempt to change anti-squat or anti-dive characteristics built into the design of the vehicle. However, if the customer notices more squat or dive than normal, then the technician should carefully inspect all suspension components, especially those mounting points to the frame or body.

STEERING KNUCKLES

A **steering knuckle** is hard to classify either as part of the suspension or as part of the wheel. A knuckle serves two purposes:

- To join the suspension to the wheel
- Usually includes the spindle where the front wheel bearings are attached
- To provide pivot points between the suspension and wheel.

Knuckles are used with independent suspensions and at the wheels that steer the vehicle. ● **SEE FIGURE 112–31.**

The only knuckle that uses a **kingpin** is a steering knuckle on an I-beam or twin I-beam front suspension. ● **SEE FIGURE 112–32.** A kingpin steering knuckle keeps the wheel rigid in relation to the I-beam during up-and-down wheel movement, but rotates around the steering axis to turn the wheels left and right. The steering axis is the vertical center of the kingpin.

CONTROL ARMS

A **control arm** is a suspension link that connects a knuckle or wheel flange to the frame. One end of a control arm attaches to the knuckle or wheel flange, generally with either a ball joint or

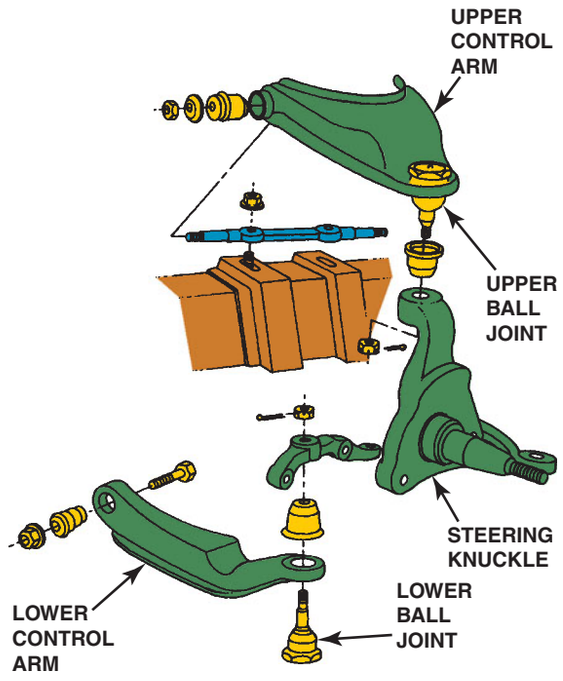

FIGURE 112–31 The steering knuckle used on a short/long-arm front suspension.

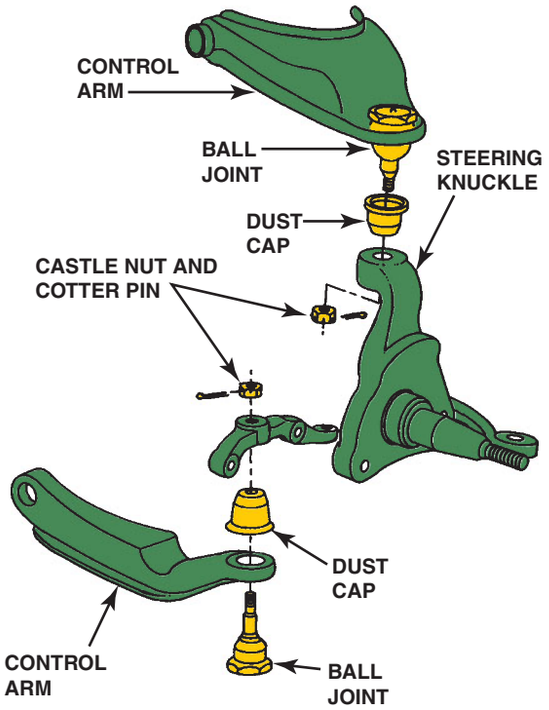

FIGURE 112–33 Control arms are used to connect the steering knuckle to the frame or body of the vehicle and provide the structural support for the suspension system.

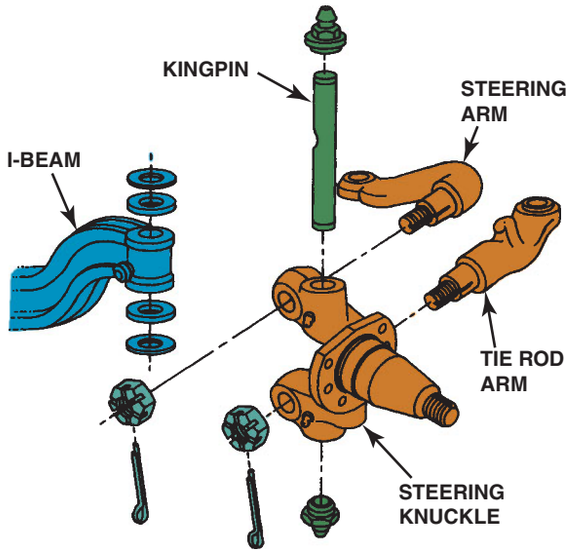

FIGURE 112–32 A kingpin is a steel shaft or pin that joins the steering knuckle to the suspension and allows the steering knuckle to pivot.

bushing. The opposite end of the arm, which attaches to a frame member, usually pivots on a bushing. ● **SEE FIGURE 112–33.** The end attached to the frame must pivot to allow the axle or knuckle to travel vertically.

BALL JOINTS

PURPOSE AND FUNCTION **Ball joints** are actually ball-and-socket joints, similar to the joints in a person's shoulder. Ball joints allow the front wheels to move up and down, as well as side to side (for steering).

A vehicle can be equipped with coil springs, mounted either above the upper control arm *or* on the lower control arm. ● **SEE FIGURE 112–34.**

If the coil spring is attached to the top of the upper control arm, then the upper ball joint is carrying the weight of the vehicle and is called the **load-carrying ball joint.** The lower ball joint is called the **non-load-carrying,** or *follower,* **ball joint.** ● **SEE FIGURE 112–35.**

If the coil spring is attached to the lower control arm, then the lower ball joint is the load-carrying ball joint and the upper joint is the follower ball joint. ● **SEE FIGURE 112–36.**

If a torsion-bar-type spring is used, the lower ball joint is a load-carrying joint because the torsion bar is attached to the lower control arm on most vehicles that use torsion bars.

BALL JOINT DESIGN There are two basic designs of ball joints: compression loaded and tension loaded. If the control arm rests on the steering knuckle, the ball joint is *compressed* into the control arm by the weight of the vehicle. If the knuckle rests on the control arm, the weight of the vehicle tends to pull the ball joint back into the control arm by *tension.* The type used is determined by the chassis design engineer, and the service technician cannot change the type of ball joint used for a particular application. ● **SEE FIGURE 112–37** on page 1303.

A specific amount of stud-turning resistance is built into each ball joint to stabilize steering. A ball joint that does not support the weight of the vehicle and acts as a suspension pivot is often called a follower ball joint or a *friction ball joint.* The load-carrying (weight-carrying) ball joint is subjected to the greatest amount of wear and is the most frequently replaced.

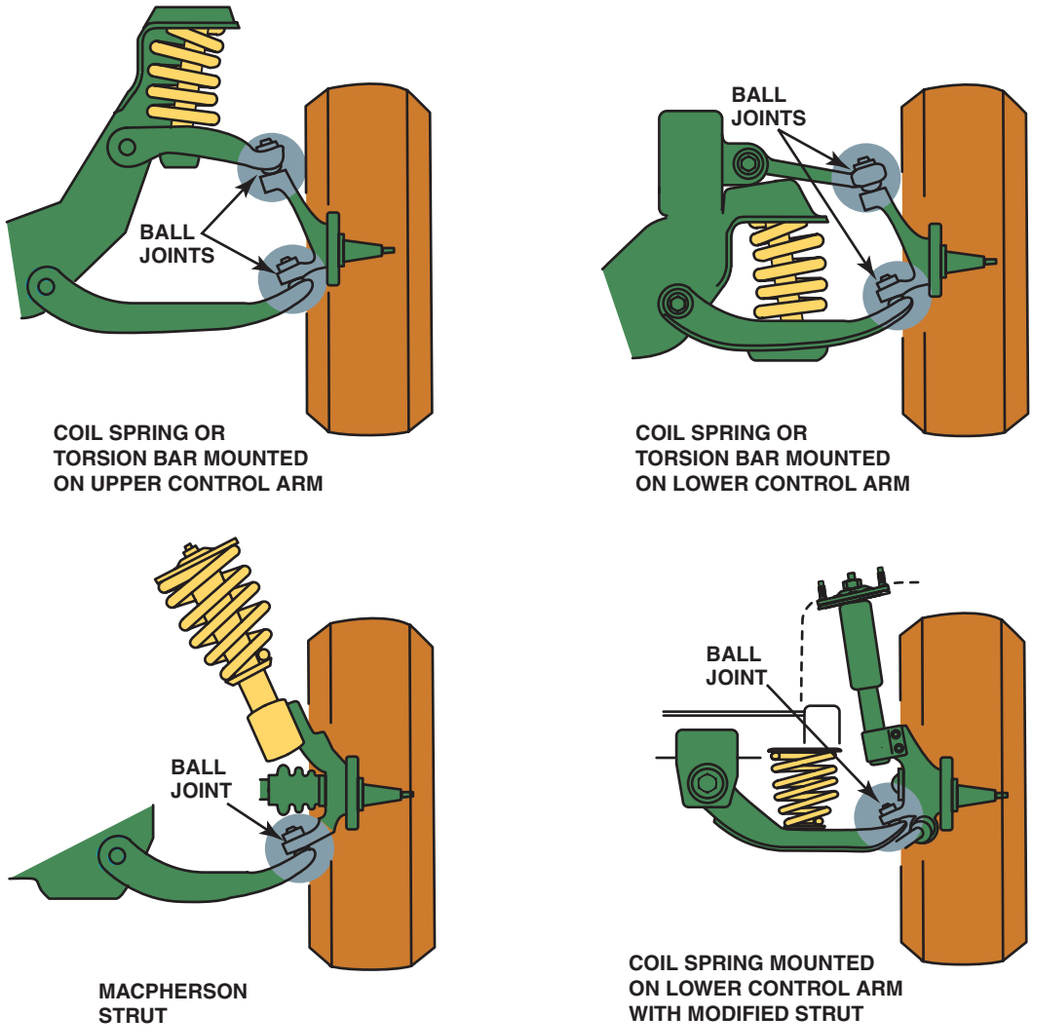

FIGURE 112–34 Ball joints provide the freedom of movement necessary for steering and suspension movements.

STRUT RODS

PURPOSE AND FUNCTION Some vehicles are equipped with round steel rods that are attached between the lower control arm at one end and the frame of the vehicle with rubber bushings, called strut rod bushings, at the other end. The purpose of these **strut rods** is to provide forward/backward support to the control arms. Strut rods are used on vehicles equipped with MacPherson struts and many short/long-arm-type suspensions. The bushings are very important in maintaining proper wheel alignment while providing the necessary up-and-down movement of the control arms during suspension travel. Strut rods prevent lower control arm movement back and forth during braking. ● **SEE FIGURE 112–38.**

TERMINOLOGY Strut rods are also called tension or compression rods or simply TC rods. Tension rods attach in *front* of the wheels to the body or frame where the rod is being pulled in tension. Compression rods attach to the body or frame *behind* the wheels where the rod is being pushed or compressed. Some vehicle manufacturers call the strut rod a drag rod because it is attached in front of the wheels, and therefore acts on the lower control arm as if to drag the wheels behind their attachment points.

The bushings are replaceable by removing a nut on the frame end of the strut rod. ● **SEE FIGURE 112–39.** If a strut rod has a nut on *both* sides of the bushings, then the strut rod is used to adjust *caster.*

STABILIZER BARS

Most cars and trucks are equipped with a **stabilizer bar** on the front suspension, which is a round, hardened steel bar (usually SAE 4560 or 4340 steel) attached to both lower control arms with bolts and rubber bushing washers called stabilizer bar bushings. ● **SEE FIGURE 112–40** on page 1304.

A stabilizer bar is also called an anti-sway bar (sway bar) or anti-roll bar (roll bar). A stabilizer bar operates by *twisting* the bar if one side of the vehicle moves up or down in relation to the other side, such as during cornering, hitting bumps, or driving over uneven road surfaces. ● **SEE FIGURE 112–41** on page 1304.

The purpose of the stabilizer bar is to prevent excessive body roll while cornering and to add stability while driving over rough road surfaces. The stabilizer bar is also used as a longitudinal (front/back) support to the lower control arm on many vehicles equipped

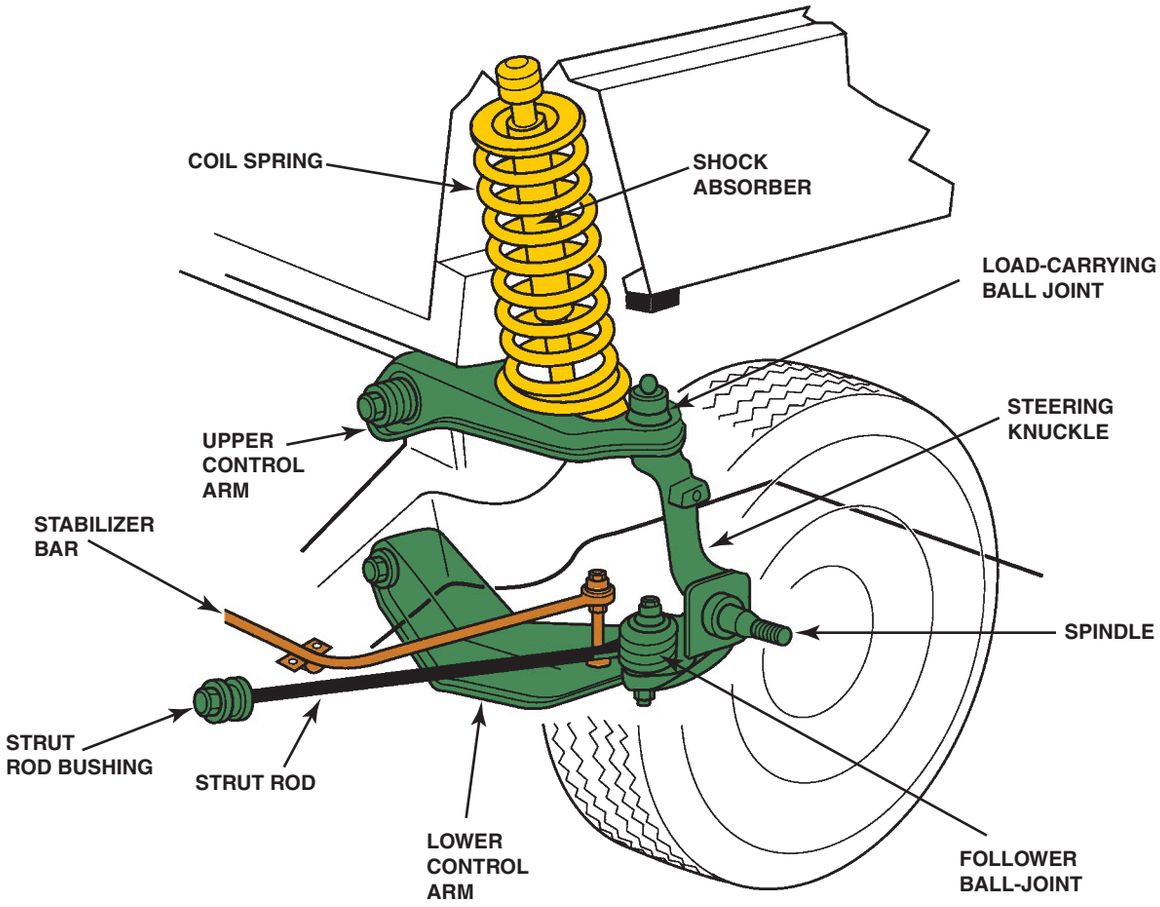

FIGURE 112–35 The upper ball joint is load carrying in this type of suspension because the weight of the vehicle is applied through the spring, upper control arm, and ball joint to the wheel. The lower control arm is a lateral link, and the lower ball joint is called a follower ball joint.

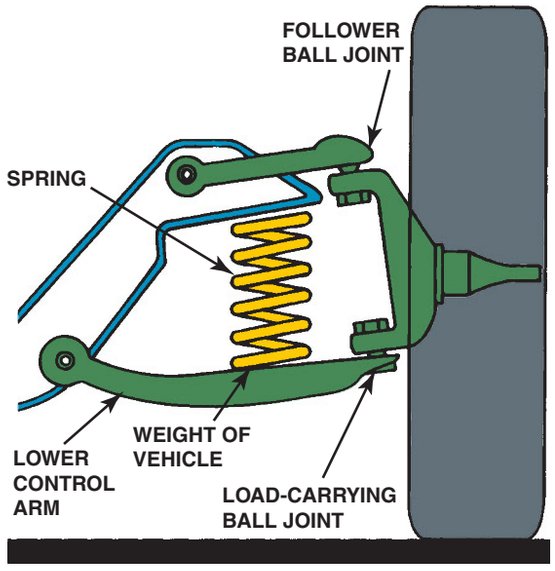

FIGURE 112–36 The lower ball joint is load carrying in this type of suspension because the weight of the vehicle is applied through the spring, lower control arm, and ball joint to the wheel.

with MacPherson struts. The effective force of a stabilizer bar is increased with the diameter of the bar. Therefore, optional suspensions often include larger-diameter stabilizer bars and bushings.

Stabilizer links connect the ends of the stabilizer bar to the lower control arm. ● **SEE FIGURES 112–42 AND 112–43.** Careful inspection of the stabilizer bar links is important. Links are commonly found to be defective (cracked rubber washers or broken spacer bolts) because of the great amount of force that is transmitted through the links and the bushings. Defective links and/or bushings can cause unsafe vehicle handling and noise.

SHOCK ABSORBERS

PURPOSE AND FUNCTION

Shock absorbers are used on all conventional suspension systems to dampen and control the motion of the vehicle's springs. Without shock absorbers (dampers), the vehicle would continue to bounce after hitting bumps. ● **SEE FIGURE 112–44.**

The major purpose of any shock or strut is to control ride and handling. Standard shock absorbers *do not* support the weight of a vehicle. *The springs support the weight of the vehicle; the shock absorbers control the actions and reactions of the springs.* Shock absorbers are also called dampers.

Most shock absorbers are *direct acting* because they are connected directly between the vehicle frame or body and the axles. ● **SEE FIGURE 112–45.**

As a wheel rolls over a bump, the wheel moves toward the body and compresses the spring(s) of the vehicle. As the spring compresses, it stores energy. The spring then releases this stored energy, causing the body of the vehicle to rise (rebound). ● **SEE FIGURE 112–46.**

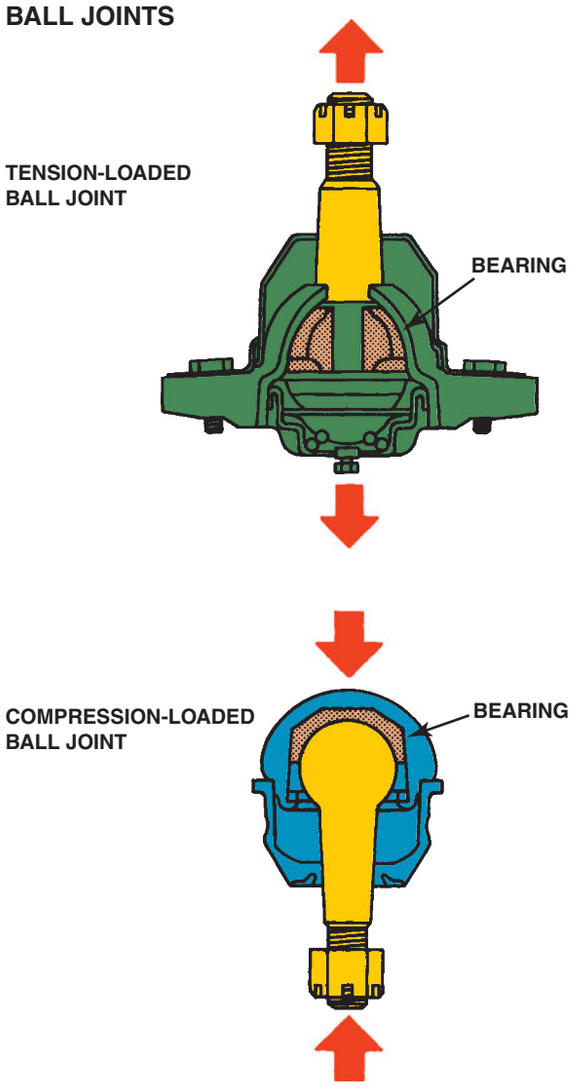

FIGURE 112–37 All ball joints, whether tension or compression loaded, have a bearing surface between the ball stud and socket.

After the energy in the spring is used up, the body starts downward, causing the spring to compress. Without shock absorbers, the energy released from the spring would be very rapid and violent. The shock absorber helps dampen the rapid up-and-down movement of the vehicle springs by converting energy of movement into heat by forcing hydraulic fluid through small holes inside the shock absorber.

SHOCK ABSORBER OPERATION The hydraulic shock absorber operates on the principle of fluid being forced through a small opening (orifice). ● **SEE FIGURES 112–47 AND 112–48.** Besides small openings, pressure relief valves are built into most shock absorbers to control vehicle ride under all operating conditions.

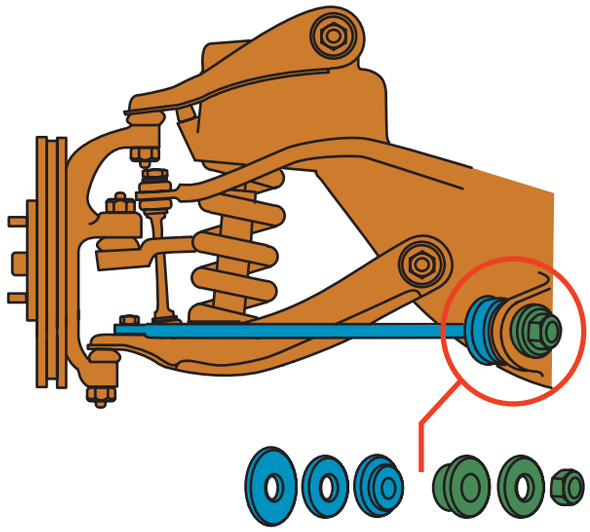

FIGURE 112–39 Strut rod bushings insulate the steel bar from the vehicle frame or body.

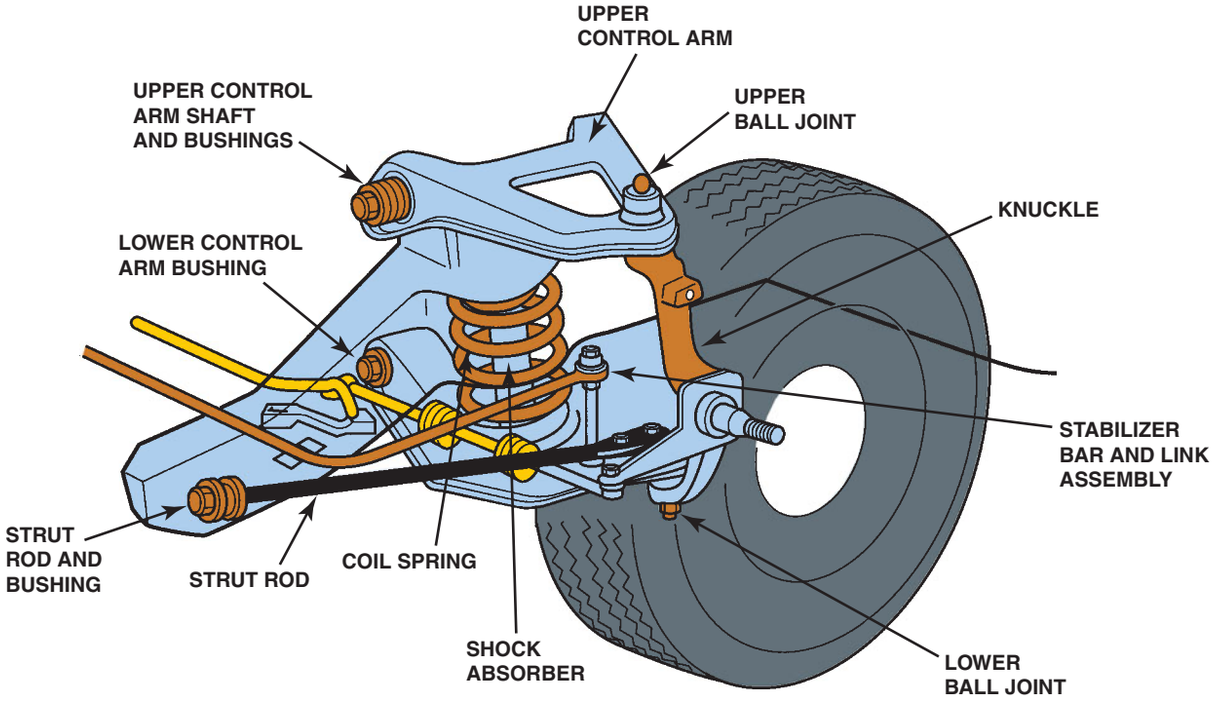

FIGURE 112–38 A strut rod is the longitudinal support to prevent front-to-back wheel movement. Struts rods are only used when there is only one lower control arm bushing and not used where there are two lower control arm bushings.

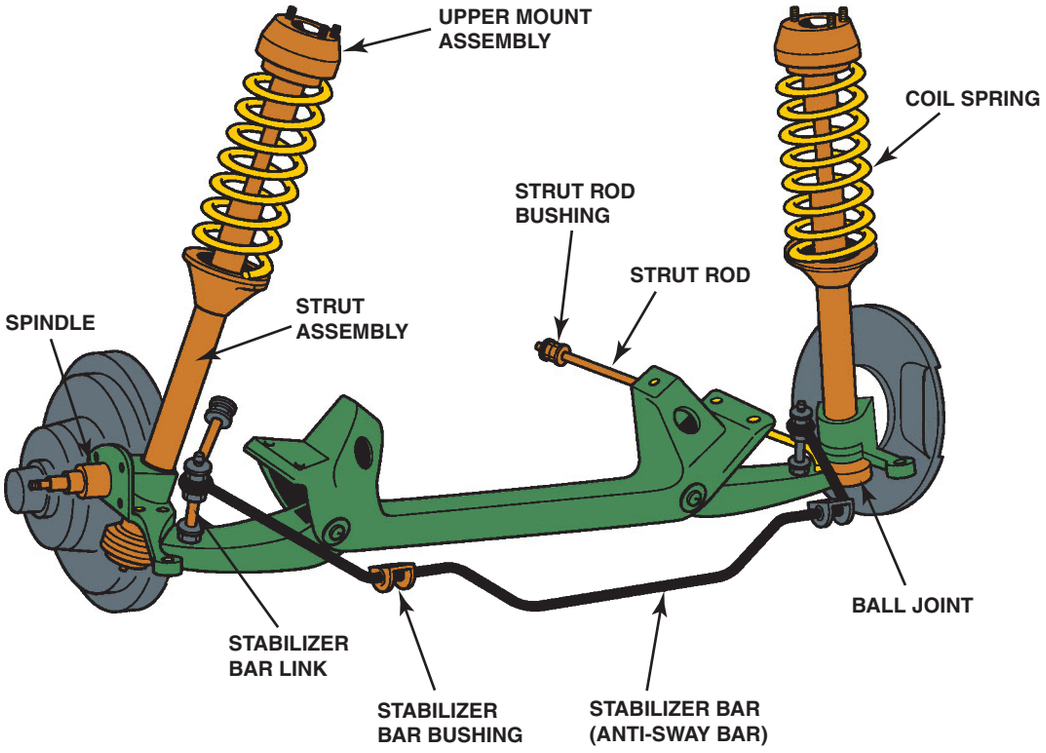

FIGURE 112–40 Typical stabilizer bar installation.

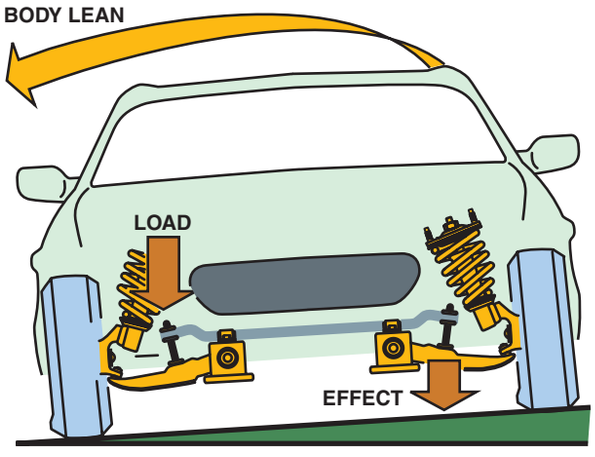

FIGURE 112–41 As the body of the vehicle leans, the stabilizer bar is twisted. The force exerted by the stabilizer bar counteracts the body lean.

The greater the pressure drop of the fluid inside the shock and the greater the amount of fluid moved through the orifice, the greater the amount of dampening; therefore, larger shock absorbers can usually provide better dampening than smaller units.

GAS-CHARGED SHOCKS Most shock absorbers on new vehicles are gas charged. Pressurizing the oil inside the shock absorber helps smooth the ride over rough roads. This pressure helps prevent air pockets from forming in the shock absorber oil as it passes through the small passages in the shock. After the oil is forced through small passages, the pressure drops and the oil expands. As the oil expands, bubbles are created. The oil becomes foamy. This air-filled oil does not effectively provide dampening. The result of all of this aeration (air being mixed with the oil) is lack of dampening and a harsh ride.

The use of higher-pressure radial tires and lighter vehicle weight has created the need for more effective shock absorbers. To meet this need, shock absorber design engineers use a pressurized gas that does not react chemically with the oil in the shock. If a substance does not react with any other substances, it is called *inert.* The gas most often used is nitrogen, which is about 78% of our atmosphere. Typical gas-charged shocks are pressurized with 130 to 150 PSI (900 to 1,030 kPa) to aid in both handling and ride control. Some shocks use higher pressures, but the higher the pressure, the greater the possibility of leaks and the harsher the ride.

Some gas-charged shock absorbers use a single tube that contains two pistons that separate the high-pressure gas from the working fluid. Single-tube shocks are also called monotube or DeCarbon after the French inventor of the principle and manufacturer of suspension components. ● **SEE FIGURE 112–49.**

AIR SHOCKS/STRUTS Air-inflatable shock absorbers or struts are used in the rear of vehicles to provide proper vehicle ride height while carrying heavy loads. Many air shock/strut units are original

? **FREQUENTLY ASKED QUESTION**

What Are Remote Reservoir Shocks?

Remote reservoir shock absorbers are units designed for heavy-duty use that use a separate container for the working fluid. ● **SEE FIGURE 112–50** on page 1308.

The purpose of the remote fluid reservoir is to keep the temperature of the fluid stable, which helps the shock absorber provide consistent dampening under all conditions.

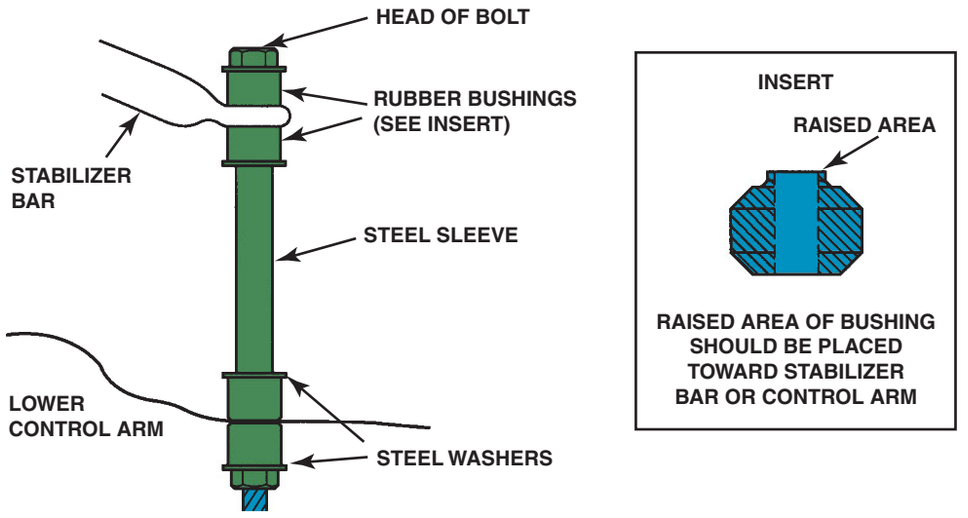

FIGURE 112–42 Stabilizer bar links are sold as a kit consisting of the long bolt with steel sleeve and rubber or urethane bushings. Steel washers are used on both sides of the rubber bushings as shown.

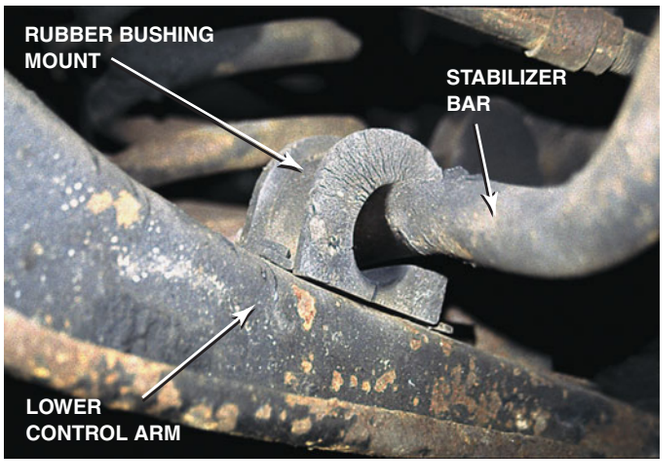

FIGURE 112–43 Notice how the lower control arm pulls down on the mounting bushing when the vehicle is hoisted off the ground, allowing the front suspension to drop down. These bushings are a common source of noise, especially when cold. Lubricating the bushings with paste silicone grease often cures the noise.

equipment. They are often combined with a built-in air compressor and ride height sensor(s) to provide automatic ride height control.

Air-inflatable shocks are standard shock absorbers with an air chamber and a rubber bag built into the dust cover (top) of the shock. ● **SEE FIGURE 112–51** on page 1308.

Air pressure is used to inflate the bag, which raises the installed height of the shock. As the shock increases in height, the rear of the vehicle is raised. Typical maximum air pressure in air shocks ranges from 90 to 150 PSI (620 to 1,030 kPa). As the air pressure increases in the air-inflatable reservoir of the shock, the stiffness of the suspension increases. This additional stiffness is due to the shock taking weight from the spring, and therefore the air in the air shock becomes an air spring. Now, with two springs to support the vehicle, the spring rate increases and a harsher ride often results. *It is important that the load capacity of the vehicle not be exceeded or serious damage can occur to the vehicle's springs, axles, bearings, and shock support mounts.*

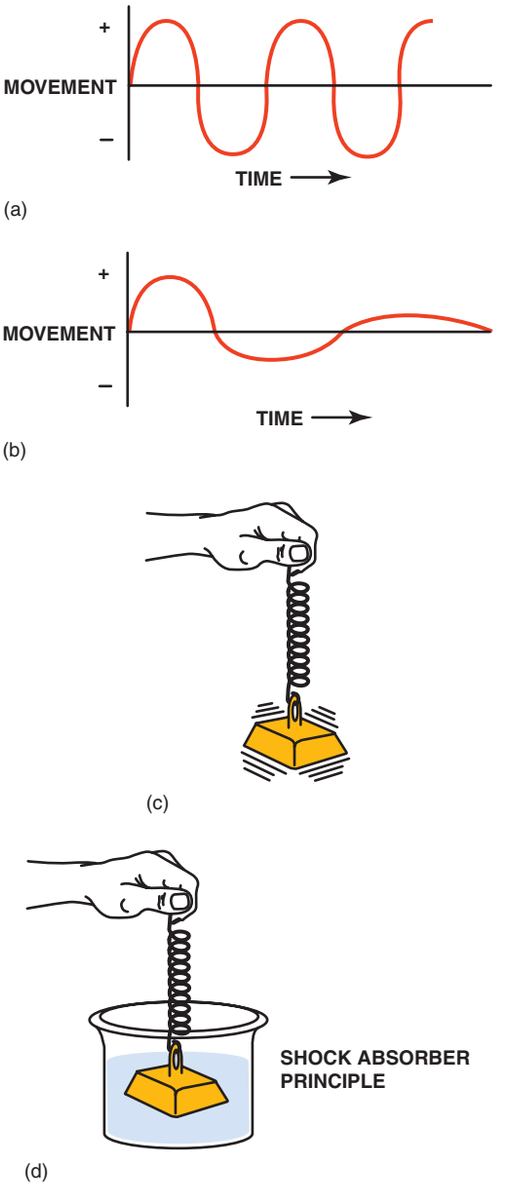

FIGURE 112–44 (a) Movement of the vehicle is supported by springs without a dampening device. (b) Spring action is dampened with a shock absorber. (c) The function of any shock absorber is to dampen the movement or action of a spring, similar to using a liquid to control the movement of a weight on a spring (d).

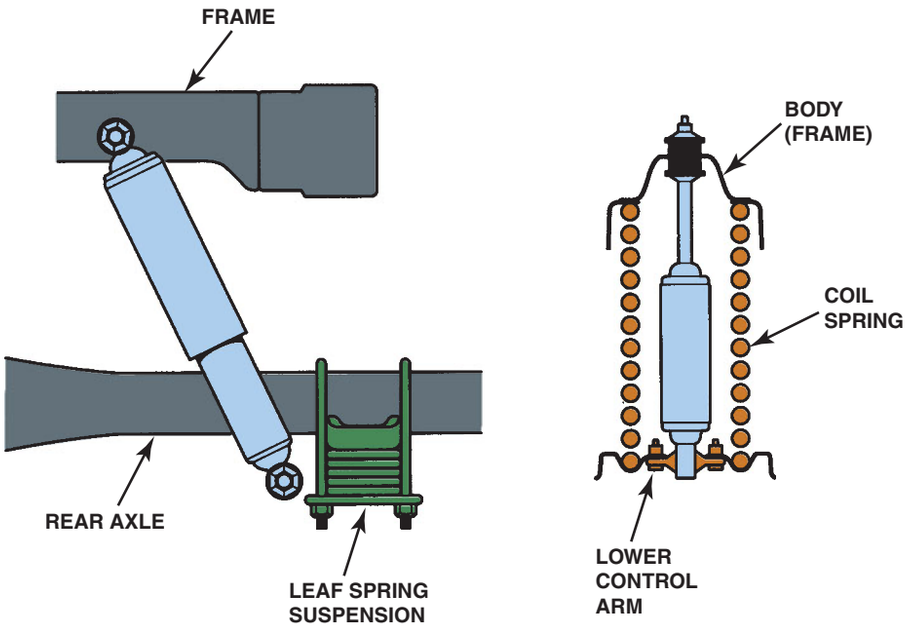

FIGURE 112–45 Shock absorbers work best when mounted as close to the spring as possible. Shock absorbers that are mounted straight up and down offer the most dampening.

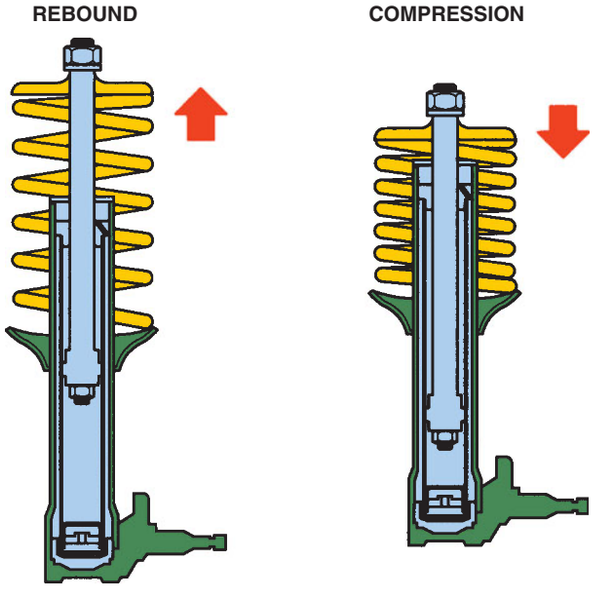

FIGURE 112–46 When a vehicle hits a bump in the road, the suspension moves upward. This is called compression or jounce. Rebound is when the spring (coil, torsion bar, or leaf) returns to its original position.

AIR SPRINGS

Some electronically controlled suspension systems use air springs. A basic **air spring** consists of a rubber air chamber, generally closed at the bottom by a piston fitted into a control arm, or by a strut shock absorber. ● **SEE FIGURE 112–52** on page 1309.

Electronically controlled suspension systems that use air springs as the only springs are available on some Hummer, and many Ford, Mercury, and Lincoln vehicles.

Some air springs are in effect auxiliary springs inside a coil-spring strut. In these designs, the coil spring supports the weight of the vehicle, while the air spring raises or lowers the body to adjust ride height according to load. ● **SEE FIGURE 112–53** on page 1309.

COIL-OVER SHOCKS. A coil-over shock absorber uses the force of an external coil spring to boost the performance of the basic shock absorber. ● **SEE FIGURE 112–54** on page 1309. The spring usually extends from the upper shock mount to a seat on the lower portion of the cylinder. The spring rate added to the hydraulic resistance makes the shock stiffer.

STRUTS

PURPOSE AND FUNCTION

A **strut** is a sturdy shock absorber that is also a structural component of the suspension. A strut is a suspension link as well as a shock absorber. The casing of a strut must be strong and rigid to function as a suspension link. The shock absorber assembles inside the casing of a strut, and may be either a removable cartridge or an integral part of the strut.

MACPHERSON STRUTS

The MacPherson strut, which is named after Earle S. MacPherson, who developed the suspension design in the late 1940s and patented it in 1953, is the most commonly used type. A MacPherson strut includes the suspension spring—a coil spring that surrounds the strut casing—so that it transfers the weight of the body to the wheel. ● **SEE FIGURE 112–55.**

A MacPherson strut typically incorporates an upper and a lower spring seat, a shock absorber mount and dust cap, a dust cover for the piston rod, and a bump stop. The upper mount secures the upper spring seat to the strut tower. A rubber bushing at the top of the strut absorbs vibrations. A bearing on a front-wheel strut allows it to rotate on the vertical steering axis without rubbing against the strut tower when the steering knuckle turns. The lower spring seat is attached to the strut casing.

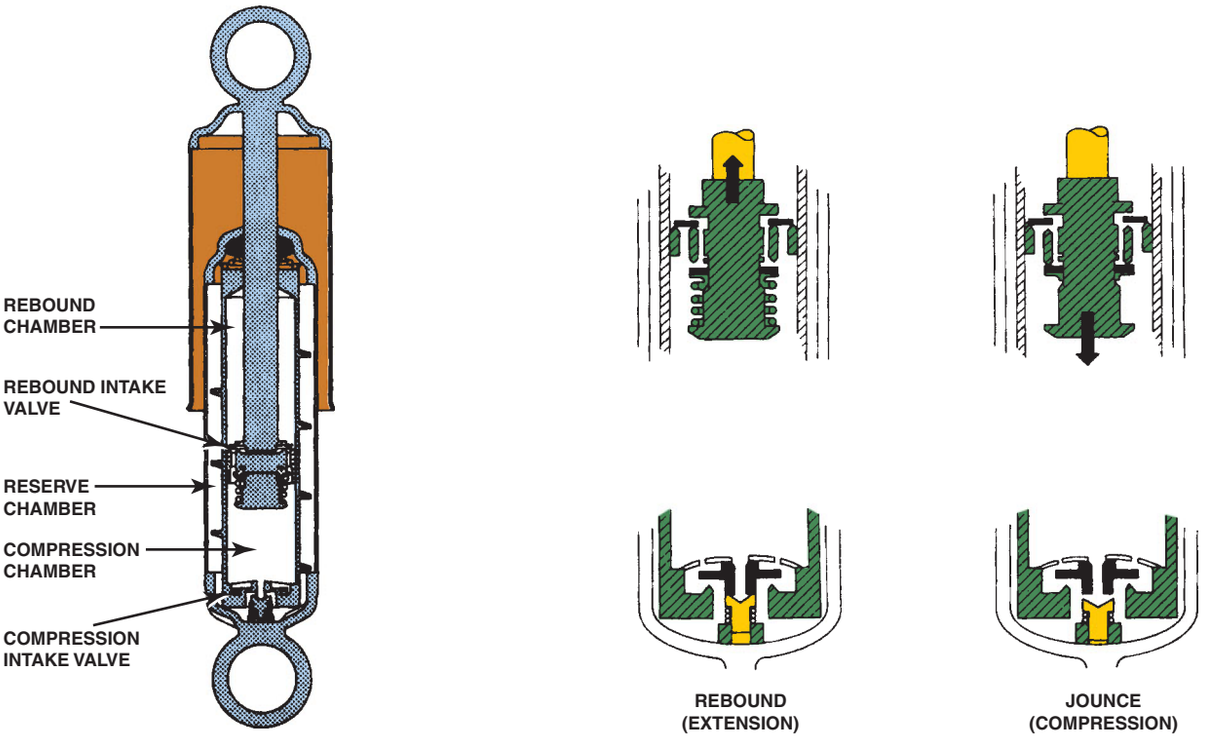

FIGURE 112–47 (a) A cutaway drawing of a typical double-tube shock absorber. (b) Notice the position of the intake and compression valve during rebound (extension) and compression.

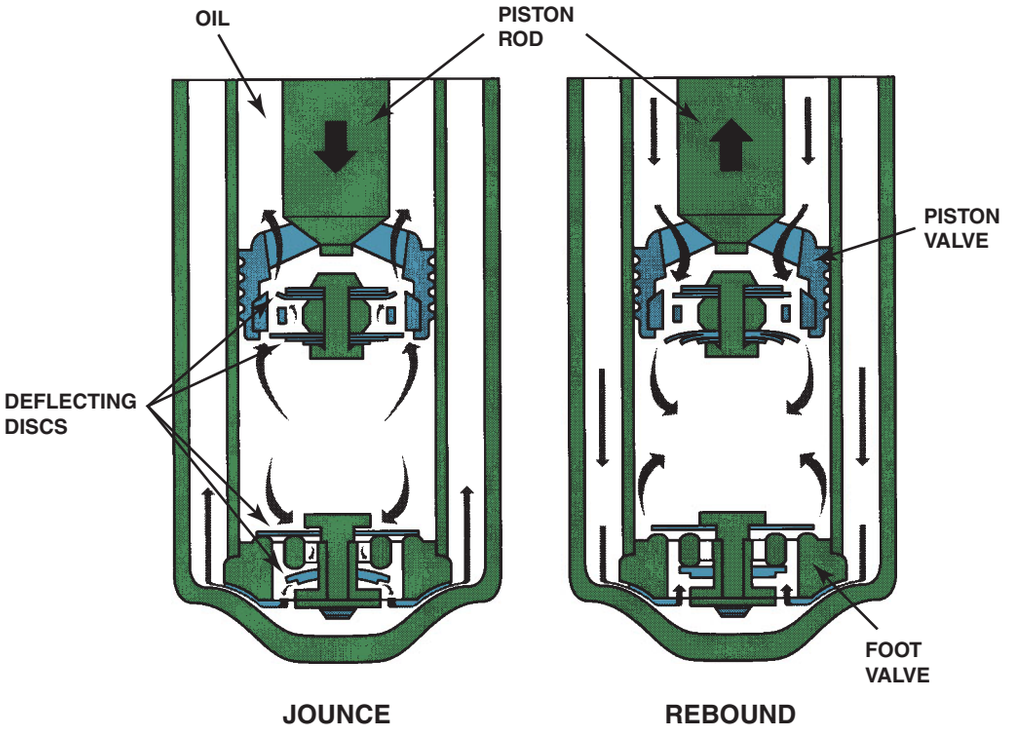

FIGURE 112–48 Oil flow through a deflected disc-type piston valve. The deflecting disc can react rapidly to suspension movement. For example, if a large bump is hit at high speed, the disc can deflect completely and allow the suspension to reach its maximum jounce distance while maintaining a controlled rate of movement.

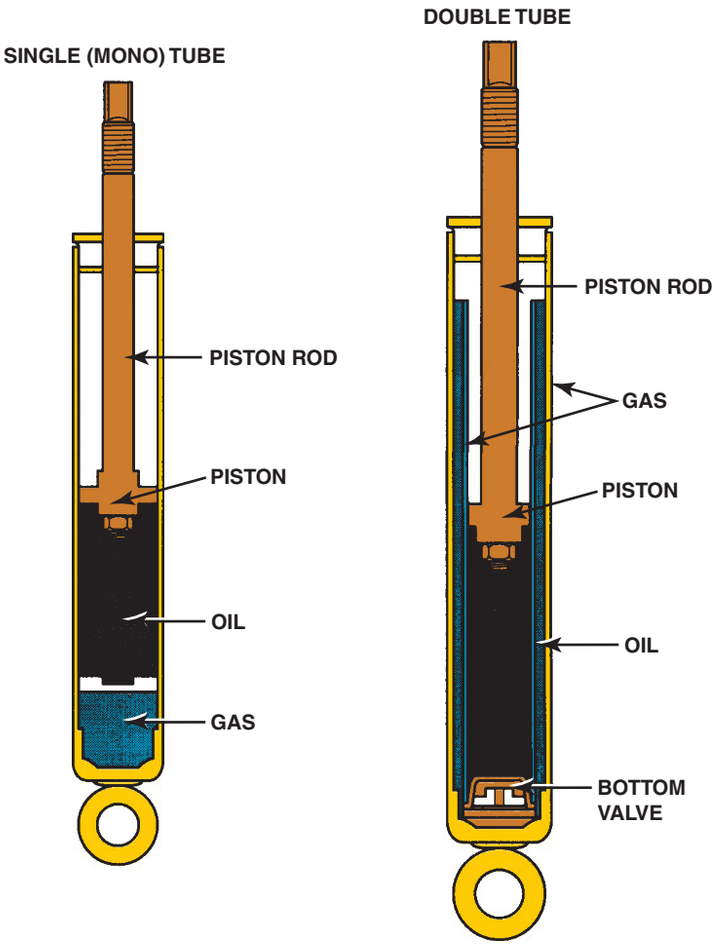

FIGURE 112–49 Gas-charged shock absorbers are manufactured with a double-tube design similar to conventional shock absorbers and with a single or monotube design.

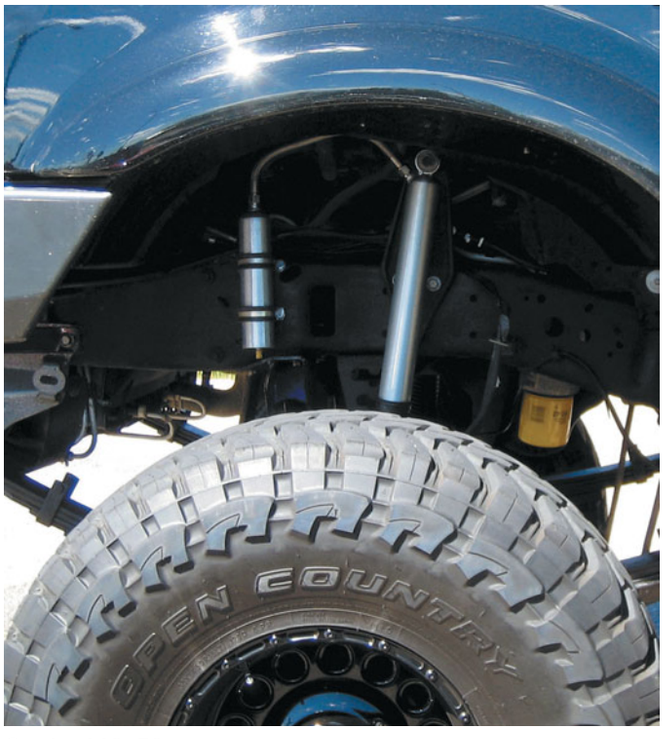

FIGURE 112–50 The shock absorber is on the right and the fluid reservoir for the shock is on the left.

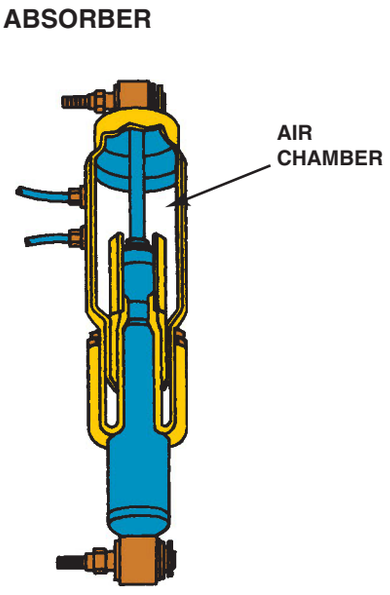

FIGURE 112–51 A rubber tube forms an inflatable air chamber at the top of an air shock. The higher the air pressure in the chamber, the stiffer the shock.

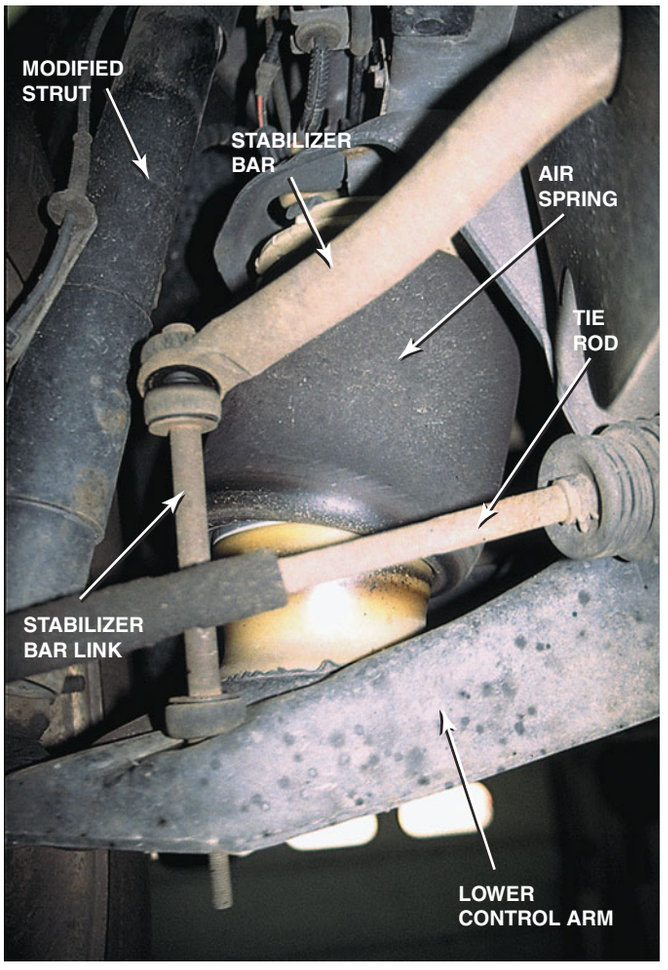
MODIFIED STRUTS Unlike a MacPherson unit, a modified strut does not include a spring as part of the assembly and is used in the front on some vehicles and on the rear of others. ● **SEE FIGURE 112–56.** Most modified strut rear suspensions use coil springs mounted on the lower control arm.

BUMP STOPS



All suspension systems have a limit of travel. If the vehicle hits a large bump in the road, the wheels are forced upward toward the vehicle with tremendous force. This force is absorbed by the springs of the suspension system. If the bump is large enough, the suspension is compressed to its mechanical limit. Instead of allowing the metal components of the suspension to hit the frame or body of the vehicle, a rubber or foam bumper is used to absorb and isolate the suspension from the frame or body. ● **SEE FIGURE 112–57.**

These bumpers are called **bump stops,** suspension bumpers, strike-out bumpers, or jounce bumpers. *Jounce* means jolt, or to cause to bounce or move up and down. Bumpers are made from rubber or microcellular urethane. Urethane is a high-strength material with good resistance to wear and tear as well as good chemical resistance to most fluids. Forming urethane foam with small, regular air cells makes the material ideal for jounce bumpers.

Damaged suspension-limiting bump stops can be caused by the following:

1. Sagging springs that result in lower-than-normal ride (trim) height
2. Worn or defective shock absorbers

Most suspensions also use a rubber or foam stop to limit the downward travel of the suspension during rebound. The rebound stop also prevents metal-to-metal contact of the suspension on the frame when the vehicle is on a body-contact-type hoist and the wheels are allowed to hang or droop down. Some stops are built into the shock absorber or strut.

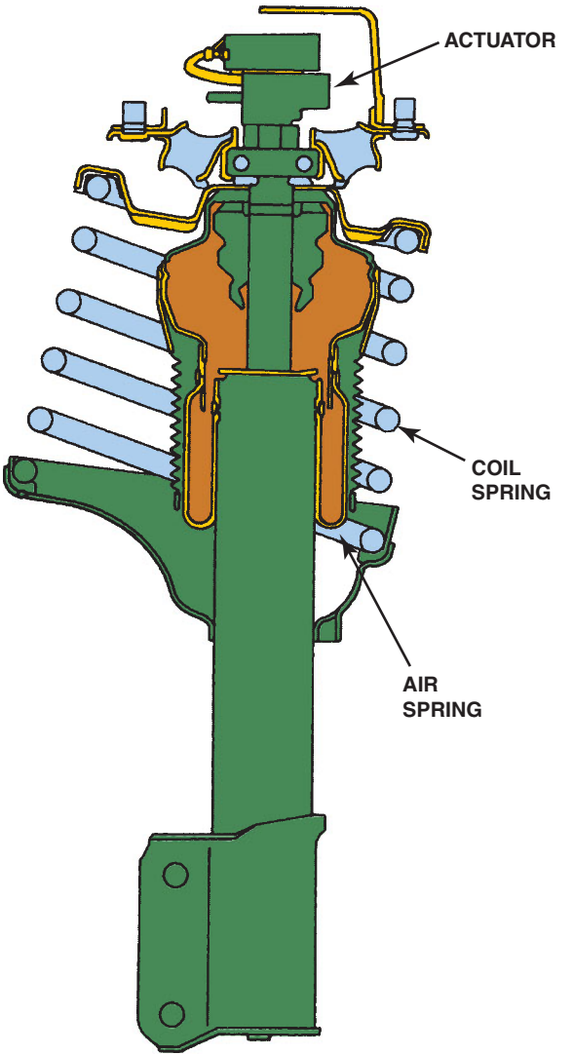

FIGURE 112–53 Some air springs are auxiliary units to the coil spring and are used to control ride height while the coil spring is the weight-bearing unit.

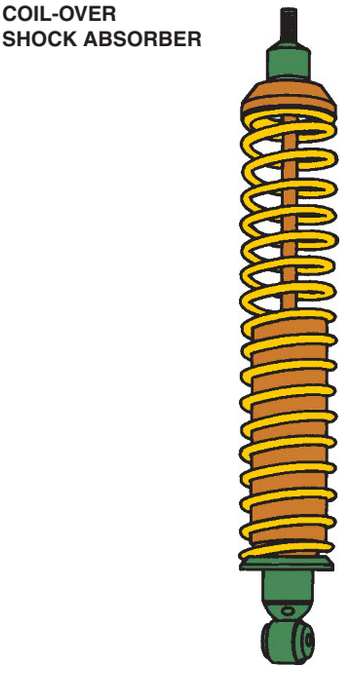

FIGURE 112–54 A coil-over shock is a standard hydraulic shock absorber with a coil spring wrapped around it to increase stiffness and/or take some of the carrying weight off of the springs.

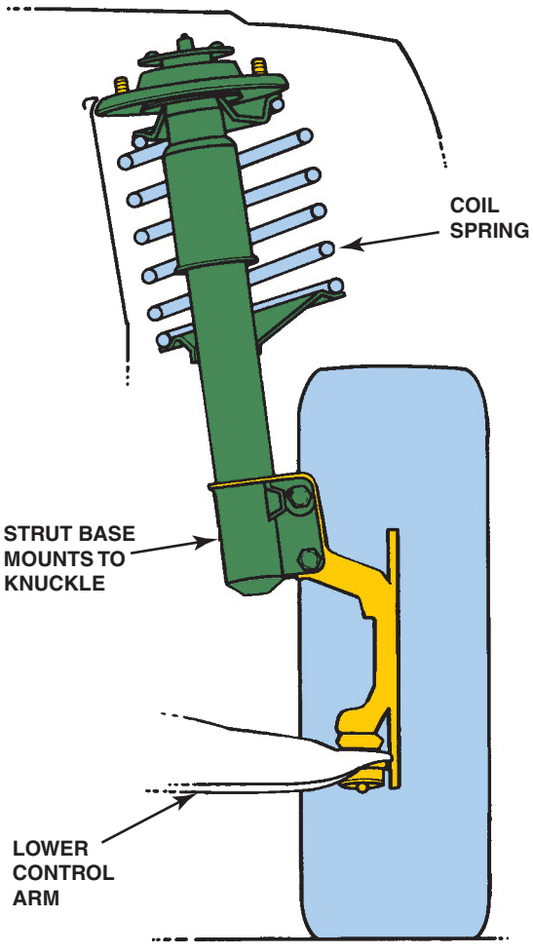

FIGURE 112–55 A strut is a structural part of the suspension and includes the spring and shock absorber in one assembly.

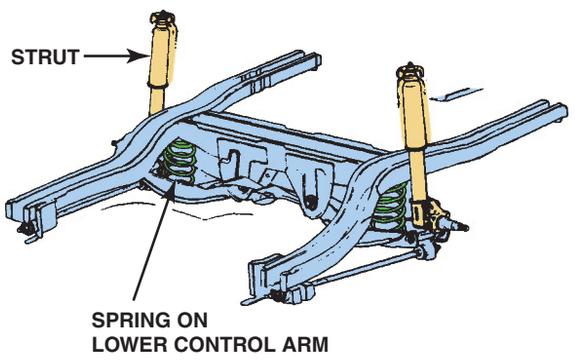

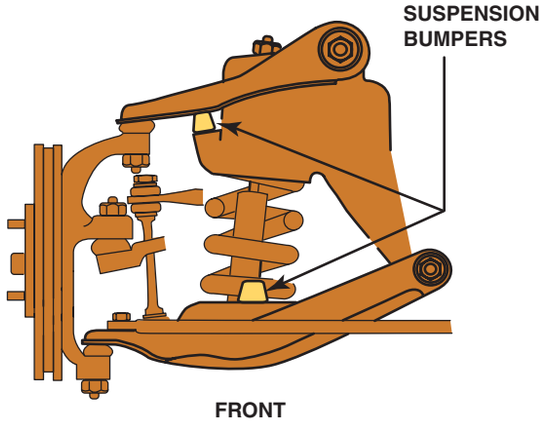

FIGURE 112–56 A modified strut used on the rear suspension; it is part of the structural part of the assembly.

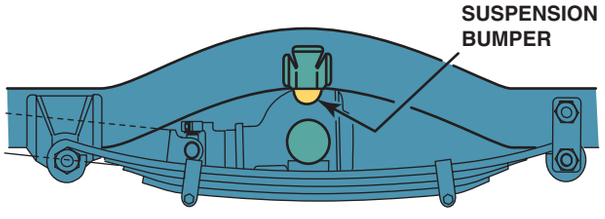

FIGURE 112–57 Suspension bumpers are used on all suspension systems to prevent metal-to-metal contact between the suspension and the frame or body of the vehicle when the suspension "bottoms out" over large bumps or dips in the road.

FREQUENTLY ASKED QUESTION

What Is a Track Rod?

A track rod, also called a Panhard rod, is used in the rear of some suspension systems to keep the rear axle centered under the center of the vehicle. It is a straight rod or channel that connects to the frame on one end and the axle on the other end.

REVIEW QUESTIONS

1. List the types of suspensions and name their component parts.
2. Explain Hooke's Law.
3. Describe the purpose and function of a stabilizer bar.
4. Explain the difference between a load-carrying and a follower (friction) ball joint.

CHAPTER QUIZ

1. The spring rate of a spring is measured in units of _____.
   a. lb per inch **c.** PSI
   b. ft-lb **d.** in.-lb
2. Two technicians are discussing torsion bars. Technician A says that many torsion bars are adjustable to allow for ride height adjustment. Technician B says that torsion bars are usually marked left and right and should not be switched side to side. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. What component(s) is considered to be unsprung weight?
   a. Frame **c.** Wheels and tires
   b. Body **d.** Both a and b
4. Two technicians are discussing MacPherson struts. Technician A says that in most applications the entire strut assembly rotates when the front wheels are turned. Technician B says a typical MacPherson strut suspension system uses only one control arm and one ball joint per side. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. Technician A says that regular replacement shock absorbers will raise the rear of a vehicle that is sagging down. Technician B says that replacement springs will be required to restore the proper ride height. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
6. What suspension component is used to counteract body lean during cornering?
   a. Torsion bar
   b. Strut rod
   c. Stabilizer bar
   d. Control arm
7. A center bolt is used in what type of spring?
   a. Coil
   b. Leaf
   c. Torsion bar
   d. All of the above
8. Two technicians are discussing air shocks. Technician A says that air is forced through small holes to dampen the ride. Technician B says that air shocks are conventional hydraulic shock absorbers with an airbag to control vehicle ride height. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
9. The owner of a pickup truck wants to cut the coil springs to lower the vehicle. Technician A says that the ride will be harsher than normal if the springs are cut. Technician B says that the springs could be damaged, especially if a cutting torch is used to cut the springs. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. A MacPherson strut is a structural part of the vehicle.
    a. True
    b. False

chapter 113

FRONT SUSPENSIONS AND SERVICE

OBJECTIVES: **After studying Chapter 113, the reader will be able to:** • Prepare for ASE Suspension and Steering (A4) certification test content area "B" (Suspension System Diagnosis and Repair). • Explain how to perform a road test, a dry park test, a visual inspection, and a bounce test. • Discuss the procedures for testing load-carrying and follower-type ball joints. • Describe ball joint replacement procedures. • List the steps required to replace control arm and stabilizer bar bushings. • Describe how to replace coil springs, MacPherson struts, and torsion bars safety. • Explain routine service procedures of the suspension system.

KEY TERMS: A-arm 1313 • Cow catcher 1325 • Cuppy tire wear 1324 • Dry park test 1317 • Durometer 1330 • Indicator ball joints 1318 • Kingpin 1312 • Pinch bolt 1321 • Radius rod 1312 • SLA 1313 • Steering knuckle 1312 • Strut suspension 1314 • Twin I-beam 1312

FIGURE 113–1 Most early vehicles used single straight axles.

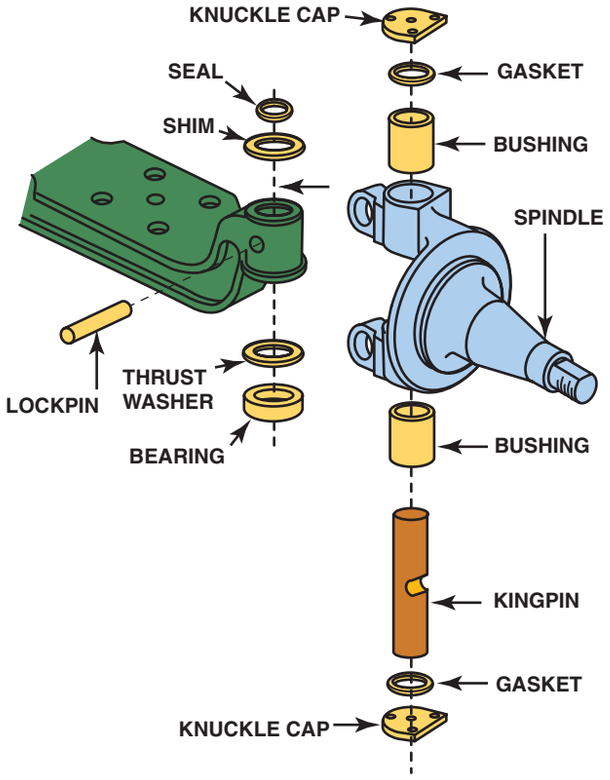

FIGURE 113–2 Typical kingpin used with a solid axle.

FRONT SUSPENSION TYPES

SOLID AXLES Early cars and trucks used a solid (or *straight*) front axle to support the front wheels. ● **SEE FIGURE 113–1.**

A solid-axle front suspension is very strong and is still being used in the manufacture of medium and heavy trucks. The main disadvantage of solid-axle design is its lack of ride quality. When one wheel hits a bump or dip in the road, the forces are transferred through the axle to the opposite wheel. Solid axles are currently used in the rear of most vehicles.

KINGPINS At the end of many solid I-beam or tube axles are **kingpins** that allow the front wheels to rotate for steering. Kingpins are hardened steel pins that attach the steering knuckle to the front axle, allowing the front wheels to move for steering. Kingpins usually have grease fittings to lubricate the kingpin bushings. Failure to keep these bushings lubricated with chassis grease can cause wear and freeplay or can cause the pins to become galled (seized or frozen), resulting in hard steering and/or loud noise while turning. ● **SEE FIGURE 113–2.**

TWIN I-BEAMS A **twin I-beam** front suspension was used for over 30 years on Ford pickup trucks and vans, beginning in the mid-1960s. Strong steel twin beams that cross provide independent front suspension operation with the strength of a solid front axle. Early versions of the twin I-beam systems used kingpins, while later models used ball joints to support the **steering knuckle** and spindle. Coil springs are usually used on twin I-beam suspensions, even though the original design and patent used leaf springs. ● **SEE FIGURE 113–3.**

To control longitudinal (front-to-back) support, a **radius rod** is attached to each beam and is anchored to the frame of the truck using rubber bushings. These bushings allow the front axle to move up and down while still insulating road noise and vibration from the frame and body.

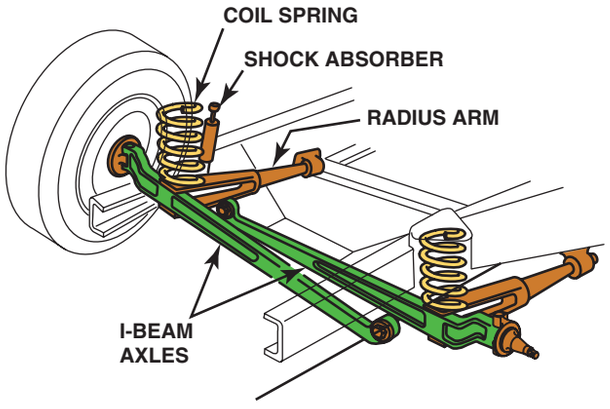

FIGURE 113–3 Twin I-beam front suspension. Rubber bushings are used to support the I-beams to the frame and help isolate road noise.

TECH TIP

Radius Rod Bushing Noise

When the radius rod bushing on a Ford truck or van deteriorates, the most common complaint from the driver is noise. ● **SEE FIGURE 113–4.** Besides causing tire wear, worn or defective radius rod bushing deterioration can cause the following:

1. A clicking sound when braking (it sounds as if the brake caliper may be loose).
2. A clunking noise when hitting bumps.

When the bushing deteriorates, the axles can move forward and backward with less control. Noise is the first sign that something is wrong. Without proper axle support, handling and cornering can also be affected.

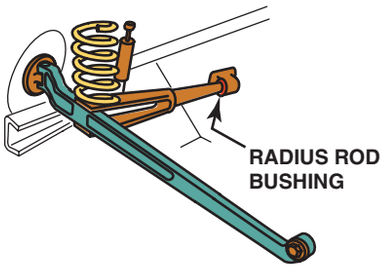

FIGURE 113–4 The rubber radius rod bushing absorbs road shocks and helps isolate road noise.

SHORT/LONG-ARM (SLA) SUSPENSION

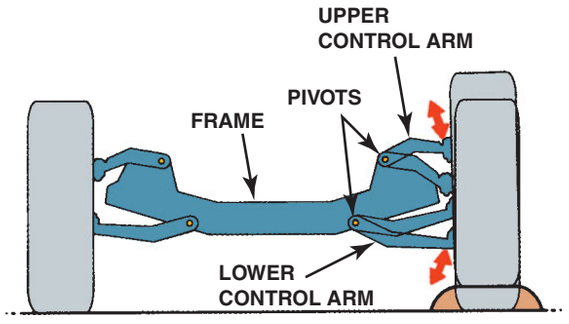

FIGURE 113–5 The upper control arm is shorter than the lower control arm on a short/long-arm (SLA) suspension.

SHORT/LONG-ARM SUSPENSIONS

The short/long-arm suspension uses a short upper control arm and a longer lower control arm and usually is referred to as the *SLA-type suspension.*

The two main links in a **short/long-arm (SLA)** suspension are the upper control arm and the lower control arm. The upper control arm is shorter than the lower one. ● **SEE FIGURE 113–5.** This type of suspension system goes by a variety of names, including unequal-arm suspension, double-wishbone suspension, or **A-arm** suspension. Unequal arm refers to the fact that the two arms are of different lengths, while double-wishbone and A-arm derive from the shape of the arms, which are frequently triangular with one mounting point at the knuckle and two at the frame. When an SLA suspension uses a straight, two-point lower control arm, there is almost always a strut rod that braces the lower arm against the frame. The strut rod can attach to the frame at a point either forward or to the rear of the control arm.

A strut rod, also called a *reaction rod,* provides support to the axle during braking and acceleration forces.

Using a strut rod provides triangulation between the wheel and the frame. *Triangulation* means that the front suspension has a three-point brace that resists forces from every direction, while still allowing the wheels to pivot on the steering axis.

Locating the coil spring on the lower control arm is the most common SLA-type suspension configuration. ● **SEE FIGURE 113–6.**

The upper control arm is A-shaped, with two mounting points at the frame side member and one at the steering knuckle. The inboard ends of the arm attach to a pivot bar that is rigidly bolted to the frame, and the outboard end connects to the steering knuckle with a ball joint. Bushings between the inner arm mounts and the pivot bar allow the arm to swing vertically. The lower control arm is also A-shaped with two inboard pivot mounts and a ball joint connection at the knuckle. Bolts attach the inboard ends of the lower arm to brackets that extend from the bottom of the frame crossmember. Bushings on the inboard mounts allow the arm to pivot vertically.

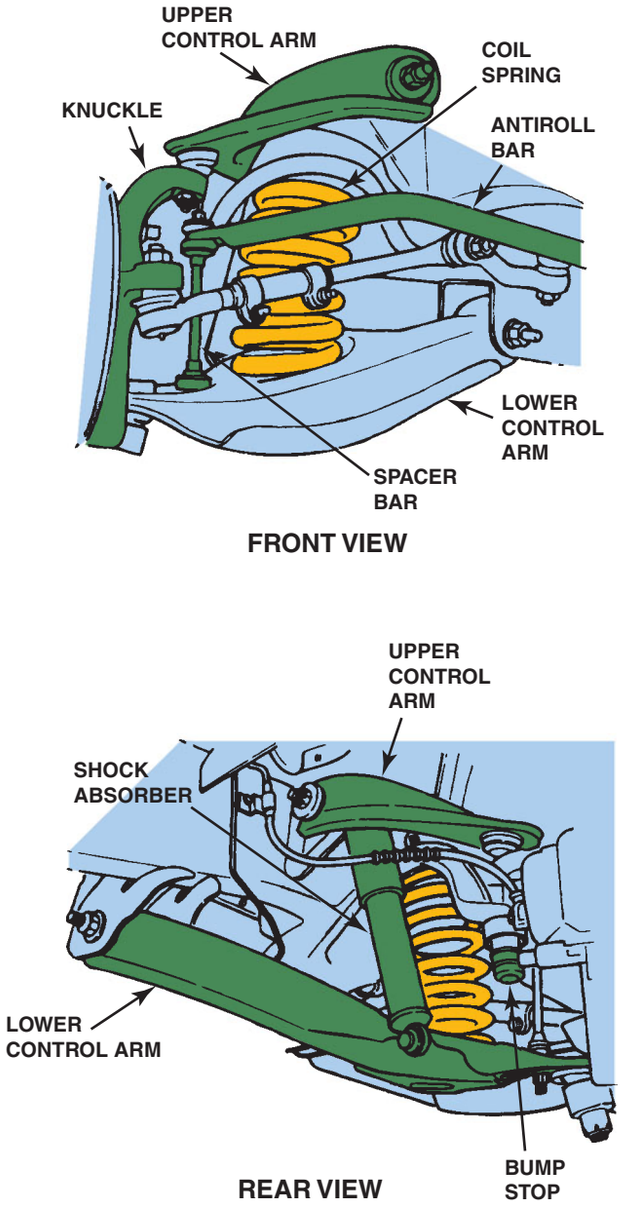

FIGURE 113–6 A typical SLA front suspension using coil springs.

The coil springs seat between the lower control arm and a bracket below the frame side member. The shock absorber attaches to the lower control arm and the frame side member.

In a typical coil spring on the upper control arm design, a portion of the unit-body wheel well is reinforced to withstand spring force and act as the upper spring seats. ● **SEE FIGURE 113–7.** Short/long-arm suspensions use longitudinal torsion bars, especially in trucks.

The forward end of the torsion bar has external splines or hexagonal (six sided) shaped end and shares the splined socket of the torque arm with the control arm through a bolt. Because the torque arm is rigidly bolted to the control arm, motion transfers to the torsion bar whenever the control arm pivots. The torsion bar extends rearward from the control arm and connects to an anchor arm that attaches to a frame crossmember. The torsion bar splines to the

SLA SUSPENSION - COIL SPRING ON UPPER ARM

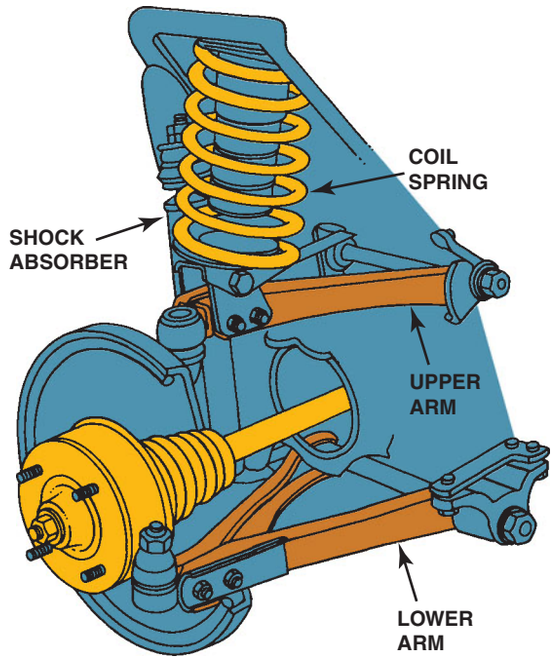

FIGURE 113–7 An SLA-type suspension with the coil spring placed on top of the upper control arm.

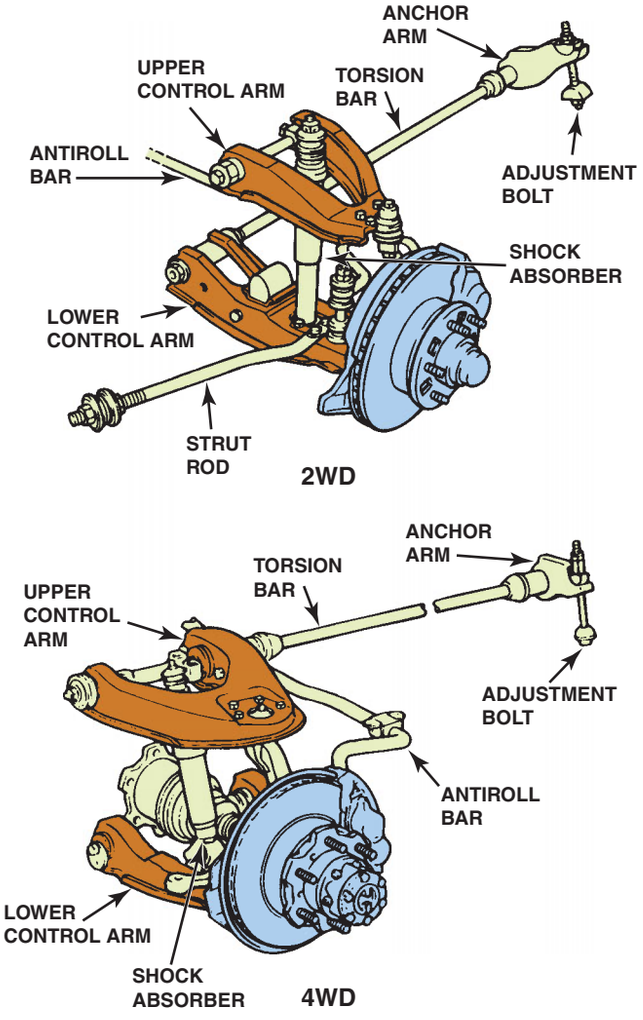

FIGURE 113–8 A torsion bar SLA suspension can use either the lower or the upper control arm.

MACPHERSON STRUT SUSPENSION

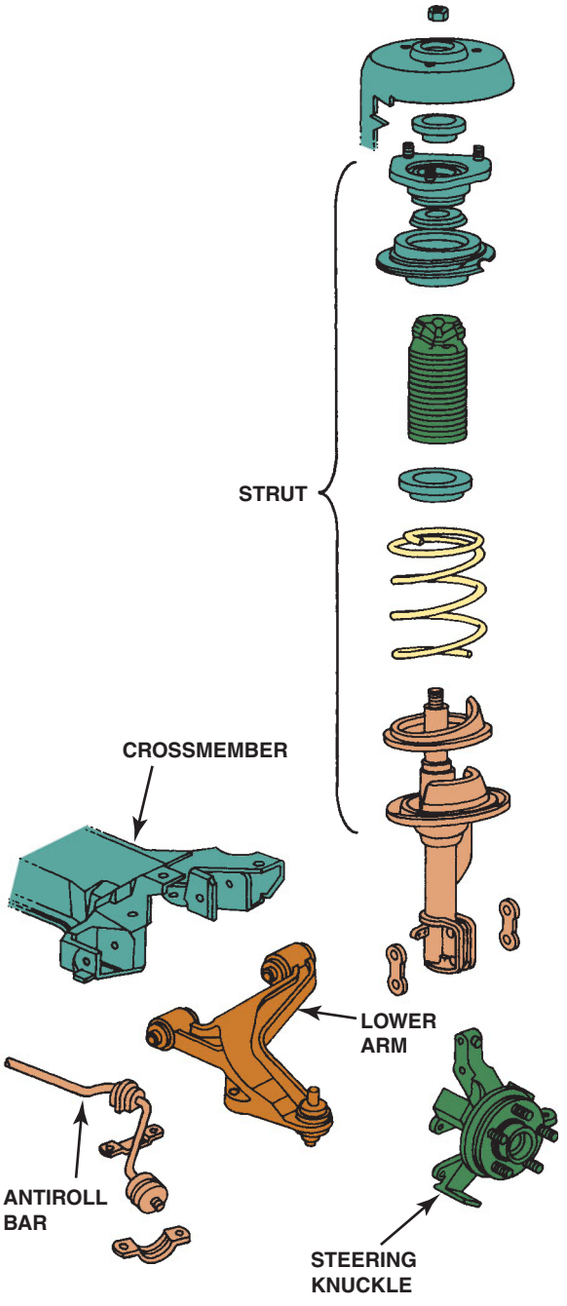

FIGURE 113–9 A typical MacPherson strut showing all of the components of the assembly. A strut includes the shock and the spring in one structural assembly.

anchor arm and the anchor arm is secured to the frame by a bolt and adjusting nut. The adjusting nut varies the spring force of the torsion bar to establish the ride height of the vehicle. ● **SEE FIGURE 113–8.**

STRUT SUSPENSION

Strut suspension can be of several types. A MacPherson strut includes the suspension spring that transfers the weight of the body to the wheel. A MacPherson strut is the main, load-carrying suspension spring. ● **SEE FIGURE 113–9.**

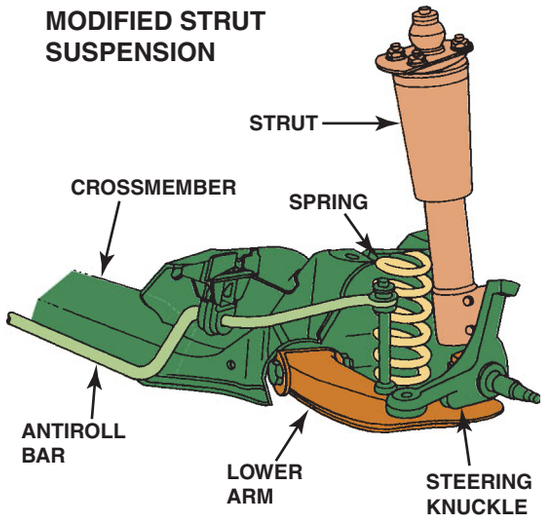

FIGURE 113–10 The modified strut front suspension is similar to a MacPherson strut suspension except that the coil spring is seated on the lower control arm and is not part of the strut assembly.

A MacPherson strut typically incorporates an upper and a lower spring seat, a shock absorber mount and dust cap, a dust cover for the piston rod, and a bump stop. The upper mount secures the upper spring seat to the strut tower. A rubber bushing at the top of the strut absorbs vibrations. In most applications, a bearing on the top of a front-wheel strut allows it to rotate on the vertical steering axis without rubbing against the strut tower when the steering knuckle turns. The lower spring seat is attached to the strut casing. The piston rod dust cover is similar to the dust cover on a conventional shock absorber, and a bump stop at the top of the piston rod keeps the strut from bottoming out during suspension jounce.

A modified strut does not include a spring as part of the assembly. ● **SEE FIGURE 113–10.** A modified strut is used on the rear of some GM vehicles. Except for the lack of a spring and spring seats, the construction and function of a modified strut are basically the same as those of a MacPherson strut. When used on the front suspension, a modified strut also rotates on the steering axis when the wheels turn.

A multilink front suspension uses two control arms as well as a structural strut assembly. This type of suspension is also called a strut/SLA or long spindle, short/long-arm suspension. ● **SEE FIGURE 113–11.**

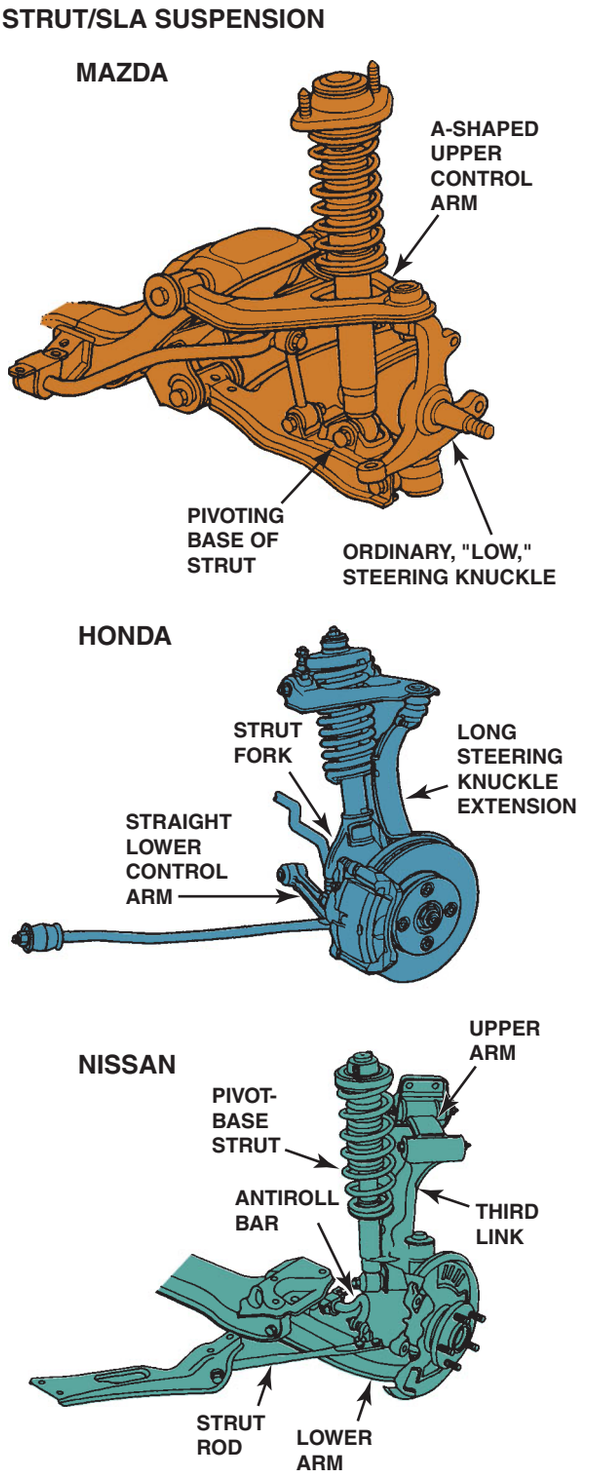

FIGURE 113–11 Multilink front suspension design varies depending on the vehicle manufacturer.

SERVICING THE SUSPENSION SYSTEM

Suspension systems are designed and manufactured to provide years of trouble-free service with a minimum amount of maintenance. In fact, the suspension system is often "invisible" or "transparent" to the driver because the vehicle rides and handles as expected. It is when the driver notices that the vehicle is not riding or handling as it did, or should, that a technician is asked to repair or align the vehicle and fix the problem.

The smart technician should always road test any vehicle before and after servicing (see Tech Tip for details). *The purpose of any diagnosis is to eliminate known good components.* (See the suspension problem symptom chart for a list of components that can cause the problem or customer complaint.)

SUSPENSION PROBLEM SYMPTOM CHART

Item or System to Check	CONCERN/PROBLEM: Noise	Instability/ Wander	Pull to One Side	Excessive Steering Play	Hard Steering	Shimmy
Tires/Wheels	Road/tire noise	Low/uneven air pressure	Low/uneven air pressure, mismatched tire sizes	Low/uneven air pressure	Low/uneven air pressure	Wheel out of balance/uneven tire wear/ overworn tires
Shock Absorbers (Struts)	Loose/worn mounts/ bushings	Loose/worn mounts/ bushings, worn/ damaged struts/shock absorbers			Loose/worn mounts/ bushings on strut assemblies	Worn/damaged struts/shock absorbers
Strut Rods (If Equipped)	Loose/worn mounts/ bushings	Loose/worn mounts/ bushings	Loose/worn mounts/ bushings			Loose/worn mounts/ bushings
Springs	Broken/ unseated	Broken/ unseated	Broken/ unseated especially rear			
Control Arms	Steering knuckle contacting control arm stop, worn/damaged mounts/bushings	Worn/damaged mounts/ bushings	Worn/damaged mounts/ bushings		Worn/damaged mounts/ bushings	Worn/damaged mounts/ bushings
Steering System	Component wear/damage	Component wear/damage	Component wear/damage	Component wear/damage	Component wear/damage	Component wear/damage
Wheel Alignment		Front and rear, especially caster	Front, camber and caster	Front alignment	Front, especially caster	Front, especially caster
Wheel Bearings	Front-wheel bearings	Loose/worn (front and rear)	Loose/worn (front and rear)	Loose/worn (front and rear)		Loose/worn (front and rear)
Brake System			Stuck caliper/slide			
Other					Ball joint lubrication	Loose/worn friction ball joints

CAUTION: More than one factor may be the cause of a problem. Be sure to inspect all suspension components, and repair all parts that are worn or damaged. Failure to do so may allow the problem to reoccur and cause premature failure of other suspension components.

ROAD TEST DIAGNOSIS

If possible, perform a road test of the vehicle with the owner of the vehicle. It is also helpful to have the owner drive the vehicle. While driving, try to determine when and where the noise or problem occurs, such as the following:

1. In cold or warm weather
2. With cold or warm engine/vehicle
3. While turning, left only, right only

A proper road test for any suspension system problem should include the following:

1. **Drive beside parked vehicles.** Any noise generated by the vehicle suspension or tires is reflected off solid objects, such as a row of parked vehicles along a street. For best results, drive with the windows down and drive close to parked vehicles or a retaining wall on the left side. Repeat the drive for the right side. Defective wheel bearings or power steering pumps usually make noise and can be heard during this test.
2. **Drive into driveways.** Suspension problems often occur when turning at the same time the suspension hits a bump. This action is best repeated by driving slowly into a driveway with a curb. The curb causes the suspension to compress while the wheels are turned (see the Real World Fix titled "The Rock-Hard Problem" for an example). Defective stabilizer bar bushings, control arm bushings, and ball joints will usually make noise during this test procedure.
3. **Drive in reverse while turning.** This technique is usually used to find possible defective outer CV joints used on the drive axle

TECH TIP

Road Test—Before and After

Many times technicians will start to work on a vehicle based on the description of the problem by the driver or owner. A typical conversation was overheard where the vehicle owner complained that the vehicle handled "funny," especially when turning. The owner wanted a wheel alignment, and the technician and shop owner wanted the business. The vehicle was aligned, but the problem was still present. The real problem was a defective tire. The service technician should have road-tested the vehicle *before* any service work was done to confirm the problem and try to determine its cause. Every technician should test drive the vehicle *after* any service work is performed to confirm that the service work was performed correctly and that the customer complaint has been resolved. This is especially true for any service work involving the steering, suspension, or braking systems.

shaft of front-wheel-drive vehicles. This technique also forces the suspension system to work in reverse of normal. Any excessive clearances in the suspension system are reversed and often make noise or cause a vibration during the test. Besides defective CV joints, this test can often detect worn control arm bushings, ball joints, stabilizer bar bushings, or links. This test can also detect defective or worn steering system components such as an idler arm, tie rod end, or center link.

4. **Drive over a bumpy road.** Worn or defective suspension (and steering) components can cause the vehicle to bounce or dart side to side while traveling over bumps and dips in the road. Worn or defective ball joints, control arm bushings, stabilizer bar bushings, stabilizer bar links, or worn shock absorbers can be the cause.

Once the problem has been confirmed, then a further inspection can be performed in the service bay.

DRY PARK TEST (SUSPENSION)

A **dry park test** can also be used to help locate worn or defective suspension components. The dry park test is performed by having an assistant move the steering wheel side to side while feeling and observing for any freeplay in the steering or suspension. For best results, the vehicle should be on a level floor or on a drive-on-type hoist with the front wheels pointing straight ahead. In this suspension analysis using the dry park test, the technician should observe the following for any noticeable play or unusual noise:

1. **Front wheel bearings.** Loose or defective wheel bearings are often overlooked as a possible cause of poor handling or darting vehicle performance.
2. **Control arm bushing wear or movement.** Check for any abnormal movement in upper control arm bushings or lower control arm bushings.
3. **Ball joint movement.** Check for any noticeable play or noise from both load-carrying and follower-type ball joints on both sides of the vehicle.

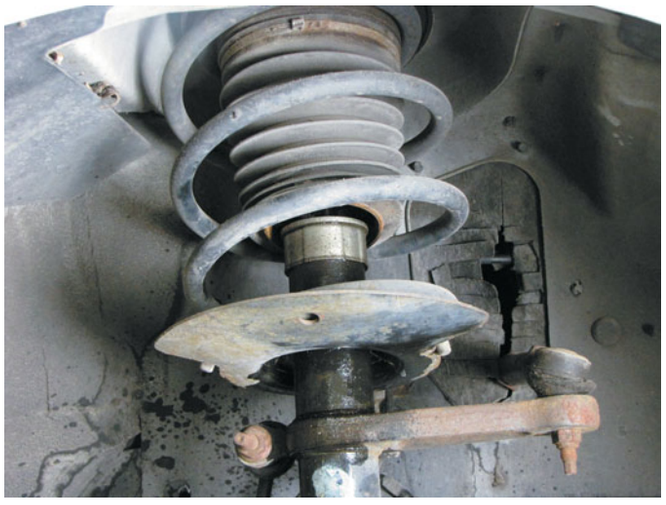

FIGURE 113–12 A leaking strut. Either a cartridge insert or the entire strut will require replacement. If a light film of oil is seen, this is to be considered normal. If oil is dripping, then this means that the rod seal has failed.

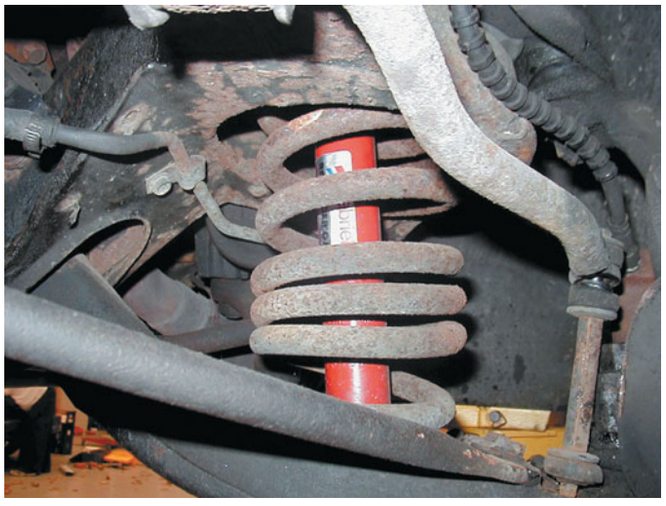

FIGURE 113–13 This front coil spring looks as if it has been heated with a torch in an attempt to lower the ride height of the vehicle. Both front springs will require replacement.

NOTE: The dry park test (and many other chassis system tests) relies on the experience of the technician to be able to judge normal wear from abnormal wear. It is extremely important that all beginning technicians work closely with an experienced technician to gain this knowledge.

VISUAL INSPECTION

All suspension components should be carefully inspected for signs of wear or damage. A thorough visual inspection should include checking all of the following:

1. Shock absorbers or struts. ● **SEE FIGURE 113–12.**
2. Springs. ● **SEE FIGURE 113–13.**
3. Stabilizer bar links

FIGURE 113–14 It is easy to see that this worn control arm bushing needed to be replaced. The new bushing is shown next to the original.

4. Stabilizer bar bushings
5. Upper and lower shock absorber mounting points
6. Bump stops
7. Body-to-chassis mounts
8. Engine and transmission (transaxle) mounts
9. Suspension arm bushings. ● **SEE FIGURE 113–14.**

Alignment equipment and procedures can often determine if a suspension component is bent or has been moved out of position. A careful *visual* inspection can often reveal suspected damaged components by observing scrape marks or rusty sections that could indicate contact with the road or another object.

While an assistant bounces the vehicle up and down, check to see if there is any freeplay in any of the suspension components.

BALL JOINTS

DIAGNOSIS AND INSPECTION The life of ball joints depends on driving conditions, vehicle weight, and lubrication. Even with proper care and lubrication, the load-carrying (weight-carrying) ball joints wear more than the follower ball joints. Ball joints should be replaced in pairs, both lower or both upper, to ensure the best handling.

Defective or worn ball joints can cause looseness in the suspension and the following common driver complaints:

1. Loud popping or squeaking whenever driving over curbs, such as into a driveway
2. Shimmy-type vibration felt in the steering wheel
3. Vehicle wander or a tendency not to track straight
4. Excessive freeplay in the steering wheel

A ball joint inspection should also be performed when an alignment is performed or as part of any other comprehensive vehicle inspection.

INDICATOR BALL JOINTS Many load-carrying ball joints have wear indicators with a raised area around the grease fitting, called **indicator ball joints.** ● **SEE FIGURES 113–15 AND 113–16.**

Always check wear-indicator-type ball joints with the wheels of the vehicle on the ground. If the raised area around the grease fitting is flush or recessed with the surrounding area, the ball joint is worn more than 0.050 in. and must be replaced.

FIGURE 113–15 Grease fitting projecting down from the surrounding area of a ball joint. The ball joint should be replaced when the area around the grease fitting is flush or recessed.

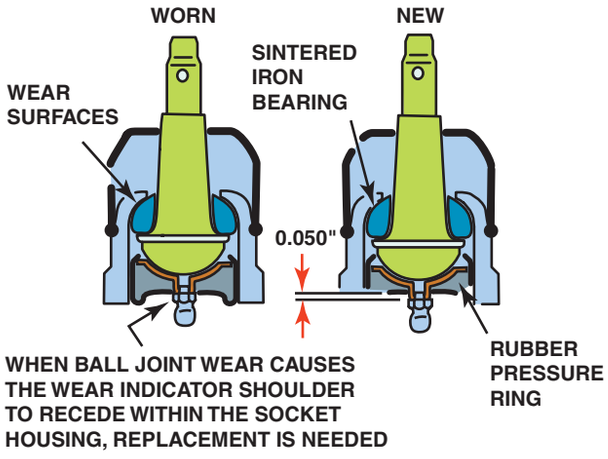

FIGURE 113–16 Indicator ball joints should be checked with the weight of the vehicle on the ground.

TECH TIP

Think of a Nickel

Most ball joints must be replaced if the joint has more than 0.050 in. axial (up-and-down) movement. To help visualize this distance, consider that the thickness of an American nickel coin is about 0.060 in. It is helpful to know that maximum wear should be less than the thickness of a nickel. A dial indicator (gauge) can be used to measure the exact movement of the ball joint so it can be compared to factory specifications. ● **SEE FIGURE 113–17.**

NON-INDICATOR BALL JOINT TESTING To perform a proper non-indicator-type ball joint inspection, the force of the vehicle's springs *must* be *unloaded* from the ball joint. If this force is not relieved, the force of the spring pushes the ball and socket joint tightly together and any wear due to movement will not be detected.

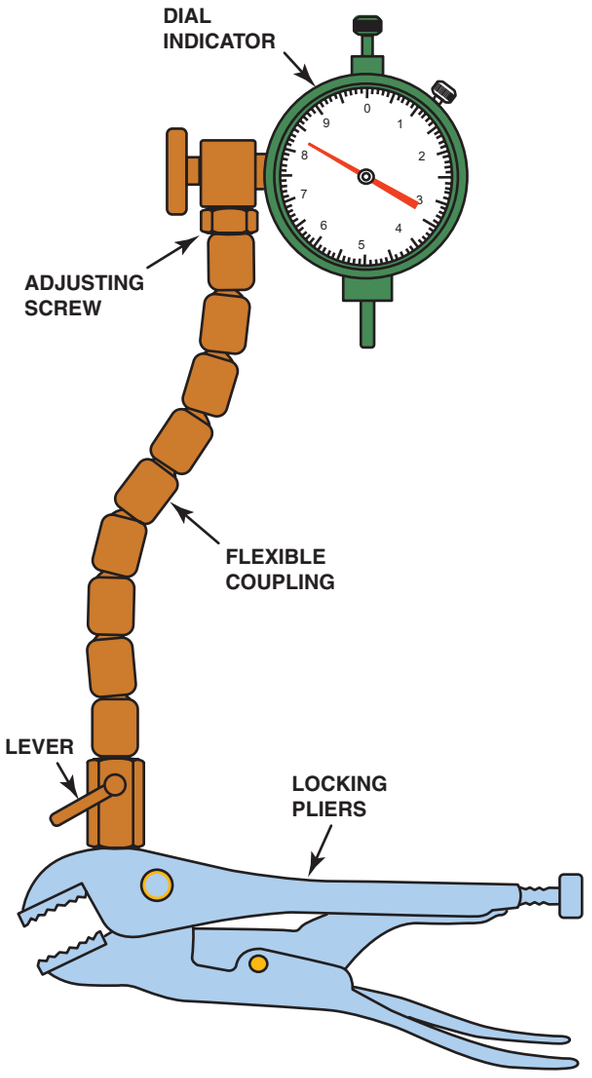

FIGURE 113–17 Typical dial indicator used to measure the suspension component movement. The locking pliers attach the gauge to a stationary part of the vehicle and the flexible coupling allows the dial indicator to be positioned at any angle.

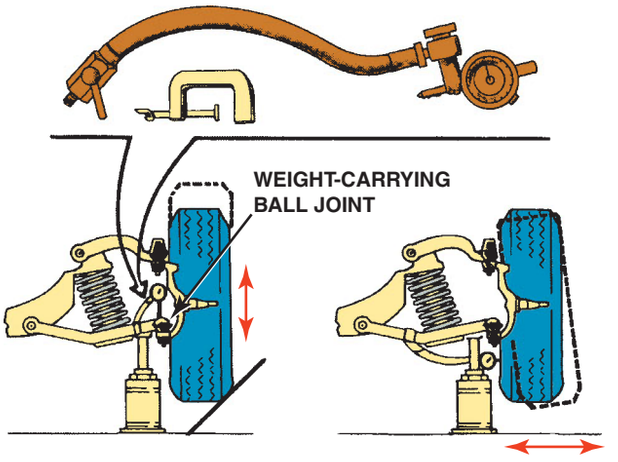

FIGURE 113–18 If the spring is attached to the lower control arm as in this SLA suspension, the jack should be placed under the lower control arm as shown. A dial indicator should be used to measure the amount of freeplay in the ball joints. Be sure that the looseness being measured is not due to normal wheel bearing endplay.

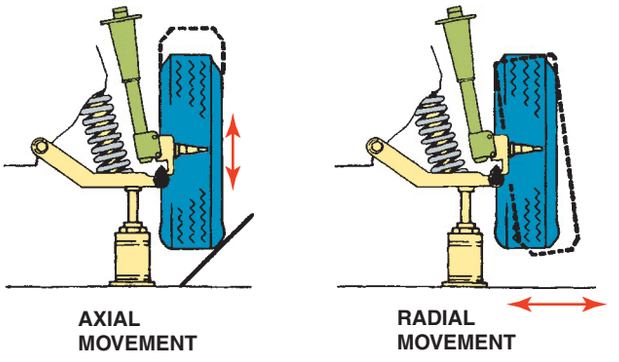

FIGURE 113–19 The jack should be placed under the lower control arm of this modified MacPherson-type suspension.

NOTE: The location of the load-carrying ball joint is closest to the seat of the spring or torsion bar.

If the coil spring or torsion bar is attached to the *lower* control arm, the *lower* ball joint is the load-carrying ball joint. ● **SEE FIGURE 113–18.** This includes vehicles equipped with modified MacPherson-strut-type suspension. ● **SEE FIGURE 113–19.**

1. Place the jack under the lower control arm as close to the ball joint as possible and raise the wheels approximately 1 to 2 in. (2.5 to 5 cm) off the ground to unload the lower ball joint.
2. Using a pry bar under the tire, lift the wheel up. If there is excessive vertical movement in the ball joint itself, it must be replaced. Most manufacturers specify a maximum vertical play of approximately 0.050 in. (1.3 mm), or the thickness of a nickel. Always check the manufacturer's specifications for exact maximum allowable movement. Vertical movement of a ball joint is often called axial play because the looseness is in the same axis as the ball joint stud. To check for *lateral* play, grip the tire at the top and bottom and move your hands in opposite directions.

NOTE: Be sure that the cause of any freeplay or looseness is not due to the wheel bearing. Closely observe the exact source of the freeplay movement.

If the coil spring is attached to the *upper* control arm, the *upper* ball joint is the load-carrying ball joint.

1. Place a block of wood (2 × 4 in.) between the upper control arm and the frame, or use a special tool designed for this purpose. ● **SEE FIGURE 113–20.**
2. Place the jack under the vehicle's *frame* and raise the wheel approximately 1 in. to 2 in. off the ground. (The wood block or special tool keeps the weight of the vehicle off the upper ball joint.)
3. Using a pry bar under the tire, lift the wheel. If there is excessive vertical movement in the ball joint itself, it must be replaced. Always check the manufacturer's specifications for exact maximum allowable movement.

Follower ball joints (friction ball joints) should also be inspected while testing load-carrying ball joints. Grasp the tire at the top and the bottom and attempt to shake the wheel assembly while looking directly at the follower ball joint. Generally, there should be no lateral or axial movement at all in the follower ball joint. However, some manufacturers specify a maximum of 0.250 in. (1/4 in. or 0.6 cm) measured at the top of the tire. Always check the manufacturer's specifications before condemning a ball joint because of excessive play.

MacPherson-strut-equipped vehicles do not have a load-carrying ball joint. The weight of the vehicle is carried through the upper strut mount and bearing assembly. ● **SEE FIGURE 113–21.**

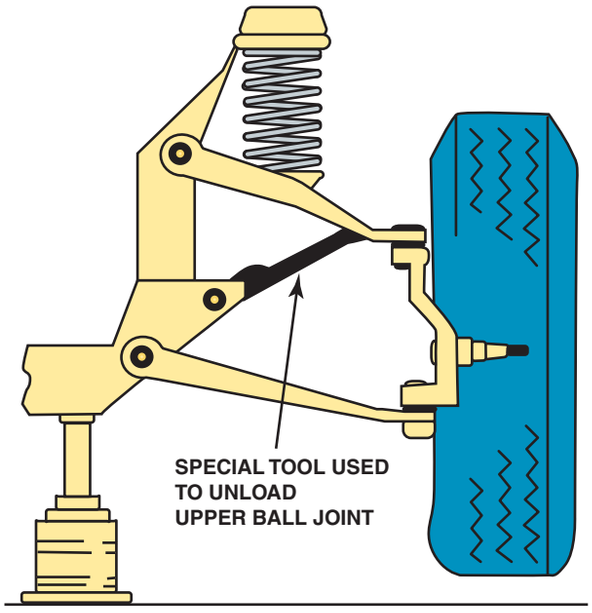

FIGURE 113–20 A special tool or a block of wood should be inserted between the frame and the upper control arm before lifting the vehicle off the ground. This tool stops the force of the spring against the upper ball joint so that a true test can be performed on the condition of the ball joint.

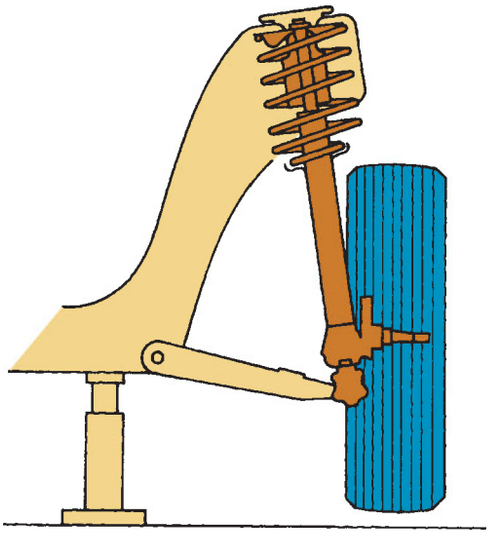

FIGURE 113–21 The jacking point is under the frame for checking the play of a lower ball joint used with a MacPherson strut.

FIGURE 113–22 This worn and rusty ball joint was found by moving the wheel and looking for movement in the joint.

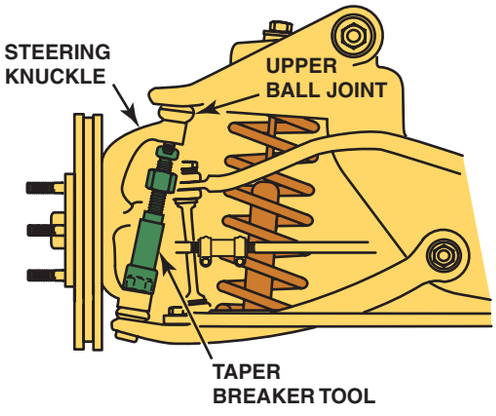

FIGURE 113–23 Taper breaker tool being used to separate the upper ball joint from the steering knuckle. This is especially important for vehicles equipped with aluminum alloy control arms.

FREQUENTLY ASKED QUESTION

What Is the Difference Between a Low-Friction Ball Joint and a Steel-on-Steel Ball Joint?

Before the late 1980s, most ball joints were constructed with a steel ball that rubbed on a steel socket. This design created friction and provided for a tight high-friction joint until wear caused looseness in the joint.

Newer designs use a polished steel ball that is installed in a hard plastic polymer, resulting in a low-friction joint assembly. Because of the difference in friction characteristics, the vehicle may handle differently than originally designed if incorrect-style ball joints are installed. Most component manufacturers state that low-friction ball joints in a vehicle originally equipped with steel-on-steel high-friction ball joints are usually acceptable, but high-friction replacement ball joints should be avoided on a vehicle originally equipped with low-friction ball joints.

After checking axial play in a ball joint, grasp the tire from the side at the top and bottom and alternately push and pull. *Any* lateral movement at the ball joint should generally be considered a good reason to replace the ball joints. ● **SEE FIGURE 113–22.**

BALL JOINT REMOVAL Take care to avoid damaging grease seals when separating ball joints from their mounts. *The preferred method to separate tapered parts is to use a puller-type tool that applies pressure to the tapered joint as the bolt is tightened on the puller.* ● **SEE FIGURE 113–23.**

Sometimes the shock of a hammer can be used to separate the ball joint from the steering knuckle. For best results, another hammer should be used as a backup while striking the joint to be separated on the side with a heavy hammer.

CAUTION: The use of tapered "pickle forks" should be avoided, unless the part is to be replaced, because they often damage the grease seal of the part being separated.

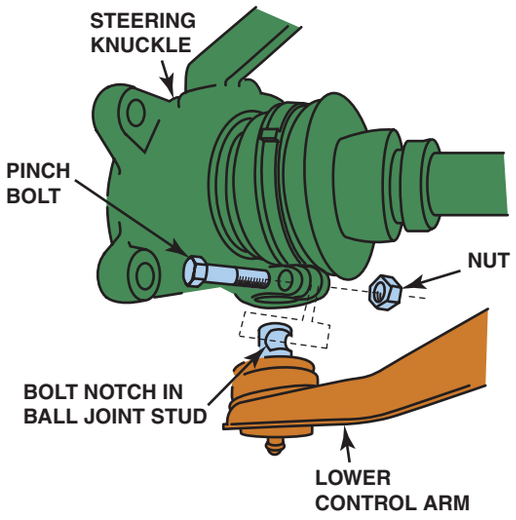

FIGURE 113–24 A pinch bolt attaches the steering knuckle to the ball joint. Remove the pinch bolt by turning the nut, not the bolt.

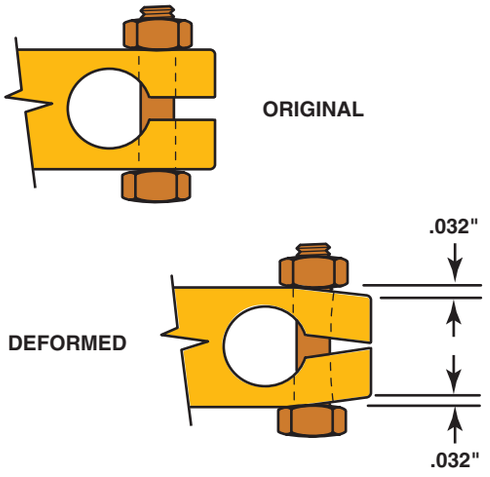

FIGURE 113–25 If the pinch bolt is overtightened, the steering knuckle can be deformed. A deformed knuckle can cause the pinch bolt to break and the ball joint could become separated from the steering knuckle.

PINCH BOLT BALL JOINTS Some ball joint studs have a slot or groove where a **pinch bolt** is used to hold the ball joint to the steering knuckle. ● **SEE FIGURE 113–24.** Use penetrating oil in the steering knuckle groove and rotate the knuckle several times. Do not use a hammer on the pinch bolt because this can cause damage to the bolt and the ball joint. Do not widen the slot in the steering knuckle. Once separated, check the shape of the steering knuckle. ● **SEE FIGURE 113–25.** If the pinch bolt has been deformed by overtightening, the steering knuckle should be replaced.

RIVETED BALL JOINTS When removing ball joints that are riveted in place, always cut off or drill rivet heads before separating the ball joint from the spindle. This provides a more solid base to assist in removing rivets. *The preferred method to remove rivets from ball joints is to center punch and drill out the center of the rivet before using a drill or an air-powered chisel to remove the rivet heads.* Be careful not to drill or chisel into the control arms. ● **SEE FIGURES 113–26 THROUGH 113–28.**

Press-in-type ball joints are removed and installed using a special C-clamp-type tool. ● **SEE FIGURE 113–29.**

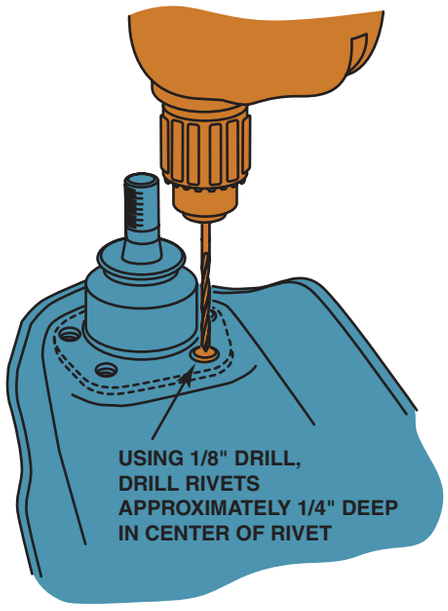

FIGURE 113–26 By drilling into the rivet, the holding force is released.

FIGURE 113–27 The head of the rivet can be removed by using a larger-diameter drill bit as shown.

NOTE: Many replacement press-in-type ball joints are slightly larger in diameter—about 0.050 in. (1.3 mm)—than the original ball joint to provide the same press fit. If the ball joints have been replaced before, then the control arm must be replaced.

Avoid using heat to remove suspension or steering components. Many chassis parts use rubber and plastic that can be damaged if heated with a torch. *If heat is used to remove a part, it must be replaced.* For best results, try soaking with a penetrating oil and use the proper tools and procedures as specified by the manufacturer.

NON-REPLACEABLE BALL JOINTS Many vehicles are equipped with nonreplaceable ball joints, and the entire control arm must be replaced if the ball joint is worn or defective.

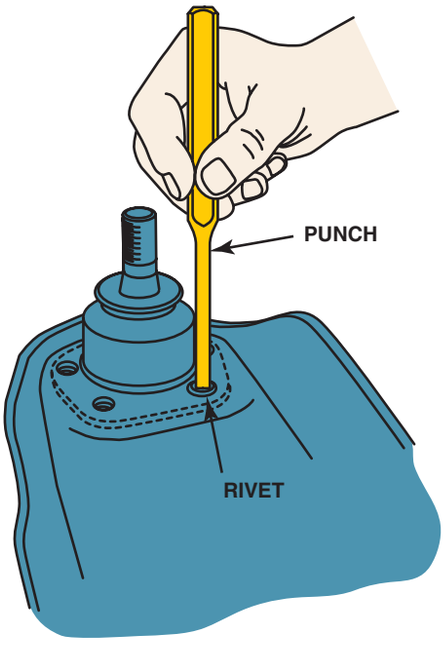

FIGURE 113–28 Using a punch and a hammer to remove the rivet after drilling down through the center and removing the head of the rivet.

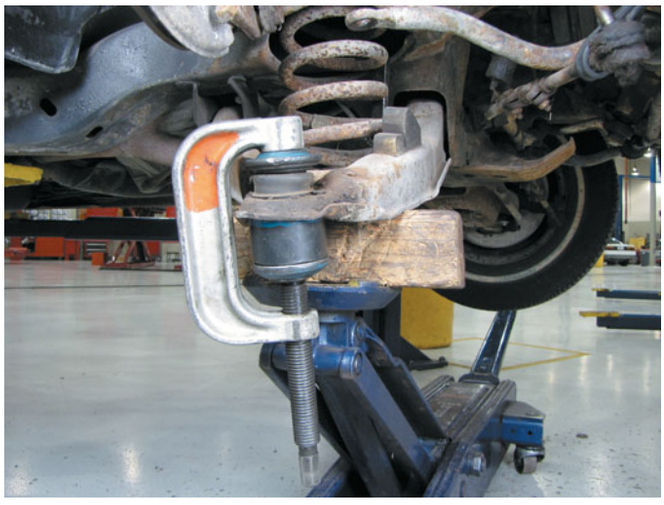

FIGURE 113–29 Press-in ball joints are best removed using a large C-clamp press, as shown.

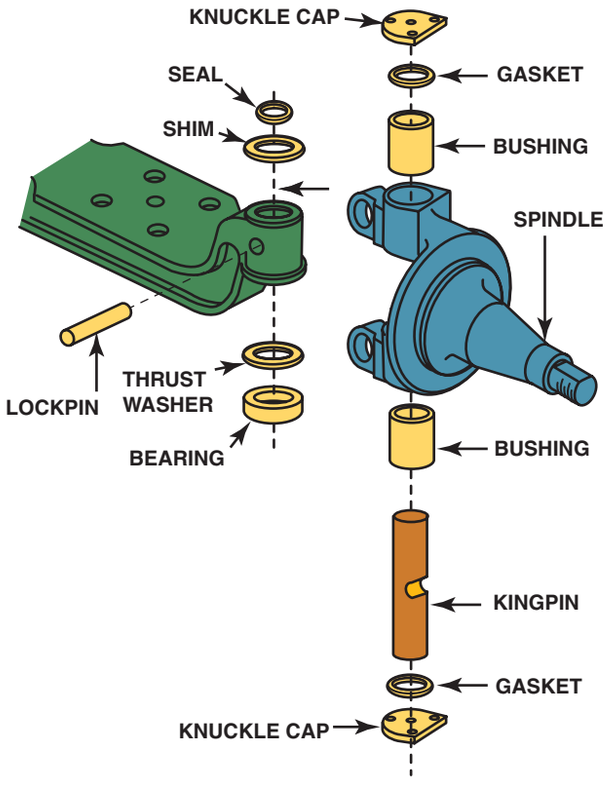

FIGURE 113–30 Typical kingpin assembly.

REAL WORLD FIX

The Rattle Story

A customer complained that a rattle was heard every time the vehicle hit a bump. The noise sounded as if it came from the rear. All parts of the exhaust system and suspension system were checked. Everything seemed okay until the vehicle was raised with a frame-type hoist instead of a drive-on type. Then, whenever the right rear wheel was lifted, the noise occurred. The problem was a worn (elongated) shock absorber mounting hole. A washer with the proper-size hole was welded over the worn lower frame mount and the shock absorber was bolted back into place.

CAUTION: Always follow manufacturers' recommended installation instructions whenever replacing any suspension or other chassis component part. Tie rod ends and ball joints use a taper to provide the attachment to other components. Whenever a nut is used to tighten a tapered part, it is important not to back off (loosen) the nut after tightening. As the nut is being tightened, the taper is being pulled into the taper of the adjoining part. The specified torque on the nut ensures that the two pieces of the taper are properly joined. If the cotter key does not line up with the hole in the tapered stud when the nut has been properly torqued, tighten it more to line up a hole—never loosen the nut.

KINGPIN DIAGNOSIS AND SERVICE

DIAGNOSIS Kingpins are usually used on trucks, and other heavy-duty vehicles. ● **SEE FIGURE 113–30.**

Kingpins are designed to rotate inside kingpin bushings with a clearance between them of approximately 0.001 to 0.003 in. (0.025 to 0.075 mm). As wear occurs, this clearance distance increases and the kingpin becomes loose. Looseness in the kingpin causes looseness in the wheels and steering. *Kingpins can also gall or seize due to lack of lubrication, resulting in very hard steering.*

After supporting the vehicle safely off the ground, inspect for looseness by positioning a dial gauge (indicator) on the extreme inside bottom of the edge of the wheel and rock the tire. If the dial indicator registers more than 1/4 inch (6 mm), replace the kingpin and/or kingpin bushings.

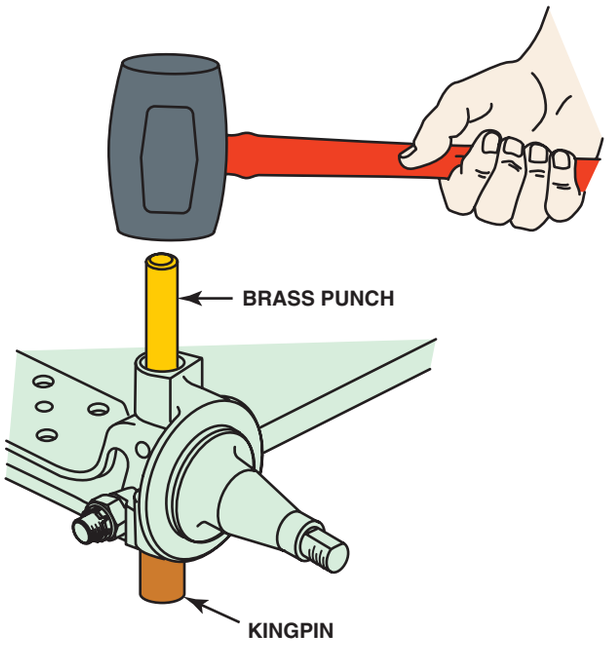

FIGURE 113–31 Driving a kingpin out with a hammer.

KING PIN REPLACEMENT To remove a typical kingpin, follow these basic steps:

STEP 1 Remove the tire, brake drum, and backing plate or caliper.

STEP 2 Remove the lockpin. The lockpin is usually tapered with a threaded end for the nut. Drive the lockpin out with a drift (punch).

STEP 3 Remove the grease caps and drive the kingpin from the steering knuckle and axle with a hammer and a brass punch or a hydraulic press, if necessary. ● **SEE FIGURE 113–31.**

To replace the kingpin bushings and/or kingpin, refer to the manufacturer's procedure and specifications. ● **SEE FIGURE 113–32.**

Some bronze bushings must be sized by reaming or honing to provide from 0.001 to 0.003 in. (0.025 to 0.075 mm) clearance between the kingpin and the bushing.

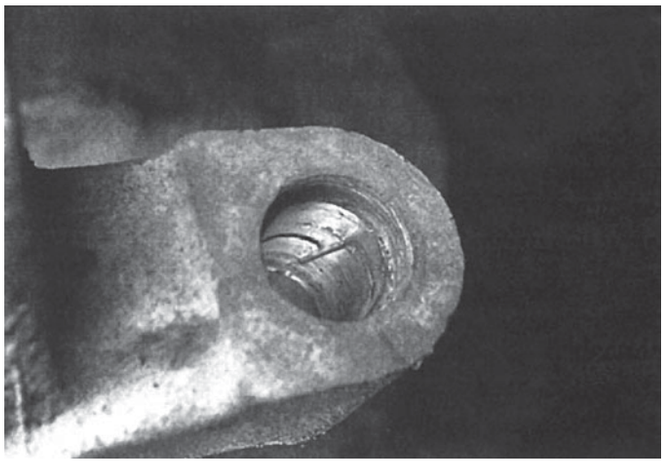

FIGURE 113–32 This galled kingpin bushing must be replaced.

TECH TIP

The Shock Stud Trick

Front shock absorbers used on many rear-wheel-drive vehicles equipped with an SLA-type front suspension are often difficult to remove because the attaching nut is rusted to the upper shock stub. A common trick is to use a deep-well 9/16-in. socket and a long extension and repeatedly bend the shock stud until it breaks off. At first you would think that this method causes harm, and it does ruin the shock absorber—but the shock absorber is not going to be reused and will be discarded anyway.

The usual procedure followed by many technicians is to simply take a minute or two to break off the upper shock stud, then hoist the vehicle to allow access to the lower two shock bolts, and then the shock can easily be removed. To install the replacement shock absorber, attach the lower bolts, lower the vehicle, and attach the upper rubber bushings and retaining nut.

SHOCK ABSORBERS AND STRUTS

DIAGNOSIS Shock absorber life depends on how and where the vehicle is driven. Original equipment (OE) shock absorbers are carefully matched to the vehicle springs and bushings to provide the best ride comfort and control. As the control arm bushings and ball joints age, the energy built up in the springs of the vehicle is controlled less by the friction of these joints and bushings, requiring more control from the shock absorbers. Shock absorber action is also reduced as the seals inside wear. Replacement shock absorbers may be required when any or all of the following symptoms appear:

1. **Ride harshness.** As the effectiveness of the shock absorber decreases, the rapid forces of the springs are not as dampened or controlled. Worn shocks can cause ride harshness and yet not cause the vehicle to bounce after hitting a bump.
2. **Frequent bottoming out on rough roads.** Shock absorbers provide a controlled movement of the axle whenever the vehicle hits a bump or dip in the road. As fluid is lost or wear occurs, the shock absorber becomes weaker and cannot resist the forces acting on the axle. The worn shock absorber can allow the spring to compress enough so that the axle contacts the jounce bumper (bump stop) on the body or frame of the vehicle.

NOTE: Frequent bottoming out is also a symptom of reduced ride height due to sagging springs. Before replacing the shock absorbers, always check for proper ride height as specified in the vehicle service manual or any alignment specification booklet available from suppliers or companies of alignment or chassis parts and equipment.

3. **Extended vehicle movement after driving on dips or a rise in the road.** The most common shock absorber test is the bounce test. Push down on the body of the vehicle and let go; the vehicle should return to its normal ride height and stop. Worn shock absorbers can cause poor driver control due to excessive up-and-down suspension movements. If the vehicle

continues to bounce two or three times, then the shocks or struts are worn and must be replaced.

4. **Cupped-type tire wear.** Defective shock absorbers can cause **cupped tire wear.** This type of tire wear is caused by the tire's bouncing up and down as it rotates.
5. **Leaking hydraulic oil.** When a shock or strut leaks oil externally, this indicates a defective seal. The shock absorber or strut cannot function correctly when low on oil inside.
6. **Springs and shock absorbers should be replaced in pairs.** Both front or both rear shocks should be replaced together to provide the best handling and control.

NOTE: Shock absorbers do not affect ride height except where special air shocks or coil overload carrying shocks are used. If a vehicle is sagging on one side or in the front or the rear, the springs should be checked and replaced if necessary.

Shock absorbers are filled with fluid and sealed during production. They are not refillable; if worn, damaged, or leaking, they must be replaced. A slight amount of fluid may bleed by the rod seal in cold weather and deposit a light film on the upper area of the shock absorber. This condition will not hurt the operation of the shock and should be considered normal. If noisy when driving, always check the tightness and condition of all shock absorber mounts.

Replacement shock absorbers and/or struts should match the original equipment unit in physical size.

FRONT SHOCK REPLACEMENT

Front shock absorbers provide ride control and are usually attached to the lower control arm by bolts and nuts. The upper portion of the shock usually extends through the spring housing and is attached to the frame of the vehicle with rubber grommets to help insulate noise, vibration, and harshness.

Most front shock absorbers can be replaced either with the vehicle still on the ground or while on a hoist. The front suspension of most vehicles allows the removal of the shocks without the need to support the downward travel of the lower control arm. The downward travel limit is stopped by a rubber stop or by the physical limit of the suspension arms.

Special sockets and other tools are available to remove the nut from the shocks that use a single mounting stem. The removal of the lower mounting of most front shock absorbers usually involves the removal of two bolts. After removal of the attaching hardware, the shock absorber is simply pulled through the front control arm. ● **SEE FIGURE 113–33.**

Reverse the removal procedure to install replacement shock absorbers. Always consult the manufacturer's recommended procedures and fastener tightening torque.

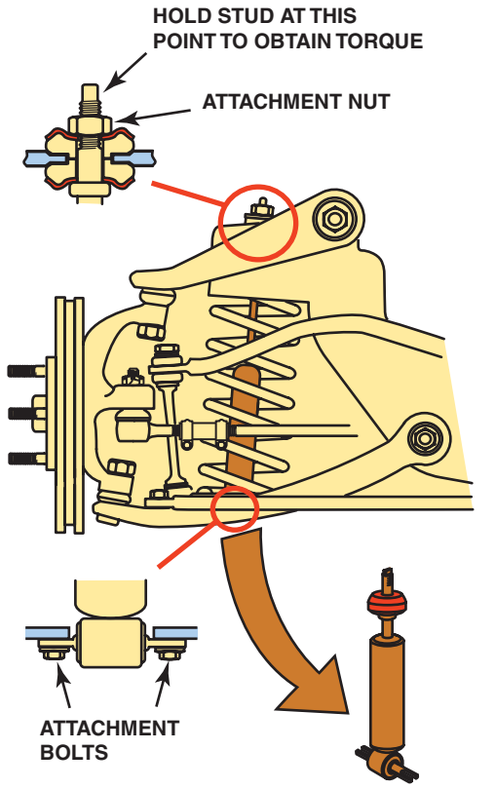

FIGURE 113–33 Most shock absorbers used on the front suspension can be removed from underneath the vehicle after removing the attaching bolts or nuts.

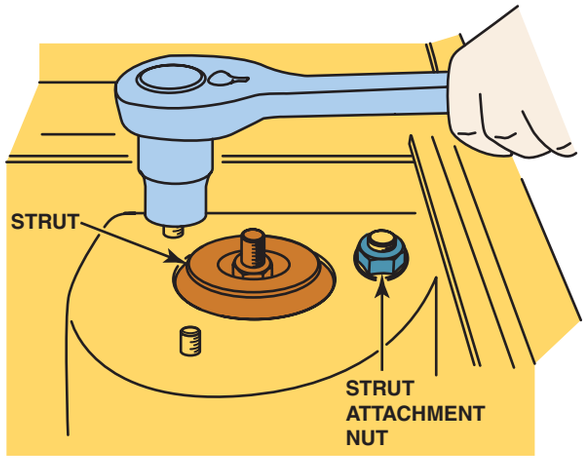

FIGURE 113–34 Removing the upper strut mounting bolts. Some experts recommend leaving one of the upper strut mount nuts loosely attached to prevent the strut from falling when the lower attaching bolts are removed.

MACPHERSON STRUT REPLACEMENT

On most vehicles equipped with MacPherson strut suspensions, strut replacement involves the following steps.

CAUTION: Always follow the manufacturer's recommended methods and procedures whenever replacing a MacPherson strut assembly or component.

1. Hoist the vehicle, remove the wheels, and mark the attaching bolts/nuts.
2. Remove the upper strut mounting bolts except for one to hold the strut until ready to remove the strut assembly. ● **SEE FIGURE 113–34.**
3. Remove the brake caliper or brake hose from the strut housing. ● **SEE FIGURE 113–35.**
4. After removing all lower attaching bolts, remove the final upper strut bolt and remove the strut assembly from the vehicle. Place the strut assembly into a strut spring compressor fixture or use manual spring compressors as shown in ● **FIGURE 113–36.**

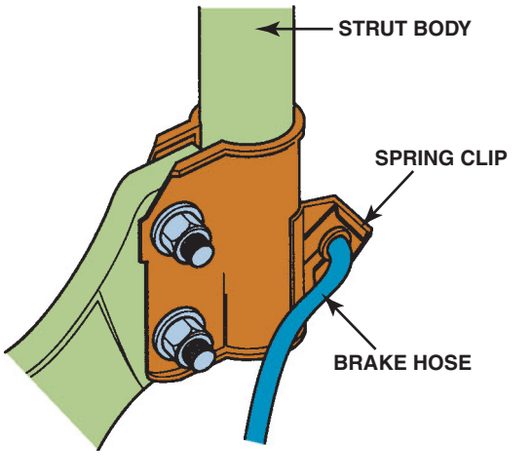

FIGURE 113–35 A brake hydraulic hose is often attached to the strut housing. Sometimes all that is required to separate the line from the strut is to remove a spring clip.

FIGURE 113–36 Use a strut spring compressor fixture to compress the spring on a MacPherson strut before removing the strut retaining nut.

5. Mark the relationship of the coil spring to the strut before removing. This step helps insure that the assembly will be reassembled correctly.
6. Compress the coil spring enough to relieve the tension on the strut rod nut. Remove the strut rod nut as shown in ● **FIGURE 113–37**.
7. After removing the strut rod nut, remove the upper strut bearing assembly and the spring. ● **SEE FIGURE 113–38**.

NOTE: The bearing assembly should be carefully inspected and replaced if necessary. Some automotive experts recommend replacing the bearing assembly whenever the strut is replaced.

8. Many MacPherson struts are replaced as an entire unit assembly. Other struts can have the cartridge inside the housing replaced. The cartridge is installed after removing the gland nut at the top of the strut tube and removing the original strut rod, valves, and hydraulic oil. Always replace the cartridge assembly per the manufacturer's recommended procedure. ● **SEE FIGURES 113–39, 113–40, AND 113–41**.
9. Reinstall the strut in the vehicle.

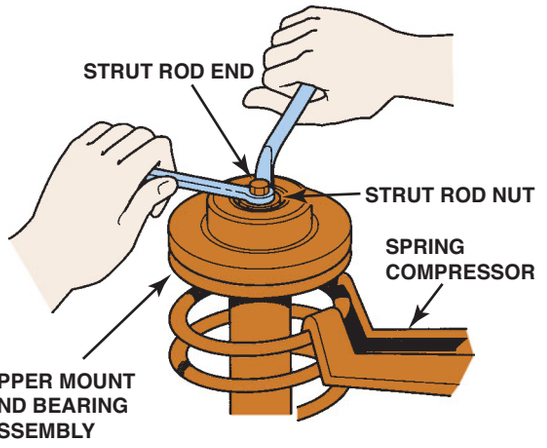

FIGURE 113–37 Removing the strut rod nut. The strut shaft is being helped with one wrench while the nut is being removed with the other wrench. Notice that the spring is compressed before the nut is removed.

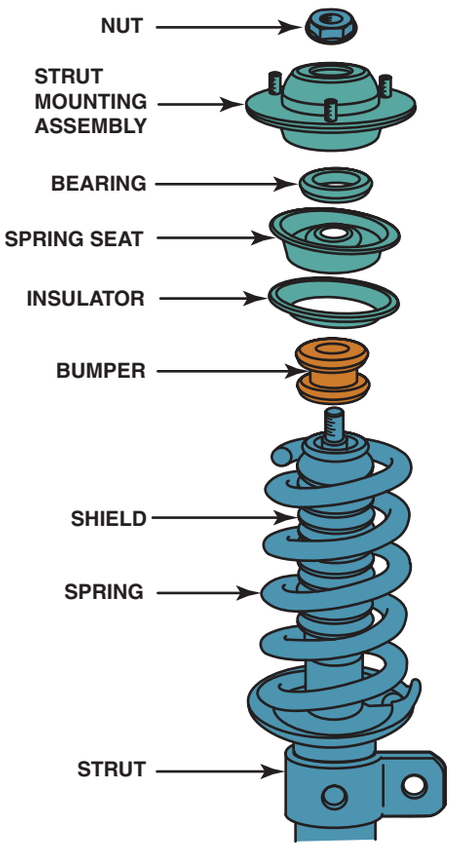

FIGURE 113–38 Typical MacPherson strut showing the various components.

CAUTION: Many GM front-wheel-drive vehicles use a MacPherson strut with a large-diameter spring seat area. GM chassis engineers call this a cow catcher design. If the coil spring breaks, the extra-large cow catcher will prevent the end of the broken spring from moving outward where it could puncture a tire and possibly cause an accident. Always use a replacement strut that has this feature.

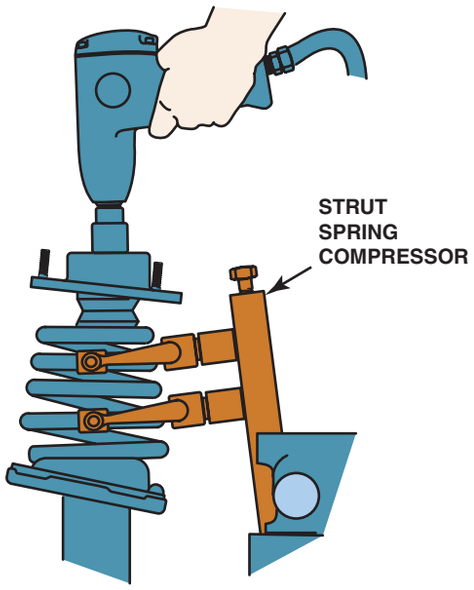

FIGURE 113–39 After installing the replacement strut cartridge, reinstall the spring and upper bearing assembly after compressing the spring. Notice that the strut is being held in a strut spring compressor fixture.

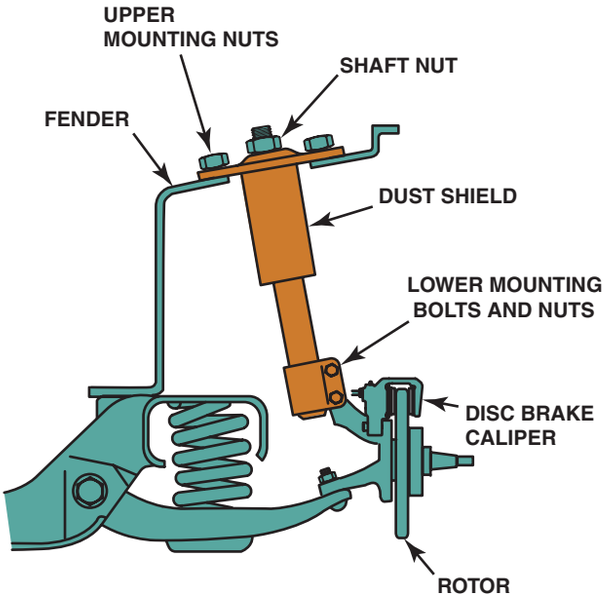

FIGURE 113–41 The strut on a modified MacPherson strut assembly can be replaced by removing the upper mounting nuts.

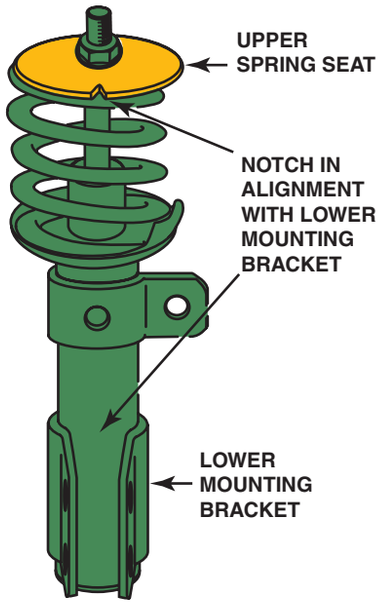

FIGURE 113–40 Before final assembly, make sure the marks you made are aligned. Some struts are manufactured with marks to ensure proper reassembly.

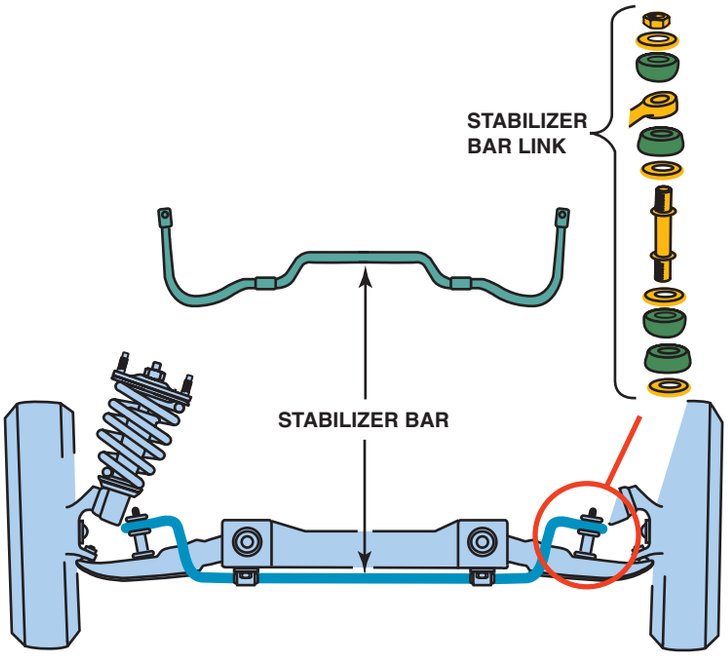

FIGURE 113–42 Stabilizer bar links should be replaced as a pair.

STABILIZER BAR LINK AND BUSHING SERVICE

DIAGNOSIS Stabilizer bars twist whenever a vehicle turns a corner or whenever one side of the vehicle rises or lowers. The more the body of the vehicle leans, the more the bar twists, and the more the bar counteracts the roll of the body. A great deal of force is transferred from the stabilizer bar to the body or frame of the vehicle through the stabilizer links at the control arm and the stabilizer bar mounting bushings on the body or frame. *The most common symptom of defective stabilizer bar links or bushings is noise while turning, especially over curbs.* When driving up and over a curb at an angle, one wheel is pushed upward. Since the stabilizer bar connects both wheels, the bar tends to resist this motion by twisting. If one or both links are broken, a loud knock or clanking sound is heard as the bar contacts the control arm. Any sound heard when driving should be investigated and the cause determined by a thorough visual inspection.

REPLACEMENT Stabilizer links are usually purchased as a kit consisting of replacement rubber bushings, retainers, a long bolt, and spacer with a nut and lock nut. General Motors recommends that stabilizer links be replaced in pairs and two kits purchased so that the links on both the left and the right can be replaced at the same time. ● **SEE FIGURE 113–42.**

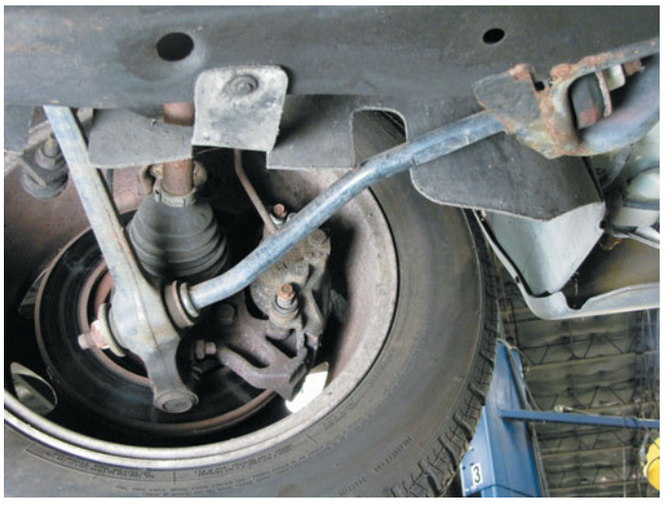

FIGURE 113–43 A strut rod as viewed from the front of the vehicle.

Stabilizer links are replaced by simply unbolting the old parts and installing replacement parts. Special precautions are usually not necessary, but, as always, consult a service manual for the exact recommended procedure and fastener torque.

If the mounting bushings (also called isolator bushings) on the body or frame are worn or defective, a loud squeaking or knocking sound is usually heard.

Stabilizer bar bushings often fail because the rubber has deteriorated from engine oil or other fluid leaks. Before replacing defective bushings, make certain that all other fluid leaks are stopped. Stabilizer bar bushing replacement involves the removal (unbolting) of the bushing retainers that surround the bushing and attach to the vehicle body or frame. The bushings are usually split so that they can be easily removed and replaced on the stabilizer bar and can slide into proper position. Reinstall the bushing retainer bolts and tighten to the specified torque.

STRUT ROD BUSHINGS

DIAGNOSIS Strut rods are used on the front suspension of many front-wheel-drive and rear-wheel-drive vehicles. As with any rubber suspension component, strut rod bushings can deteriorate and crack. When strut rod bushings fail, the lower control arm can move forward and backward during braking or when hitting bumps in the road.

Since the lower control arm position is important to vehicle control, when the bushing fails, a pulling or drifting of the vehicle often occurs. *A common symptom of a defective strut rod bushing is noise and a pull toward one side while braking.*

REPLACEMENT To replace a strut rod bushing, the nut on the end of the strut rod has to be removed. ● **SEE FIGURE 113–43.** As the nut is being removed, the lower control arm is likely to move forward or backward, depending on the location of the strut rod frame mount. After removing the strut rod nut, remove the one or two fasteners that retain the strut rod to the lower control arm. The strut rod can now be removed from the vehicle and the replacement rubber bushings can be installed. Install the strut rod in the reverse order of installation. Most bushings use a serrated spacer to maintain the proper force on the rubber bushings; this prevents the technician from compressing the rubber bushing when the strut rod nut is tightened. ● **SEE FIGURE 113–44.**

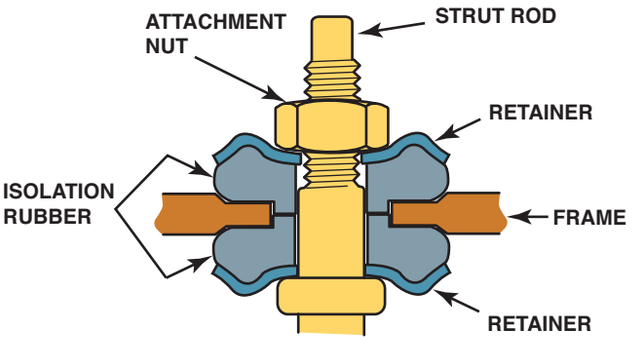

FIGURE 113–44 Typical strut rod bushing with rubber on both sides of the frame to help isolate noise, vibration, and harshness from being transferred to the passengers.

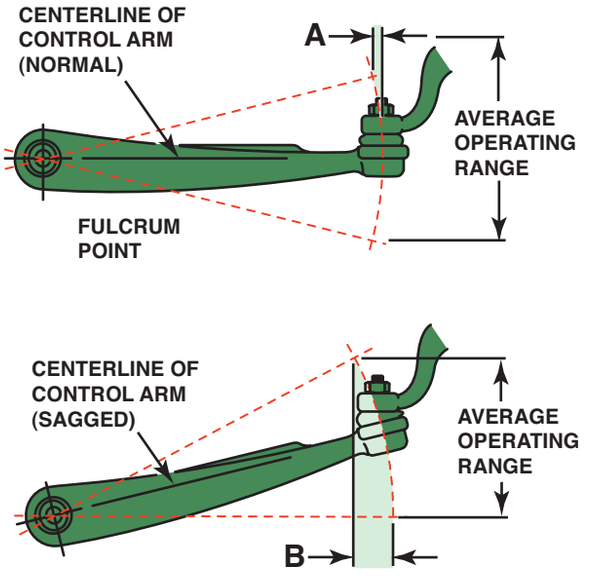

FIGURE 113–45 Notice that if the front coil springs are sagging, the resulting angle of the lower control arm causes the wheels to move from side to side as the suspension moves up and down. Note the difference between the distance at "A" with good springs and the distance at "B" with sagging springs.

CAUTION: Some suspension bushings are directional and must be installed according to the vehicle manufacturer's instructions. For example, on some vehicles, the bushings have a slit or void which must face the front of the vehicle. Always check service information when installing new bushings.

FRONT COIL SPRINGS

DIAGNOSIS Coil springs should be replaced in pairs if the vehicle ride height is lower than specifications. Sagging springs can cause the tires to slide laterally (side to side) across the pavement, causing excessive tire wear. ● **SEE FIGURE 113–45.** Sagging springs can also cause the vehicle to bottom out against the suspension bumpers when traveling over normal bumps and dips in the road.

If a vehicle is overloaded, the springs of the vehicle can *take a set* and not recover to the proper ride height. This commonly occurs with all types of vehicles whenever a heavy load is carried, even on a short trip.

FIGURE 113–46 Spring compressing tool in place to hold the spring as the ball joint is separated. Note that the stabilizer bar links have been removed to allow the lower control arm to move downward enough to remove the coil spring.

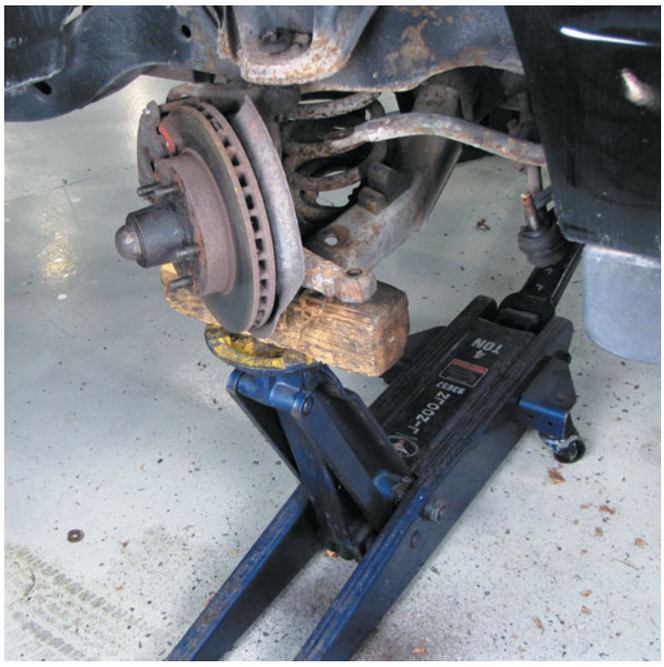

FIGURE 113–47 The steering knuckle has been disconnected from the lower ball joint. The lower control arm and coil spring are being held up by a floor jack.

It is normal for the rear of a vehicle to sag when a heavy load is carried, but it can permanently damage the spring by exceeding the yield point of the steel spring material.

REPLACEMENT The only solution recommended by the vehicle manufacturer is to replace the damaged springs in pairs (both front and both rear, or all four). Several aftermarket alternatives include the following:

- **Helper or auxiliary leaf springs.** These helper springs are usually designed to increase the load-carrying capacity of leaf springs or to restore the original ride height to sagging springs.
- **Spring inserts for coil springs.** Hard rubber or metal spacers are *not recommended* because they create concentrated pressure points on the coils that can cause the spring to break. Hard rubber stabilizers that bridge the gap between two coils without raising the ride height stiffen the ride by locking two coils together. With two coils connected, the spring rate increases and the spring becomes stiffer.
- **Air shocks or airbag devices.** Air shocks or airbags are generally used to restore or increase the load-carrying capacity to the rear of the vehicle. While these devices do allow the ride height to be maintained, the extra load is still being supported by the tires and rear axle bearings. Caution should be used not to overload the basic chassis or powertrain of the vehicle.

There are two designs for vehicles that use coil springs. The most commonly used design places the coil spring between the vehicle frame and the lower control arm.

Both front-suspension designs require that the front shock absorbers be removed in order to replace the coil springs. This first step in the coil spring removal procedure can be performed on the ground or on any type of hoist. After removing the shock absorber, use a coil spring compressor and install it through the center of the coil spring. ● **SEE FIGURE 113–46.** Hook the arms of the coil spring compressor over the rungs of the coil spring and rotate the adjusting nut on the spring compressor with a wrench to shorten the spring. Coil spring clips or the use of a floor jack can also be used to retain the coil spring.

CAUTION: When compressed, all springs contain a great deal of stored energy. If a compressed spring were to become disconnected from its spring compressor or clips, it could be projected outward with enough force to cause injury or death.

After the coil spring is compressed and retained, the control arm can be separated from the steering knuckle and the coil spring can be removed as shown in ● **FIGURES 113–47 AND 113–48.**

Replacement springs should be compressed and installed using the reverse procedure.

NOTE: Many automotive experts recommend that new coil insulators be installed every time the coil springs are replaced.

Make sure that the spring is positioned correctly in the control arm and that the spring insulators are installed correctly. ● **SEE FIGURE 113–49.** Most control arms use two holes for the purpose of coil spring seating. The end of the spring should cover one hole completely and partially cover the second hole. ● **SEE FIGURE 113–50.**

STEERING KNUCKLES

DIAGNOSIS Most steering knuckles are constructed of cast or forged cast iron. The steering knuckle usually incorporates the wheel spindle and steering arm. The steering knuckle/steering arm can become bent if the vehicle is in an accident or hits a curb sideways. Often this type of damage is not apparent until vehicle handling or excessive

FIGURE 113–48 A rubber mallet is being used to support the upper control arm as the lower control is being lowered using a floor jack. After all of the tension has been removed from the coil spring it can be removed and the replacement installed.

FIGURE 113–50 The holes in the lower arm are not only used to allow water to drain from the spring seat, but also are used as a gauge to show the service technician that the coil spring is correctly seated.

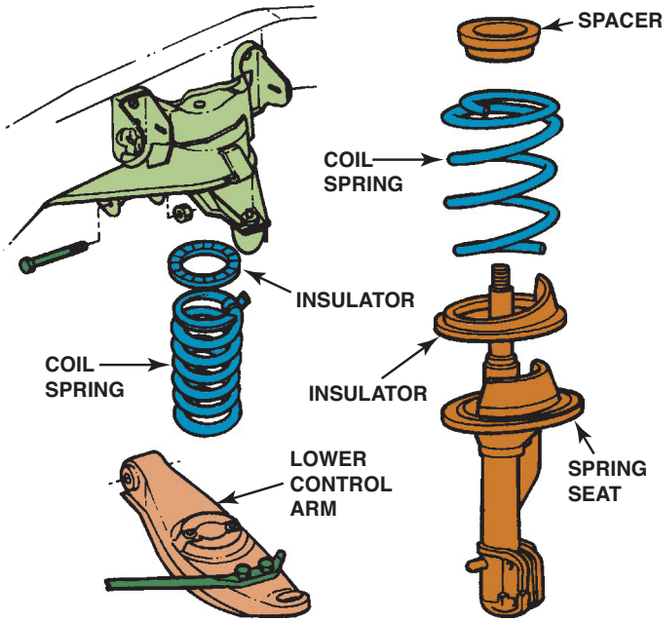

FIGURE 113–49 Spring insulators install between the spring seat and the coil spring to reduce noise.

tire wear is noticed. Unless a thorough inspection is performed during a wheel alignment, a bent steering knuckle is often overlooked.

REPLACEMENT If the steering knuckle is bent or damaged, it must be replaced. It should *not* be bent back into shape or repaired. To replace the steering knuckle, the ball joint(s) must be disconnected from the knuckle and the brake components removed. Be sure to support the control arm and spring properly during the procedure. See a factory service manual for the exact procedure and fastener torque for the vehicle you are servicing.

TORSION BARS

ADJUSTMENT Most torsion bar suspensions are designed with an adjustable bolt to permit the tension on the torsion bar to be increased or decreased to change the ride height. Unequal side-to-side ride height can be corrected by adjusting (turning) the torsion bar tension bolt. ● **SEE FIGURE 113–51.**

Torsion bar adjustment should be made if the difference in ride height from one side to another exceeds 1/8 in. (0.125 in. or 3.2 mm). If the ride height difference side to side is greater than 1/8 in., the vehicle will tend to wander or be unstable, with constant steering wheel movements required to maintain straight-ahead direction.

TORSION BAR REPLACEMENT Torsion bars do not need to be replaced as part of regular service. If the vehicle height is lower than specified, the adjustment bolt can be rotated to restore proper suspension height. The torsion bar can be removed to gain access to parts of the vehicle or to replace a torsion bar damaged in a collision. To replace a torsion bar, check service information for the

REAL WORLD FIX

The Rock-Hard Problem

The owner of a six-month-old full-size pickup truck complained that occasionally when the truck was driven up into a driveway, a loud grinding sound was heard. Several service technicians worked on the truck, trying to find the cause for the noise. After the left front shock absorber was replaced, the noise did not occur for two weeks, and then started again. Finally, the service manager told the technician to replace anything and everything in the front suspension in an attempt to solve the customer's intermittent problem. Five minutes later, a technician handed the service manager a small, deformed rock. This technician had taken a few minutes to *carefully* inspect the entire front suspension. Around the bottom coil spring seat, the technician found the rock. Apparently, when the truck made a turn over a bump, the rock was forced between the coils of the coil spring, making a very loud grinding noise. But the rock did not always get between the coils. Therefore, the problem occurred only once in a while. The technician handed the rock to the very happy customer.

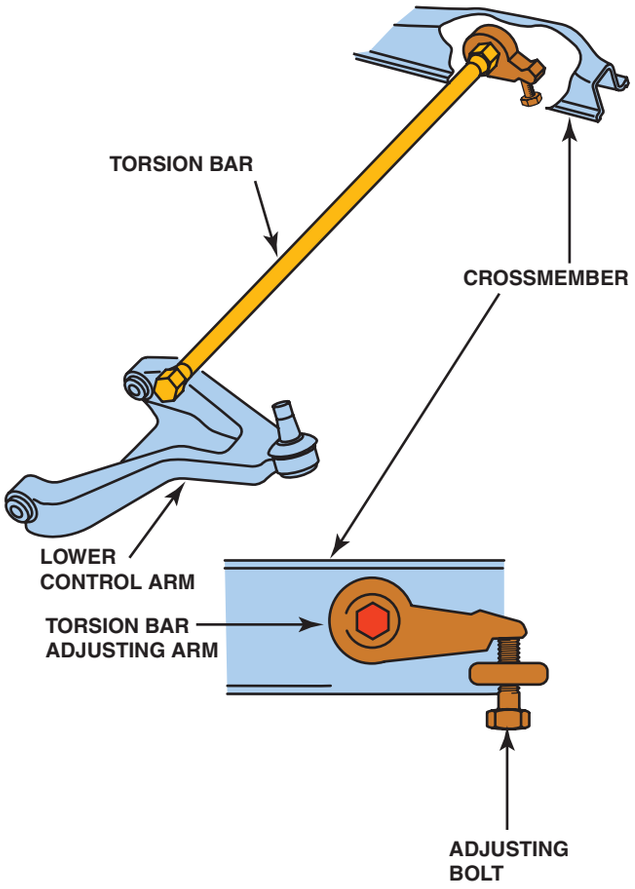

FIGURE 113–51 By rotating the adjusting bolt, the vehicle can be raised or lowered.

exact procedure to follow. Most published procedures include the following steps:

STEP 1 Hoist the vehicle safely.

STEP 2 Attach a holding fixture or large "C" clamp to the torsion bar adjusting arm. Check service information for the exact procedure and locations.

STEP 3 Loosen the torsion bar adjusting bolt until all of the tension has been relieved.

STEP 4 Slide the torsion toward the front of the vehicle (longitudinal torsion bar) until the spline or hexagonal end slips out of the adjusting arm.

STEP 5 Lower the rear of the torsion bar slightly and move the torsion bar toward the rear of the vehicle out of the lower control arm.

To install, reverse the removal procedure.

NOTE: Torsion bars should never be switched from one side of the vehicle to the other as they are twisted and work hardened in one direction and can break if installed on the opposite side of the vehicle.

CONTROL ARM BUSHINGS

DIAGNOSIS Defective control arm bushings are a common source of vehicle handling and suspension noise problems. Most suspension control arm bushings are constructed of three parts: an inner metal sleeve, the rubber bushing itself, and an outer steel sleeve. (Some vehicles use a two-piece bushing that does not use an outer sleeve.)

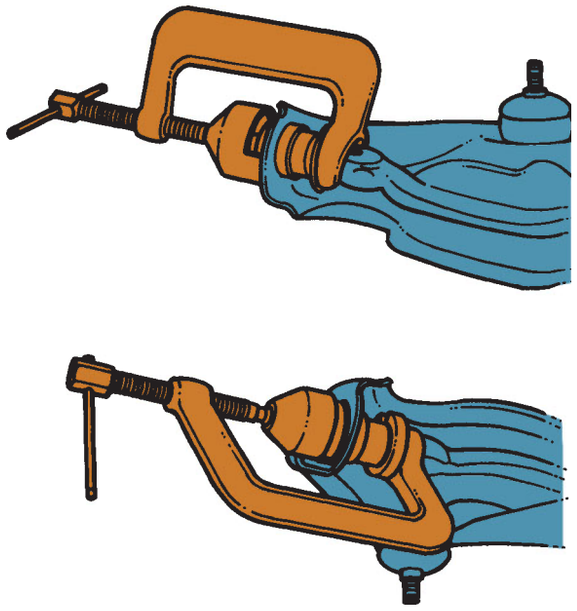

FIGURE 113–52 An adapter and a press or large clamp are used to remove the old bushing from the control arm and to install a new bushing.

REPLACEMENT To remove an old bushing from a control arm, the control arm must first be separated from the suspension and/or frame of the vehicle. Several methods can be used to remove the bushing from the control arm, but all methods apply force to the *outer* sleeve. While an air chisel is frequently used to force the steel sleeve out of the suspension member, a puller tool is most often recommended by General Motors. ● **SEE FIGURE 113–52.** The puller can be used to remove the old bushing and install the replacement bushing without harming the control arm or the new bushing. All bushings should be tightened with the vehicle on the ground and the wheels in a straight-ahead position; this prevents the rubber bushing from exerting a pulling force on the suspension.

NOTE: Some replacement control arm bushings have a higher durometer, or hardness, rating than the original. Urethane bushings are often used in sporty or race-type vehicles and deflect less than standard replacement bushings. These harder bushings also transfer more road noise, vibration, and harshness to the body.

The upper control arm bushings can be replaced in most vehicles that use a short/long-arm-type suspension by following just four easy steps:

STEP 1 Raise the vehicle and support the lower control arm with a safety stand or floor jack.

STEP 2 Disconnect the upper control arm from the frame by removing the frame-attaching nuts or bolts.

STEP 3 Using the upper ball joint as a pivot, rotate the upper control arm outward into the wheel well area. With the control arm accessible, it is much easier to remove and replace the upper control arm pivot shaft and rubber bushings.

STEP 4 After replacing the bushings, simply rotate the upper control arm back into location and reattach the upper control arm pivot shaft to the vehicle frame.

NOTE: An alignment should always be performed after making any suspension-related repairs.

1 The tools needed to replace a front strut assembly include several sockets and a ball-peen hammer, plus a strut compressor.

2 After safely hoisting the vehicle to elbow height and removing the wheel covers, mark and remove the front tire/wheel assembly.

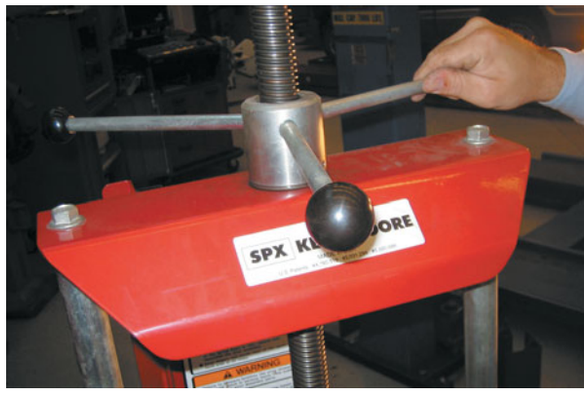
3 Remove the two strut retaining nuts.

4 Before using a hammer to drive the retaining bolts from the steering knuckle, thread the nut into the bolt backwards to prevent causing damage to the threads.

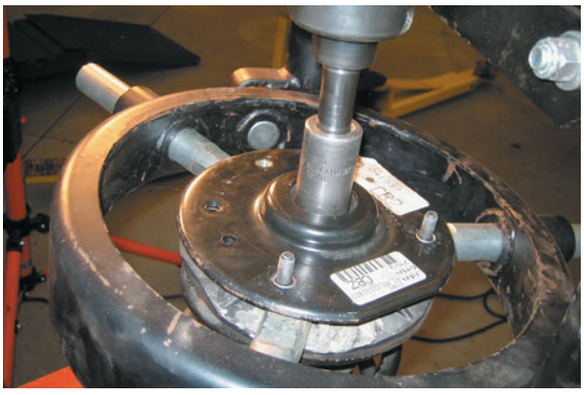
5 Remove the retaining bolts and separate the strut from the steering knuckle.

6 Lower the vehicle and remove the upper strut retaining fasteners.

CONTINUED ▶

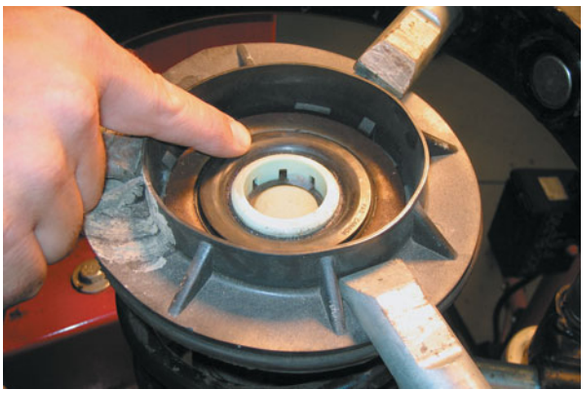


7 Hold the strut while removing the last upper retaining nut and then remove the strut assembly.



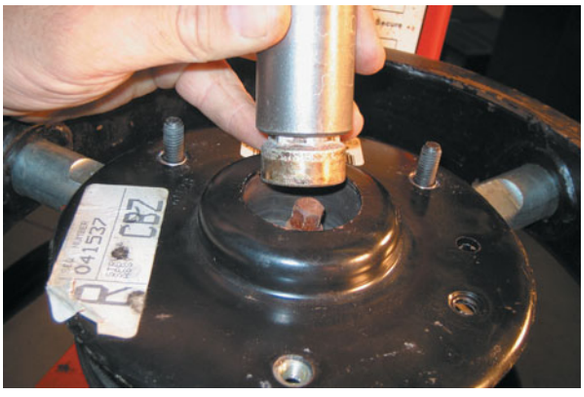
8 After the strut has been removed from the vehicle, install the assembly into a strut compressor.

9 Position the jaws of the compressor under the bearing assembly as per the vehicle manufacturer's instructions. Mark the relationship of spring to strut before disassembly.



10 Turn the compressor wheel until all tension of the spring has been relieved from the upper bearing assembly.

11 Remove the strut retaining nut.



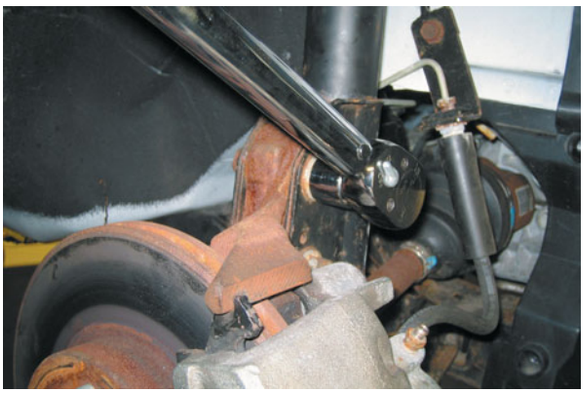
12 Remove the strut assembly.

13 Before installing the replacement strut, check the upper bearing by exerting a downward force on the bearing while rotating and check for roughness. Replace if necessary.

14 Install the strut from underneath the spring compressor fixture.

15 Install the strut retaining nut. Most vehicle manufacturers specify that the strut retaining nut be replaced and the old one discarded.

16 Before loosening the tension, check that the coil spring is correctly located at both the top and the bottom, then release the tension on the spring.



17 Remove the strut assembly from the compressor and place back into the vehicle and install the upper fasteners. Do not torque to specifications until the lower fasteners have been installed.

18 Attach the lower strut to the steering knuckle using the original hardened bolts and nuts.

CONTINUED ▶

STRUT REPLACEMENT (CONTINUED)

19 Using a torque wrench, torque all fasteners to factory specifications.

20 Install the tire/wheel assembly, lower the vehicle, and torque the lug nuts to factory specifications. Align the vehicle before returning it to the customer.

REVIEW QUESTIONS

1. Describe how to perform a proper road test for the diagnosis of suspension-related problems.
2. List four symptoms of worn or defective shock absorbers.
3. Explain the procedure for replacing front shock absorbers on an SLA-type suspension vehicle.
4. Describe the testing procedure for ball joints.
5. Describe the correct general procedure to remove and replace tapered suspension components.

CHAPTER QUIZ

1. Unusual noise during a test drive can be caused by _____.
   - **a.** Defective wheel bearings or stabilizer bar links
   - **b.** Defective or worn control arm bushings or ball joints
   - **c.** Worn or defective CV joints
   - **d.** All of the above
2. Two technicians are discussing non-indicator-type ball joint inspection. Technician A says that the vehicle should be on the ground with the ball joints *loaded,* then checked for freeplay. Technician B says that the ball joints should be *unloaded* before checking for freeplay. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
3. Most manufacturers specify a maximum axial play for ball joints of about _____.
   - **a.** 0.003 in. (0.076 mm)
   - **b.** 0.010 in. (0.25 mm)
   - **c.** 0.030 in. (0.76 mm)
   - **d.** 0.050 in. (1.27 mm)
4. The preferred method to separate tapered chassis parts is to use _____.
   - **a.** A pickle fork tool
   - **b.** A torch to heat the joint until it separates
   - **c.** A puller tool or two hammers to shock and separate the taper
   - **d.** A drill to drill out the tapered part
5. A light film of oil is observed on the upper area of a shock absorber. Technician A says that this condition should be considered normal. Technician B says that a rod seal may bleed fluid during cold weather, causing the oil film. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B

6. Before the strut insert can be removed from a typical MacPherson strut assembly, which operation is necessary to prevent possible personal injury?
   a. The brake caliper and/or brake hose should be removed from the strut housing
   b. The coil spring should be compressed
   c. The upper strut mounting bolts should be removed
   d. The lower attaching bolts should be removed
7. What should the technician do when replacing stabilizer bar links?
   a. The stabilizer bar should be removed from the vehicle before replacing the links.
   b. The links can be replaced individually, yet the manufacturer often recommends that the links at both ends be replaced together.
   c. The stabilizer bar must be compressed using a special tool before removing or installing stabilizer bar links.
   d. Both b and c are correct.
8. A noise and a pull toward one side during braking is a common symptom of a worn or defective _____.
   a. Shock absorber
   b. Strut rod bushing
   c. Stabilizer bar link
   d. Track rod bushing
9. To help prevent vehicle wandering on a vehicle with torsion bars, the ride height (trim height) should be within _____ side to side.
   a. 0.003 in. (0.076 mm)
   b. 0.050 in. (1.27 mm)
   c. 0.100 in. (2.5 mm)
   d. 0.125 in. (3.2 mm)
10. Two technicians are discussing suspension bushings. Technician A says that replacing control arm bushings usually requires special tools. Technician B says using high-performance urethane bushings may cause excessive noise to be transferred to the passenger compartment. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

chapter 114 REAR SUSPENSIONS AND SERVICE

OBJECTIVES: **After studying Chapter 114, the reader will be able to:** • Prepare for ASE Suspension and Steering (A4) certification test content area "B" (Suspension System Diagnosis and Repair). • Describe the various types and styles of rear suspension. • Explain the purpose and function of Panhard rods, Watt's links, and shackles. • List the steps necessary to replace rear shock absorbers. • Explain how to replace rear leaf and coil springs.

KEY TERMS: Axle windup 1336 • Chapman strut 1339 • Hotchkiss drive 1336 • IRS 1338 • Live axle 1336 • Panhard rod 1337 • Semi-independent suspension 1339 • Semi-trailing arm 1338 • Solid axle 1335 • Torque arm 1337 • Track rod 1337 • Trailing arm 1337 • Watts linkage 1338

All suspensions have two basic jobs: keeping the tires on the ground and providing a smooth ride.

SOLID REAR AXLES

A **solid axle** can be used at the rear of either a rear-wheel-drive or front-wheel-drive vehicle. ● **SEE FIGURE 114–1.** On a rear-wheel-drive vehicle, a solid rear axle consists of the differential gears and axle shafts inside a solid housing. On a front-wheel-drive vehicle, a solid axle is usually a simple U-shaped or tubular beam that may contain a torsion bar, rod, or tube to allow some twisting action.

Certain characteristics apply to any solid rear axle, while other characteristics vary by the type of suspension used to attach the axle to the frame.

Solid axles have some handling characteristics that are inferior to those of an independent suspension. Disadvantages of a solid axle include the following:

- Increased proportion of unsprung weight
- Side-to-side road shock transference
- Poorer tire adhesion

Increasing the proportion of unsprung weight decreases ride quality. Transferring road shock from side-to-side causes wheel tramp and shimmy, and poor tire adhesion accelerates tire wear. ● **SEE FIGURE 114–2.**

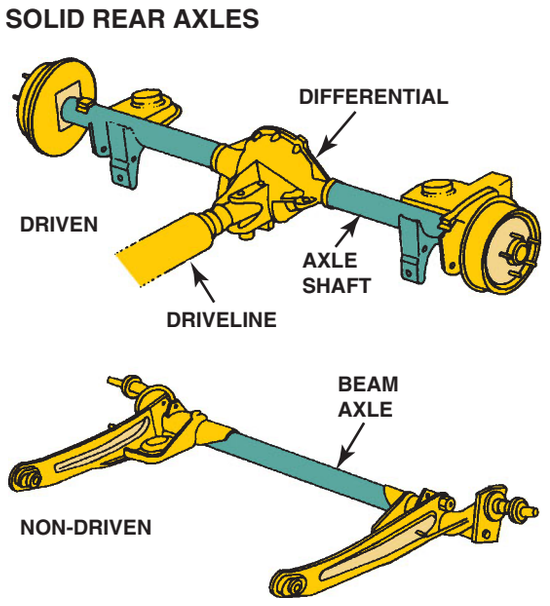


FIGURE 114–1 Solid axles are used on rear-wheel-drive vehicles as well as front-wheel-drive vehicles.

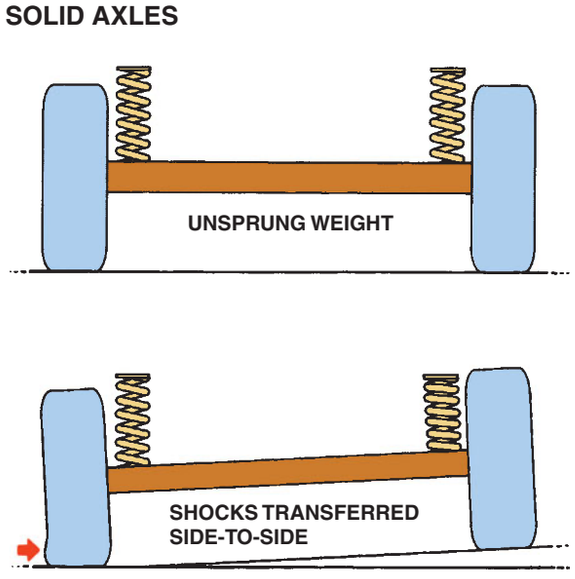

FIGURE 114–2 A solid axle supports the springs, so the axle and suspension components are unsprung weight. When one wheel rides over a bump, the force of impact transfers through the solid axle to the opposite side, leading to unstable handling.

FREQUENTLY ASKED QUESTION

What Is Axle Windup?

Axle windup is a product of the law of physics, which states that every action produces an equal and opposite reaction. As the axle shafts rotate in one direction to drive the wheels, the axle housing attempts to rotate in the opposite direction. The force of this reaction tends to lift the front end of the vehicle during acceleration. ● **SEE FIGURE 114–3.** Axle windup is a particular problem with a solid, driven rear axle because the axle housing concentrates the reacting force. Under extreme acceleration, the reacting force can actually tilt the drive shaft upward and lift the front wheels off the ground. Leaf springs, control arms, pinion snubbers, and torque arms all are means of controlling axle windup.

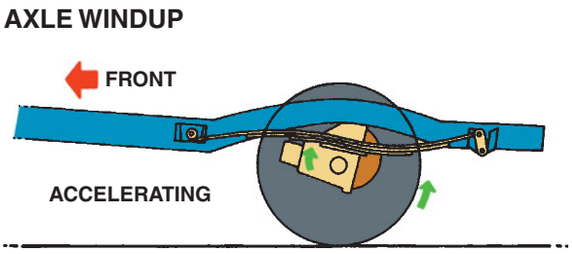

FIGURE 114–3 When the axle housing reacts against the force of axle shaft rotation, the front of the differential tilts upward, creating axle windup.

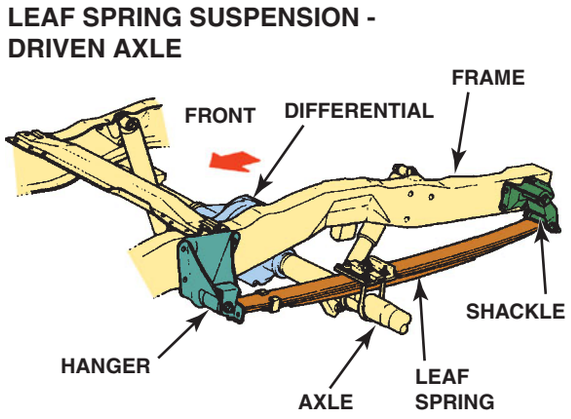

FIGURE 114–4 A typical rear-wheel-drive pickup truck rear suspension equipped with leaf springs. This type of arrangement is called a Hotchkiss drive and the drive train forces are controlled by the rear suspension components.

The sprung weight of the frame and body must be heavy to oppose the unsprung weight of a solid axle, especially on a driven axle. Unsprung weight, wheel tramp, and shimmy all reduce tire adhesion. The effects of these problems are more noticeable in rear-wheel-drive vehicles due to the weight of the rear axle and differential assembly. On a typical front-wheel-drive vehicle, the simple axle beam is not heavy enough to decrease ride quality or cause extreme tire wear. In fact, the rear tires of a front-wheel-drive model always wear more slowly than the front tires because the rear axle is so much lighter than the powertrain.

If engine torque is applied to the rear axle to drive the vehicle, the axle is referred to as a **live axle.**

LEAF SPRING REAR SUSPENSIONS

A leaf spring suspension is a simple system because it does not require control arms to brace and position the axle. The leaf springs link the axle to the frame and effectively serve two purposes:

- Absorbing road shock
- Locating the axle under the vehicle

Most rear-wheel-drive trucks use a solid rear axle with leaf springs in an arrangement called a **Hotchkiss drive.** ● **SEE FIGURE 114–4.** Leaf springs on a driven axle control axle windup

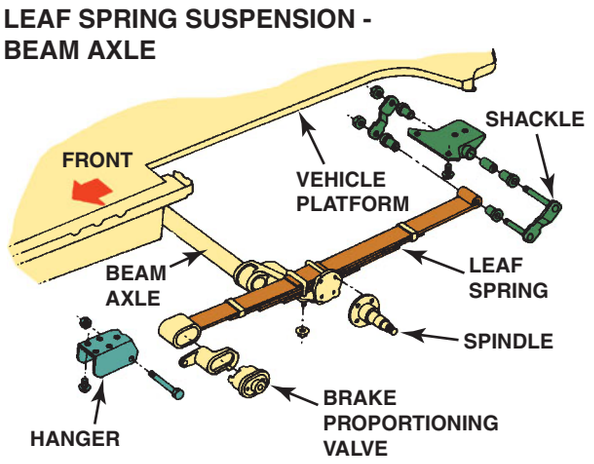

FIGURE 114–5 An exploded view of a beam axle with multi-leaf springs.

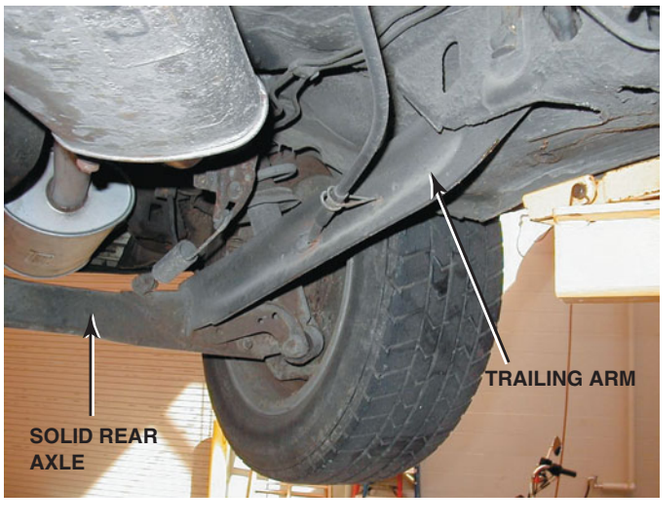

FIGURE 114–6 A trailing arm rear suspension with a solid axle used on a front-wheel-drive vehicle.

by transferring force from the axle housing to the frame. The front portion of the leaf spring, from the axle housing to the frame mount, acts like a trailing control arm. However, if the front section of the leaf spring is too flexible, it may not control axle windup as well. To compensate, some manufacturers make the front section of the spring shorter, and therefore less flexible, than the rear section.

Leaf springs are used on the rear of many light- and medium-duty trucks and vans. ● **SEE FIGURE 114–5.** A shackle attaches the rear of each spring to the unit-body frame, while the front of each spring pivots through a bolt and bushing connected to a hanger that bolts to the body.

TRAILING ARM REAR SUSPENSIONS

A **trailing arm** extends from a frame crossmember located ahead of the rear axle back to the axle housing or a wheel knuckle. Trailing arms run parallel to the centerline of the chassis. ● **SEE FIGURE 114–6.** A trailing arm mounts to the frame with bushings,

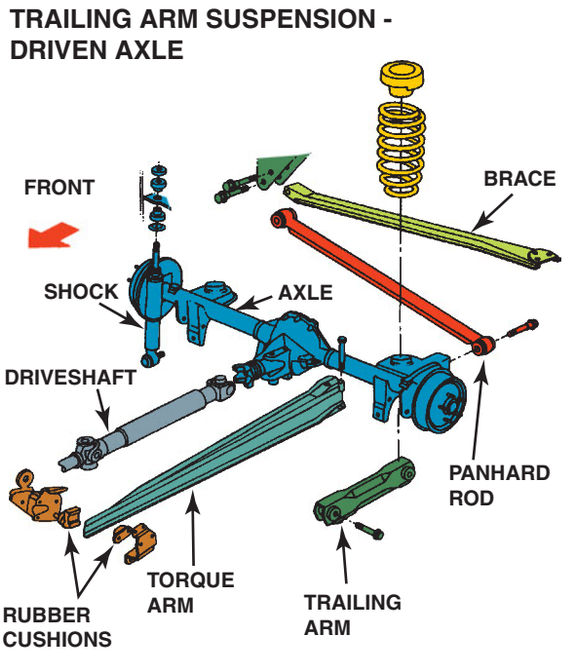

FIGURE 114–7 The Camaro and Firebird rear suspension systems use a torque arm to control axle windup. If the rubber torque arm bushings (cushions) are worn, a loud "bang" could be heard and felt when accelerating suddenly.

which allows the arm to pivot as the wheel rides over bumps. Some rear suspensions use two sets of trailing arms, one set positioned higher in the chassis than the other. Although the arms in this type of arrangement are commonly referred to as the *upper control arms* and *lower control arms,* they are usually called trailing arms. The word *trailing* applies to any link where the supported member trails the arm. Trailing arms may be used to brace either a driven or nondriven solid rear axle against front-to-rear forces, but they do not provide much resistance to side-to-side, or lateral, forces. The axle itself is one means of locating the wheels side-to-side, and solid rear suspensions frequently use another rod to provide additional support. Trailing arms transfer axle windup force to the frame and control front-to-rear axle movement. On a few models, especially those with a high-performance suspension, a **torque arm** provides additional resistance to axle windup. ● **SEE FIGURE 114–7.** The torque arm extends parallel to the drive shaft between the rear axle and the transmission. One end of the torque arm is rigidly bolted to the differential housing, while the other end attaches to the transmission through a cushioned bracket to allow some flex.

A trailing arm rear suspension on a nondriven solid axle virtually always includes a **track rod,** also called a **Panhard rod.** A track rod is a rod attached to the body or frame on one end and the rear axle on the other. The purpose of the track rod is to keep the rear axle centered under the vehicle. The suspension may use either coil springs or struts.

The rear axle is a U-shaped steel beam that is open on the bottom. ● **SEE FIGURE 114–8.** Flat metal axle end plates, to which the wheel spindles bolt, are attached to each end of the beam. A torsion tube or rod fits inside the beam and is welded to the axle end plates.

The trailing arms, which are welded to the outboard ends of the axle, extend forward and attach to the frame with pivot bushing mounts. A bracket on top of the beam axle locates the ring-type lower strut mount, and the upper strut mount attaches to a reinforced area of the wheel well.

TRAILING ARM SUSPENSION - BEAM AXLE

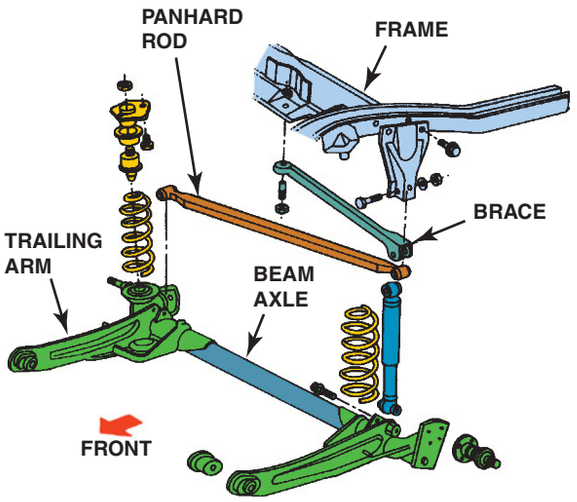

FIGURE 114–8 A typical beam axle rear suspension, which uses trailing arms and coil springs along with a track rod, also called a Panhard rod, to control side-to-side axle movement.

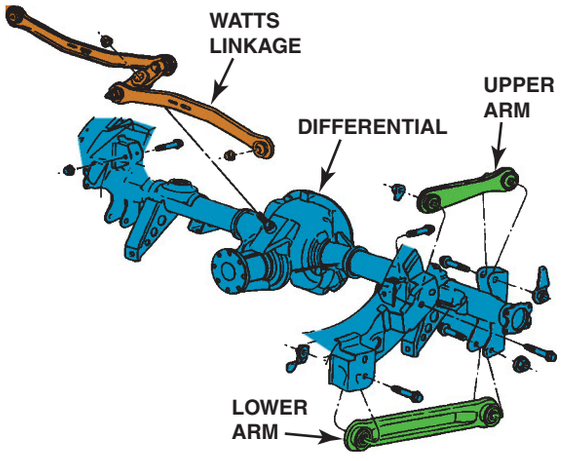

FIGURE 114–9 This Ford rear suspension uses upper and lower semi-trailing arms to mount the rear axle and a watts linkage to control side-to-side movement.

INDEPENDENT SUSPENSION

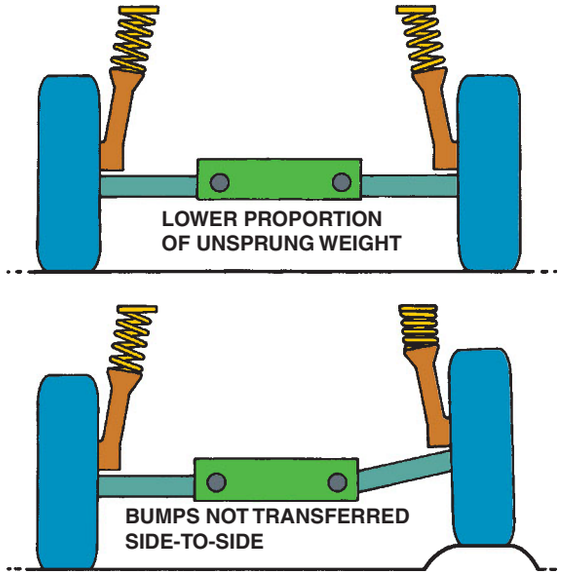

FIGURE 114–10 An independent rear suspension provides a better ride because less weight is unsprung and the suspension is able to react quickly to bumps in the road without affecting the opposite side.

SHORT-LONG-ARM (SLA) SUSPENSION

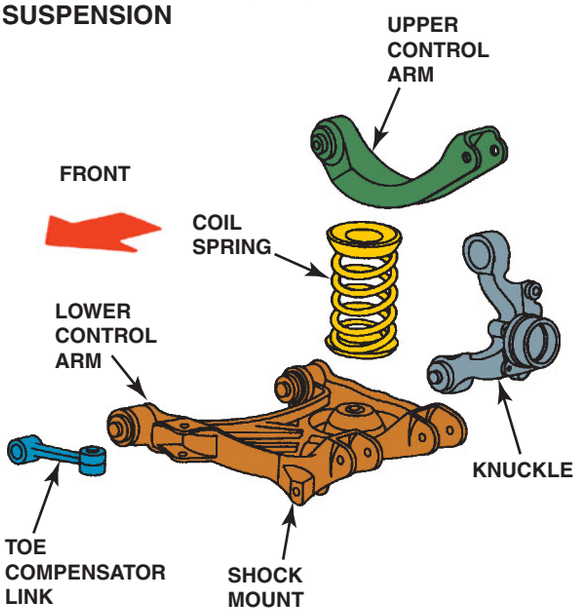

FIGURE 114–11 A typical short/long-arm independent rear suspension.

SEMI-TRAILING ARM REAR SUSPENSIONS

A **semi-trailing arm** is similar to a trailing arm in that it extends back from a frame member to the axle. However, a trailing arm is parallel to the vehicle centerline whereas a semi-trailing arm pivots at an angle to the vehicle centerline. Semi-trailing arms have an advantage over trailing arms because they control both side-to-side and front-to-rear motion. Typically, a semi-trailing arm suspension uses coil springs, air springs, or pivot-base struts.

A semi-trailing arm suspension may be used with either a solid axle or an independent suspension.

The Ford suspension uses two pairs, upper and lower, of semi-trailing arms and a center pivot arrangement to locate the driven rear axle. This axle centering pivot bracket and linkage is called a **watts linkage.** ● **SEE FIGURE 114–9.**

INDEPENDENT REAR SUSPENSIONS

The use of **independent rear suspension,** called **IRS,** has grown dramatically over the past several decades to the point where such systems are now fairly common, especially on front-wheel-drive vehicles and some rear-wheel-drive vehicles. Although rarely used on trucks, a number of rear-wheel-drive vehicles do feature an independent rear suspension.

The reduction in unsprung weight is particularly noticeable for driven axles, which are constructed to transfer the weight of the differential and axles to the frame. ● **SEE FIGURE 114–10.** A vehicle with an independent rear suspension rides and handles better than a similar vehicle equipped with a solid rear axle. An SLA-type of independent suspension may be used at the rear of a rear-wheel-drive vehicle. ● **SEE FIGURE 114–11.**

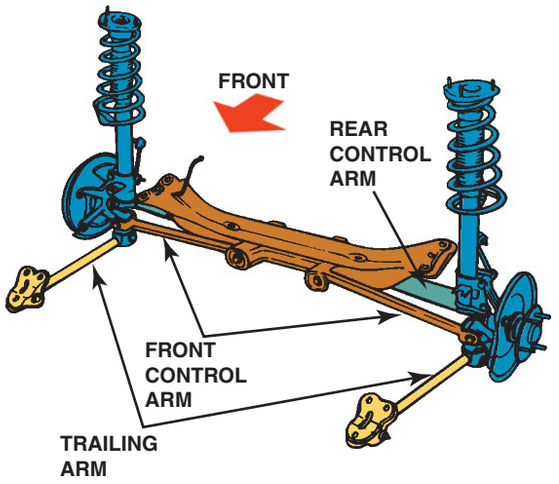

FIGURE 114–12 This independent rear suspension uses a MacPherson strut, two parallel lower transverse control arms, and a trailing arm.

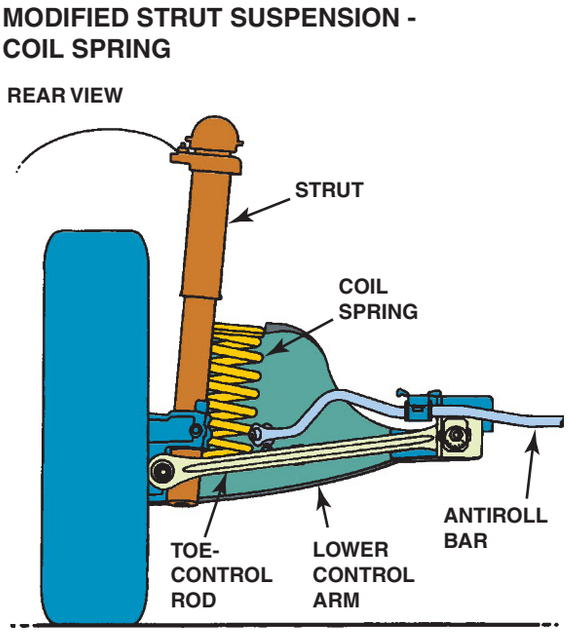

FIGURE 114–13 The toe-control rod provides an extra brace to keep the rear wheels straight ahead during braking and acceleration on this modified-strut-type independent rear suspension.

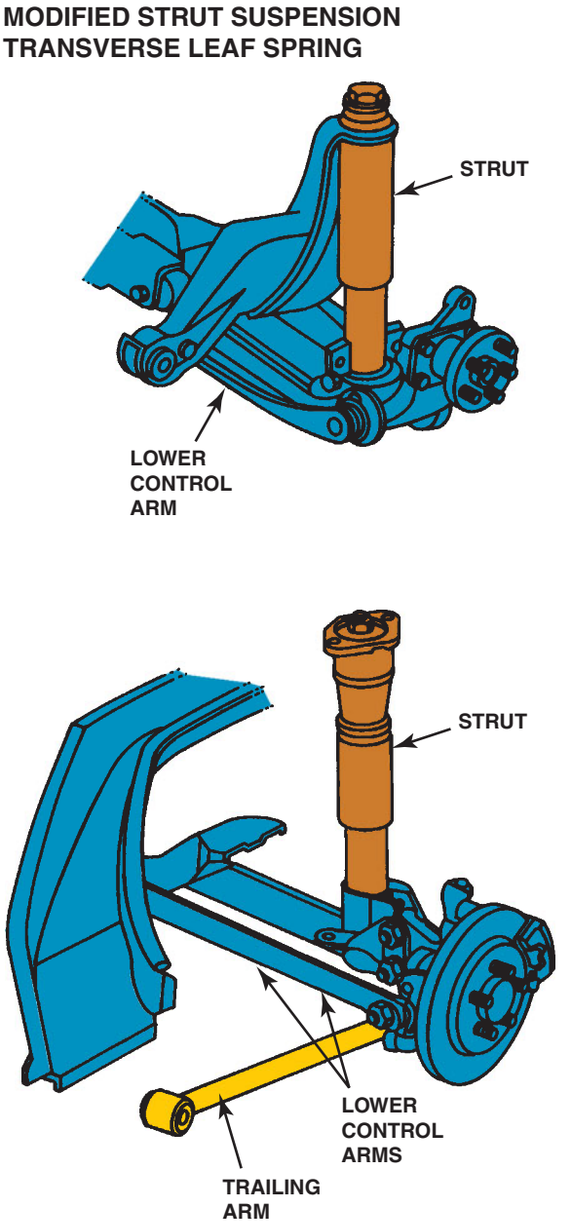

FIGURE 114–14 The upper drawing shows a transverse-leaf-spring-type independent rear suspension that uses an "H"-shaped lower control arm. The lower drawing shows a transverse leaf spring suspension that uses two parallel lower links and a trailing arm.

The differential carrier bolts to the rear subframe, which bears the weight of the axle. Equal-length axle shafts with constant-velocity (CV) joints at either end connect the differential to the rear wheels, and allow the wheels to move independently of each other.

The main benefit of an SLA suspension is that it reduces tire scrub and improves traction. The positioning of the control arms determines the suspension roll center location. In general, the lower the roll center, the less body roll.

Unit-body front-wheel-drive vehicles frequently use strut suspensions at the rear axle. Typically, the strut mounts to the knuckle and replaces the upper control arm. The first designer to put MacPherson-type struts in a rear suspension was an Englishman, Colin Chapman. For this reason, a rear strut suspension is often referred to as a **Chapman strut** suspension by European manufacturers and engineers.

The MacPherson strut system is the most popular independent rear suspension for late-model front-wheel-drive vehicles. ● **SEE FIGURE 114–12.** Modified strut rear suspensions are found on a variety of front-wheel-drive models from a number of different manufacturers. ● **SEE FIGURE 114–13.**

General Motors produced two different rear modified strut systems with transverse leaf springs. ● **SEE FIGURE 114–14.** A transverse leaf spring is also used on the Chevrolet Corvette and the Cadillac XLR.

SEMI-INDEPENDENT REAR SUSPENSIONS

A **semi-independent suspension** is used only at a nondriven rear axle. The semi-independent design is based on a crossbeam that is similar to the beam axle of a solid, nondriven rear suspension.

SEMI-INDEPENDENT SUSPENSIONS

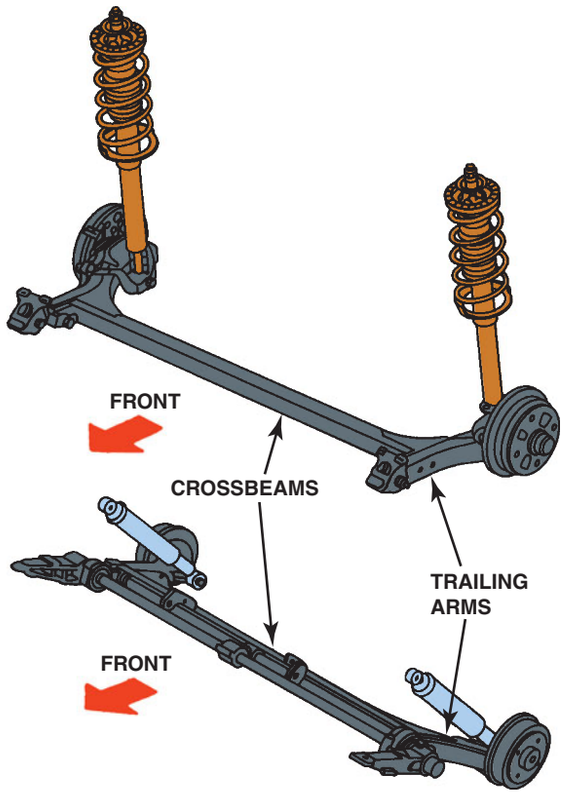

FIGURE 114–15 The crossbeam is placed toward the front of the vehicle rather than the centerline of the rear wheels on a semi-independent-type rear suspension.

SEMI-INDEPENDENT SUSPENSION-STRUT

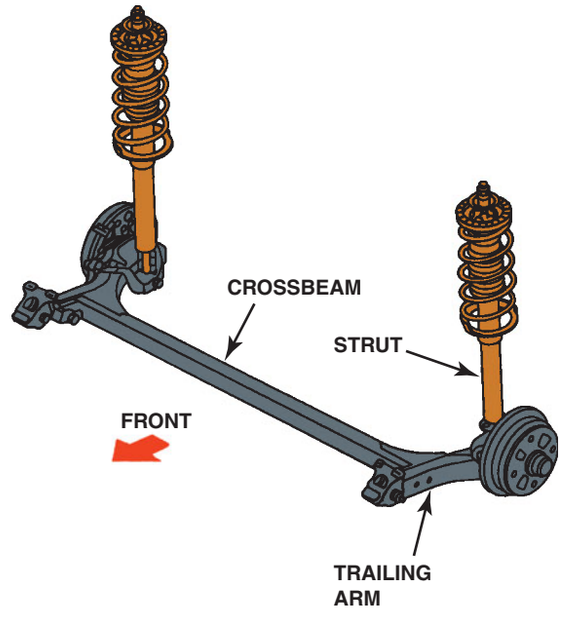

FIGURE 114–16 A semi-independent rear suspension with MacPherson struts.

However, on a semi-independent design the crossbeam is placed ahead, rather than at the centerline, of the wheels. ● **SEE FIGURE 114–15.** Trailing arms extend rearward from the crossbeam to the wheels. The name *semi-independent* indicates that although an axle does not directly link the wheels, the wheels are not completely independent of each other because they are indirectly connected through the crossbeam.

Some semi-independent rear suspensions use struts. ● **SEE FIGURE 114–16.**

FIGURE 114–17 Check all rubber bushings for excessive cracking.

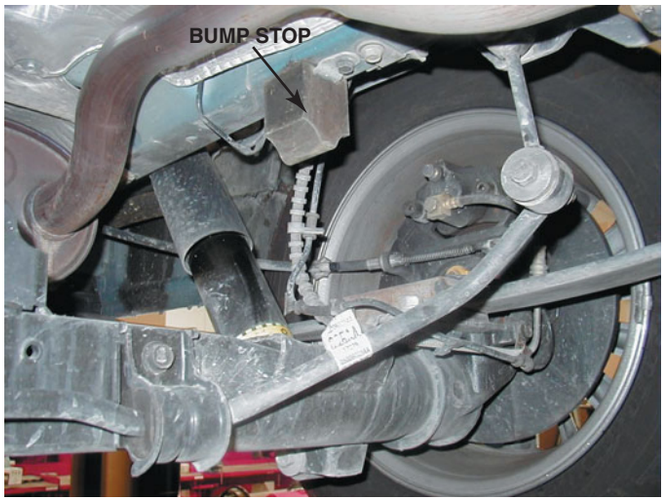

FIGURE 114–18 Carefully inspect the bump stops for damage during a thorough visual inspection.

REAR SUSPENSION SERVICE

Rear suspension service starts with a thorough test drive, to observe any unusual noises or vibrations that may be caused by a fault with a rear suspension component.

After a test drive, safely hoist the vehicle and perform a thorough visual inspection. Use an appropriate prybar and move all of the bushings and joints, checking for deterioration or freeplay. ● **SEE FIGURE 114–17.**

Inspect the shock absorber or struts for leakage or damage. Inspect the bump stops for damage. ● **SEE FIGURE 114–18.** If the bump stops are damaged, this may indicate that the springs are fatigued and the vehicle is at lower-than-normal ride height, or that the shocks or studs are unable to control the springs. ● **SEE FIGURE 114–19.**

FIGURE 114–19 A broken spring was discovered during a routine under-vehicle visual inspection. Notice the witness marks that show that the spring coils have been hitting each other.

FIGURE 114–20 The shock absorber needs to be disconnected before removing the coil spring. Installation is the reverse of removal procedure.

REAR SHOCK REPLACEMENT

PRECAUTIONS Before removing the rear shock absorbers, the rear axle must be supported to prevent stretching of the rear brake flexible hose. Shocks are attached to the frame or body of the vehicle at the top and to a bracket on the rear axle housing at the bottom. Often, the top of the rear shock absorber is fastened *inside* the vehicle. Consult the vehicle manufacturer's service information for exact procedures and fastener torque values.

NOTE: Shock absorbers and/or struts should always be replaced as a pair.

AIR SHOCK INSTALLATION Air-adjustable shock absorbers are a popular replacement for conventional rear shock absorbers. Air shocks can be used to level the vehicle while towing a trailer or when heavily loaded. When the trailer or load is removed, air can be released from the air shocks to return the vehicle height to normal.

Most replacement air shocks are directional and are labeled *left* and *right.* This ensures that the plastic air hose line exits the shock absorber toward the center or rear of the vehicle and is kept away from the wheels.

The plastic air shock line attaches to the shock absorber with an O-ring or brass ferrule and nut. An air leak can result if this O-ring or ferrule is not installed according to the manufacturer's recommendations. Route the plastic air line along the body, keeping it away from the exhaust and any other body parts where the line could be damaged. Attach the line to both shocks to a junction at a convenient location for adding or releasing air.

REAR SPRING REPLACEMENT

REAR COIL SPRINGS

REPLACEMENT. Coil springs in the rear are easily replaced on both front-wheel-drive and rear-wheel-drive vehicles. The procedure includes the following steps:

1. Raise the vehicle safely on a hoist.
2. Remove both rear wheels.
3. Support the rear axle assembly with tall safety stands.
4. Remove the lower shock absorber mounting bolts/nuts and disconnect the shock absorber from the rear axle assembly.
5. Slowly lower the rear axle assembly by either lowering the height of the adjustable safety stands or raising the height of the vehicle on the hoist.
6. Lower the rear axle just enough to remove the coil springs. ● **SEE FIGURE 114–20**.

CAUTION: The shock absorber is usually the only component that limits the downward movement of the rear axle to allow removal of the rear coil springs. Some vehicles may be equipped with rear suspension height sensors for the adjustable suspension system or an adjustable rear proportioning valve for the rear brakes. Some vehicles also require that the rear stabilizer bar or track rod be disconnected or removed before lowering the rear axle assembly. Always consult service information for the exact procedure and torque specifications for the vehicle being serviced.

REAR LEAF SPRINGS

REPLACEMENT. Rear leaf springs often need replacement due to one of the following common causes:

1. **Individual leaves of a leaf spring often crack, then break.** When a leaf spring breaks, the load-carrying capacity of the vehicle decreases and it often sags on the side with the broken spring. Metal fatigue, corrosion, and overloading are three of the most common causes of leaf spring breakage. ● **SEE FIGURE 114–21**.

   NOTE: When one rear spring on one side sags, the opposite front end of the vehicle tends to *rise.* For example, if the right rear spring breaks or sags down, the left front of the vehicle tends to rise higher than the right front. This unequal vehicle height can make the vehicle difficult to handle, especially around corners or curves.

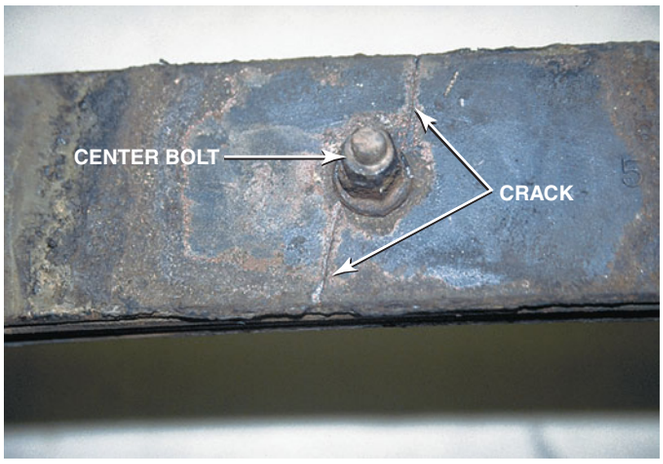

FIGURE 114–21 The center bolt is used to hold the leaves of the leaf spring together. However, the hole for the center bolt also weakens the leaf spring. The crack shown is what a technician discovered when the leaf spring was removed during the diagnosis of a sagging rear suspension.

2. **If the center bolt breaks,** the individual leaves can move and the rear axle is no longer held in the correct location. When one side of the rear axle is behind the other side, the vehicle will *dog track.* Dog tracking refers to the sideways angle of the vehicle while traveling straight. It is commonly caused by the rear axle steering the vehicle toward one side, while the driver controls the direction of the vehicle with the front wheels.

NOTE: Leaf springs should be replaced in pairs.

To replace leaf springs in the rear of a rear-wheel-drive vehicle, follow these steps:

1. Raise the vehicle safely on a hoist.
2. Support the rear axle with safety stands.
3. Remove the rear shackle bolts and forward mounting bolt or mounting bracket.
4. Remove the U-bolts.
5. Being careful of any nearby brake line, remove the spring.
6. Install the new spring, being careful to position the center bolt correctly into the hole on the axle pedestal.

REVIEW QUESTIONS

1. What are the disadvantages of a solid rear axle?
2. What is the purpose of a torque arm?
3. What must be done to ensure safety when replacing the rear shock absorbers?

CHAPTER QUIZ

1. A vehicle equipped with a coil spring front suspension and a leaf spring rear suspension "dog tracks" while driving on a straight, level road. Technician A says that a broken center bolt could be the cause. Technician B says defective rear shock absorbers could be the cause. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. When axle windup is controlled by the rear-leaf spring during acceleration, this system is called _____.
   a. Trailing arm **c.** Torque arm
   b. Semi-trailing arm **d.** Hotchkiss drive
3. A loud "bang" is heard and felt every time the accelerator is depressed or released on a rear-wheel-drive vehicle. Technician A says that a leaking shock absorber could be the cause. Technician B says a broken torque arm could be the cause. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. Technician A says that leaf springs are mounted lengthwise on the rear of many vehicles. Technician B says that some vehicles use a transversely mounted leaf spring on the rear. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
5. A strut-type suspension is used _____.
   a. In the front only
   b. In the rear only
   c. In both the front and rear
   d. In rare vehicles no longer in production
6. Two technicians are discussing rear shock absorbers. Technician A says that if one shock is leaking, then both rear shock absorbers should be replaced. Technician B says that the rear axle should be supported before removing rear shock absorbers. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. A "witness mark" is a _____.
   a. Type of fastener
   b. Type of tool
   c. Mark where two parts have rubbed or touched
   d. Identification mark
8. The left front of the vehicle is higher than the right front and the right rear is lower than the left rear. What is the most likely cause of this problem?
   a. A weak right-rear shock absorber
   b. A broken track rod
   c. A broken left-front shock absorber
   d. A sagging right-rear spring
9. One rear leaf spring is broken. Technician A says that both rear leaf springs should be replaced. Technician B says that only the broken spring needs to be replaced. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. A track rod is also called a _____.
    a. Panhard rod **c.** Handing link
    b. Control rod **d.** Semi-independent rod

chapter 115

ELECTRONIC SUSPENSION SYSTEMS

OBJECTIVES: After studying Chapter 115, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "B" (Suspension System Diagnosis and Repair). • Discuss the various types of electronic suspension systems. • Describe how suspension height sensors function. • Explain the use of the various sensors used for electronic suspension control. • Discuss the steering wheel position sensor. • Explain how solenoids and actuators are used to control the suspension.

KEY TERMS: Actuator 1343 • Air suspension 1345 • Armature 1349 • AS 1350 • Automatic level control (ALC) 1350 • CCVRTMR 1355 • Computer command ride (CCR) 1347 • Desiccant 1355 • Driver selector switch 1347 • EBCM 1346 • ECU 1343 • Electromagnet 1348 • Handwheel position sensor 1345 • Height sensor 1343 • Input 1343 • Lateral accelerometer sensor 1346 • LED 1343 • Magneto-rheological (MR) 1355 • Mode select switch 1350 • Motor 1349 • MRRTD 1355 • Output 1343 • Perform ride mode 1352 • Photocell 1343 • Phototransistor 1343 • Pulse width 1349 • Pulse-width modulation 1349 • Real-time dampening (RTD) 1345 • RPO 1352 • RSS 1345 • Selectable ride (SR) 1347 • Solenoid 1345 • Solenoid controlled damper 1352 • Stabilitrak 1352 • Steering wheel position sensor 1345 • Touring ride mode 1352 • Vehicle stability enhancement system (VSES) 1346 • VS sensor 1346 • Yaw rate sensor 1346

THE NEED FOR ELECTRONIC SUSPENSIONS

Since the mid-1980s, many vehicle manufacturers have been introducing models with electronic suspension controls that provide a variable shock stiffness or spring rate. The main advantage of electronic controls is that the suspension can react to different conditions. The system provides a firm suspension feel for fast cornering and quick acceleration and braking, with a soft ride for cruising. ● **SEE FIGURE 115–1.**

ELECTRONIC SUSPENSION CONTROLS AND SENSORS

PURPOSE AND FUNCTION Sensors and switches provide **input** to the electronic control module (ECM), or system computer. The ECM, which may also be referred to as the **electronic control unit (ECU),** is a small computer that receives input in the form of electrical signals from the sensors and switches and provides **output** electrical signals to the system actuators. ● **SEE FIGURE 115–2.** The electrical signal causes an **actuator** to perform some type of mechanical action.

HEIGHT SENSORS Sensors, which are the input devices that transmit signals to the ECM, monitor operating conditions and component functions. A **height sensor** senses the vertical relationship between the suspension component and the body. Its signal indicates to the ECM how high the frame or body is, or how compressed the suspension is. A number of sensor designs are used to determine ride height, including a **photocell** type of sensor. ● **SEE FIGURE 115–3.**

Four height sensors, one at each wheel, deliver an input signal to the ECM. All four sensors are similar and use a control link, lever, slotted disc, and four photo interrupters to transmit a signal. Each photo interrupter consists of a **light-emitting diode (LED)** and a **phototransistor,** which reacts to the LED.

Inside the sensor, the LEDs and phototransistors are positioned opposite each other on each side of the slotted disc. ● **SEE FIGURE 115–4.** When the system is activated, the ECM applies voltage to the LEDs, which causes them to illuminate. Light from an LED shining on the phototransistor causes the transistor to generate a voltage signal. Signals generated by the phototransistors are delivered to the ECM as an input that reflects ride height.

As suspension movement rotates the disc, the slots or windows on the disc either allow light from the LEDs to shine on the phototransistors or prevent it. The windows are positioned in such a manner that, in combination with the four LEDs and transistors, the sensor is capable of generating 16 different levels of voltage. This variable voltage, which is transmitted to the ECM as an input signal, directly corresponds to 1 of 16 possible positions of the suspension. This input signal tells the ECM the position of the suspension in relation to the body. Whether the input voltage signal is increasing or decreasing allows the ECM to determine if the suspension is compressing or extending.

The ECM can also determine the relative position of the body to the suspension, or the attitude of the vehicle, from the four height sensors. Comparing front-wheel input signals to those of the rear wheels determines the amount of pitch caused by forces of acceleration or deceleration. A side-to-side comparison allows the ECM to determine the amount of body roll generated by cornering force.

GENERAL MOTORS ELECTRONIC SUSPENSION SENSORS There are five different sensors found on electronic suspension systems, and GM vehicles can have between one and four of these sensors, depending on the system.

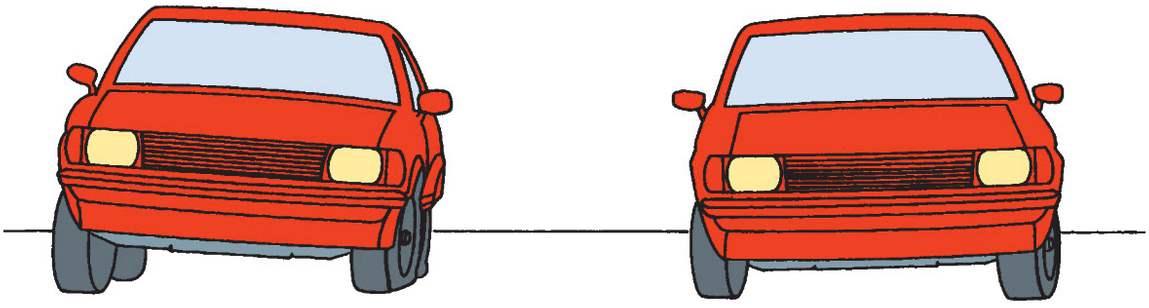

FIGURE 115–1 An electronically controlled suspension system can help reduce body roll and other reactions better than most conventional suspension systems.

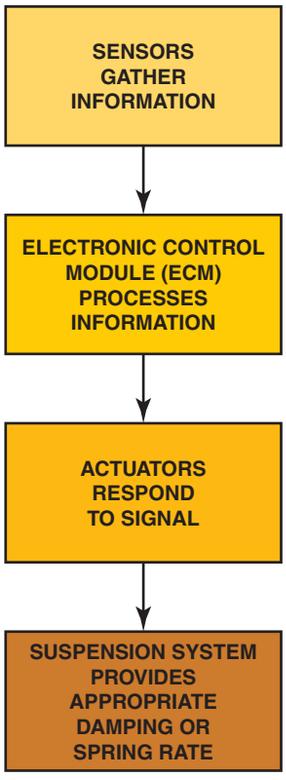

FIGURE 115–2 Input devices monitor conditions and provide information to the electronic control module, which processes the information and operates the actuators to control the movement of the suspension.

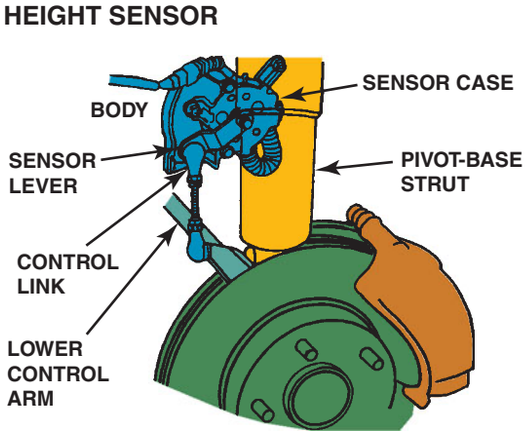

FIGURE 115–3 A typical electronic suspension height sensor, which bolts to the body and connects to the lower control arm through a control link and lever.

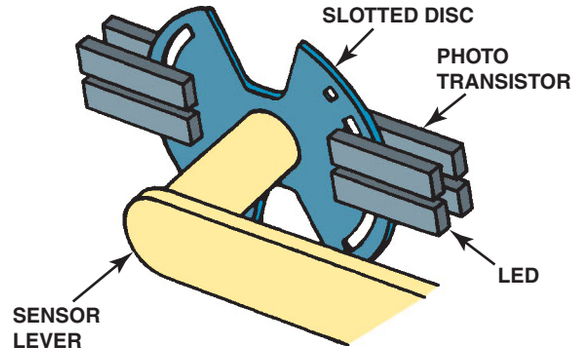

FIGURE 115–4 When suspension action moves the lever, it rotates the slotted disc and varies how much of the photo transistor is exposed to the LEDs, which vary the input signal.

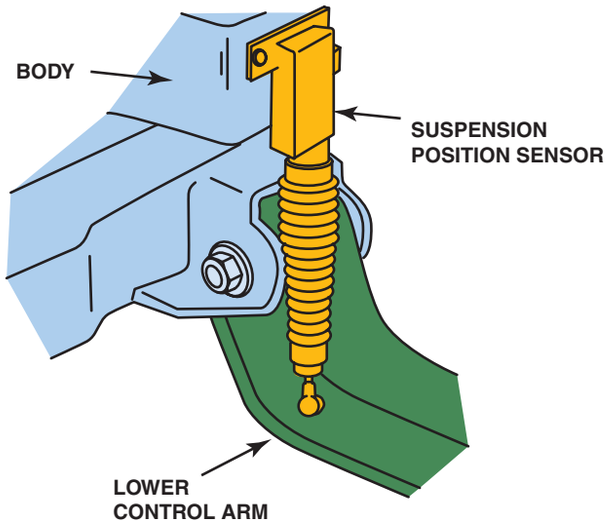

FIGURE 115–5 Typical suspension position sensor.

Depending on the vehicle, the *suspension position sensor* may be called by a different name. It can be called:

- An automatic level control sensor
- An electronic suspension position sensor
- A position sensor
- An air suspension sensor

The sensor provides the control module with information regarding the relative position and movement of suspension components. The common mounting location is between the vehicle body and the suspension control arm. ● **SEE FIGURE 115–5.**

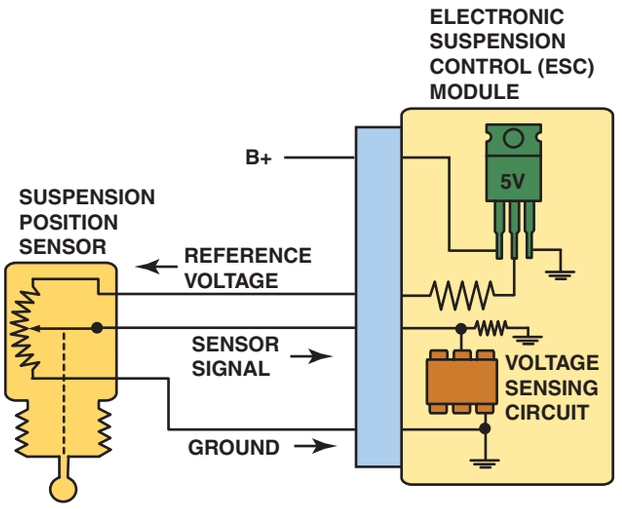

FIGURE 115–6 A three-wire suspension position sensor schematic.

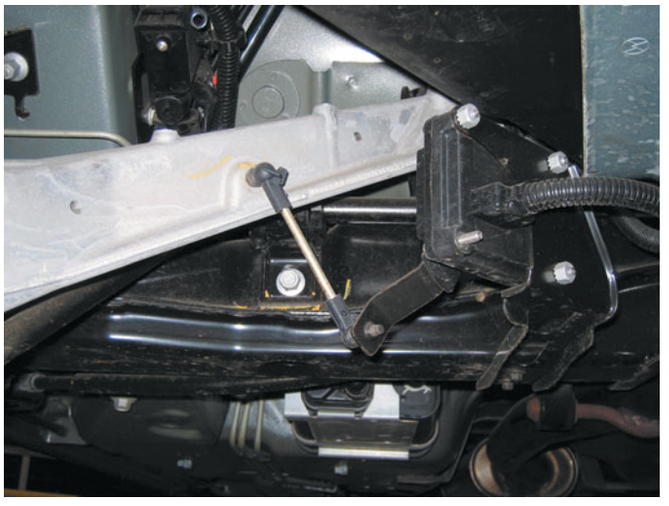

FIGURE 115–7 A suspension height sensor.

POSITION SENSOR OPERATION

The operation of the sensor is either an air suspension sensor two-wire type or a potentiometer three-wire type. The **air suspension** sensor is also known as a *linear Hall-effect* sensor. The air suspension sensor operation consists of a moveable iron core linked to the components. As the core moves, it varies the inductance of the internal sensor coil relative to suspension position.

The suspension control module energizes and de-energizes the coil approximately 20 times a second, thereby measuring sensor inductance as it relates to suspension position. The potentiometer three-wire sensor requires reference and ground voltage. Similar to the throttle position (TP) sensor, it produces a variable analog voltage signal. ● **SEE FIGURE 115–6.**

As the suspension moves up or down, an arm moves on the suspension position sensor through a ball-and-cup link. ● **SEE FIGURE 115–7.**

Suspension position sensor voltage changes relative to this movement. The sensor receives a 5-volt reference signal from the control module. The position sensor returns a voltage signal between 0 and 5 volts depending on suspension arm position.

NOTE: Some systems may require sensor learning or "reprogramming" after replacement. For instance, the sensor used on the Tahoe or Suburban needs to be programmed if replaced. Always check service information for the details and procedures to follow when replacing a sensor on the suspension.

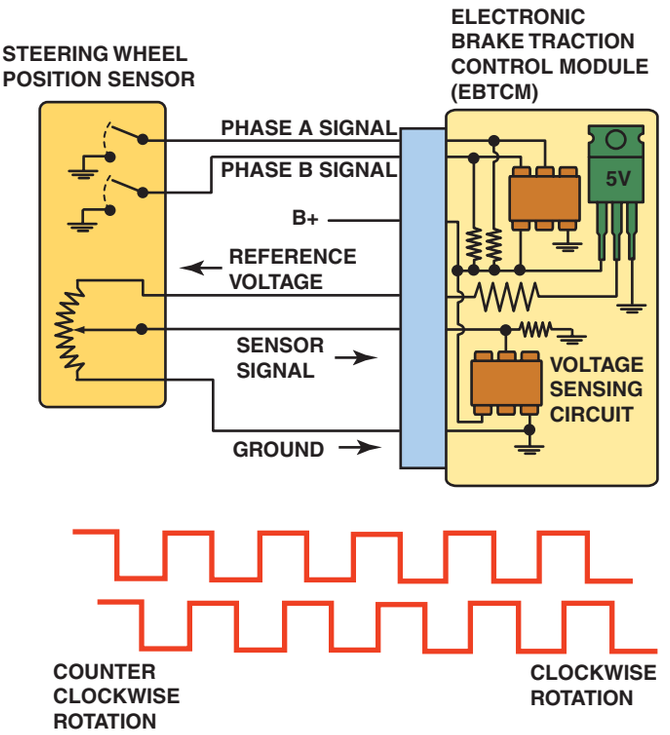

FIGURE 115–8 The steering wheel position (handwheel position) sensor wiring schematic and how the signal varies with the direction that the steering wheel is turned.

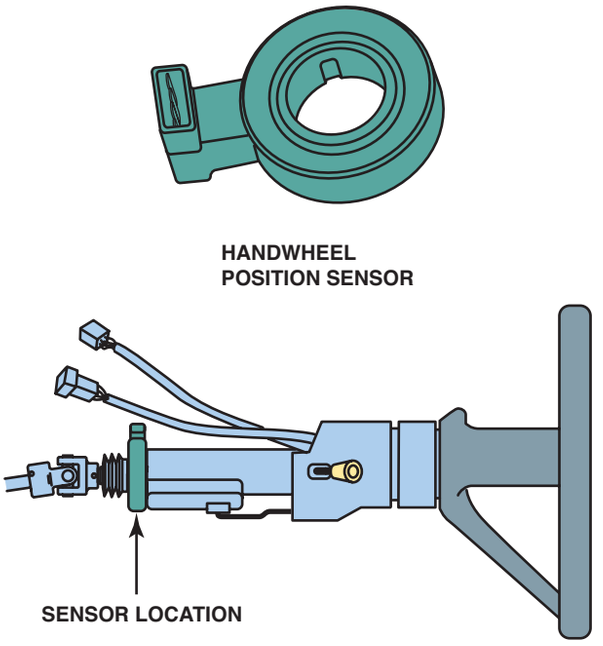

FIGURE 115–9 The handwheel position sensor is located at the base of the steering column.

STEERING WHEEL POSITION SENSOR

Depending on the vehicle, the **steering wheel position sensor** may also be called a **handwheel position sensor.** The function of this sensor is to provide the control module with signals relating to steering wheel position, the speed and direction of handwheel position.

The sensor is found on most **real-time dampening (RTD)** and **road-sensing suspension (RSS)** applications. The sensor is typically located at the base of the steering column. Always refer to service information for vehicle-specific information. ● **SEE FIGURES 115–8 AND 115–9.**

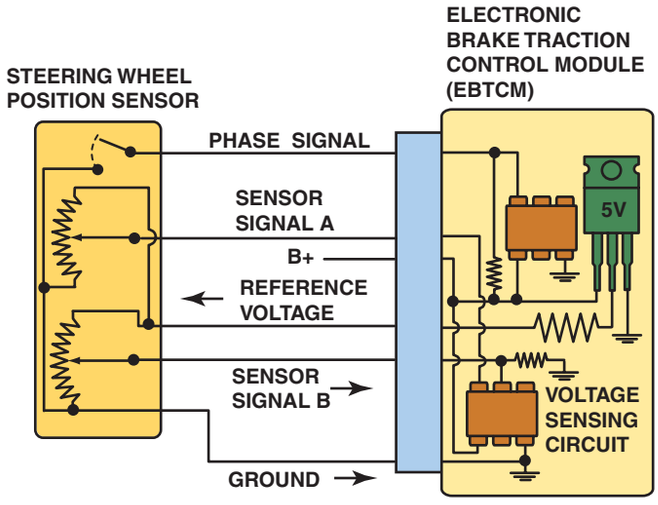

FIGURE 115–10 Steering wheel (handwheel) position sensor schematic.

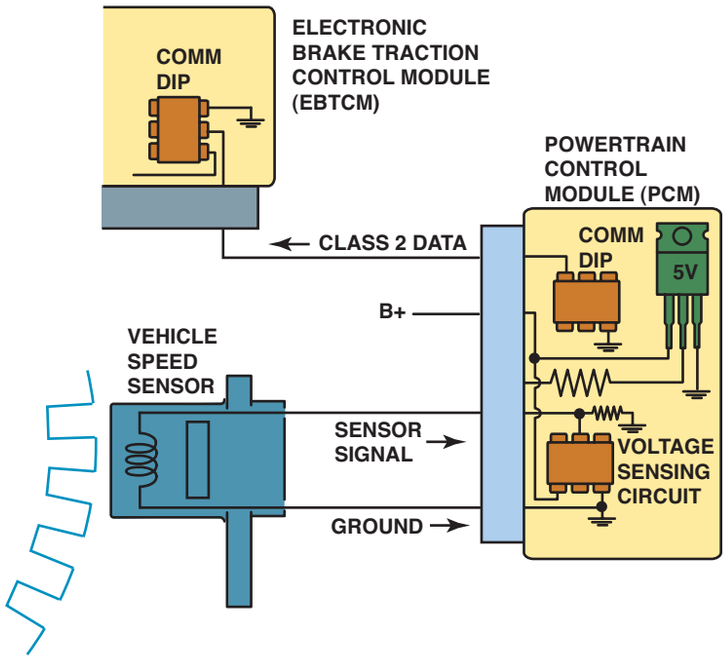

FIGURE 115–11 The VS sensor information is transmitted to the EBCM by Class 2 serial data.

The handwheel sensor produces two digital signals, which are used by the **electronic brake control module (EBCM).** These signals are produced as the steering wheel is rotated. The sensor can also produce more than two signals. As an example, the Cadillac Escalade handwheel sensor produces one analog and three digital signals.

The sensor uses a 5-volt signal reference. Analog signal voltage values increase or decrease, between 0 and 5 volts, as the steering wheel is moved left and right of center. The digital signal is also a standard power-to-ground circuit as shown in the schematic.

There are three possible digital signals:

- Phase A
- Phase B
- Index pulse

These signals provide the suspension control module with steering wheel speed and direction information. Digital signals are either high or low, 5 volts or 0 volts. ● **SEE FIGURE 115–10.**

A scan tool provides diagnostic trouble code (DTC) faults for this sensor. If there is an intermittent concern with a steering wheel position sensor, select the movie mode or snapshot features on a scan tool and slowly turn the steering wheel lock to lock. After the snapshot is complete, plot the analog sensor voltage to see if the signal dropped out. Any dropout is an indication of an intermittent problem.

VEHICLE SPEED SENSOR

The **vehicle speed (VS) sensor** is used by the EBCM to help control the suspension system. The vehicle speed sensor is a magnetic sensor and generates an analog signal whose frequency increases as the speed increases. The ride is made firmer at high speeds and during braking and acceleration and less firm at cruise speeds. ● **SEE FIGURE 115–11.**

PRESSURE SENSOR

A pressure transducer (sensor) is typically mounted on the compressor assembly. This sensor is typically found on suspension systems that use a compressor assembly. The main function of the pressure sensor is to provide feedback to the suspension control module about the operation of the compressor. The sensor assures both that a minimum air pressure is maintained in the system and that a maximum value is not exceeded. A pressure transducer (sensor) is typically mounted on the compressor assembly. This sensor is typically found on systems such as air suspension, real-time damping, and road-sensing suspension that use a compressor assembly. ● **SEE FIGURE 115–12.**

The operation of the pressure sensor requires a 5-volt reference, a ground, and a signal wire to provide feedback to the control module. The voltage output on the signal wire will vary from 0 to 5 volts based upon pressure in the system. A high voltage indicates high pressure and low voltage indicates a low pressure.

LATERAL ACCELEROMETER SENSOR

The function of the **lateral accelerometer sensor** is to provide the suspension control module with feedback regarding vehicle cornering forces. This type of sensor is also called a G-sensor, with the letter "G" representing the force of gravity. For example, when a vehicle enters a turn, the sensor provides information as to how hard the vehicle is cornering. This information is processed by the suspension control module to provide appropriate damping on the inboard and outboard dampers during cornering events. The lateral accelerometer sensor is found on the more complex suspensions systems, that incorporate the **vehicle stability enhancement system (VSES).**

This sensor can be either a stand-alone unit or combined with the yaw rate sensor. Typically, the sensor is mounted in the passenger compartment under a front seat, center console, or package shelf.

The sensor produces a voltage signal of 0 to 5 volts as the vehicle maneuvers left or right through a curve. The signal is an input to the EBCM. If zero lateral acceleration, the sensor input is 2.5 volts. Check service information for specific codes that can be set.

If driving the vehicle and the voltage values increase or decrease during cornering events, this indicates proper operation. ● **SEE FIGURE 115–13.**

YAW RATE SENSOR

The **yaw rate sensor** provides information to the suspension control module and the EBCM. This information is used to determine how far the vehicle has deviated from the driver's intended direction. The yaw sensor is used on vehicles equipped with Electronic Stability Control (ESC).

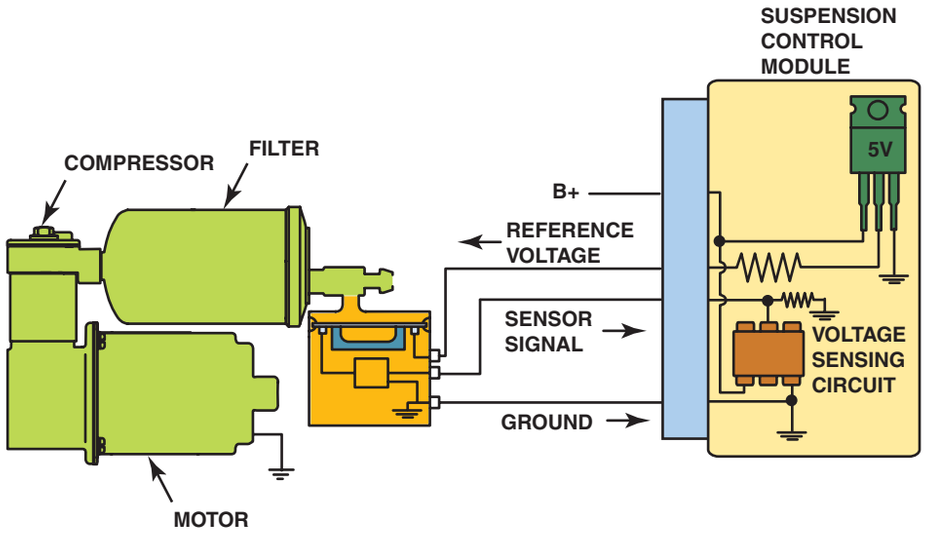

FIGURE 115–12 An air pressure sensor.

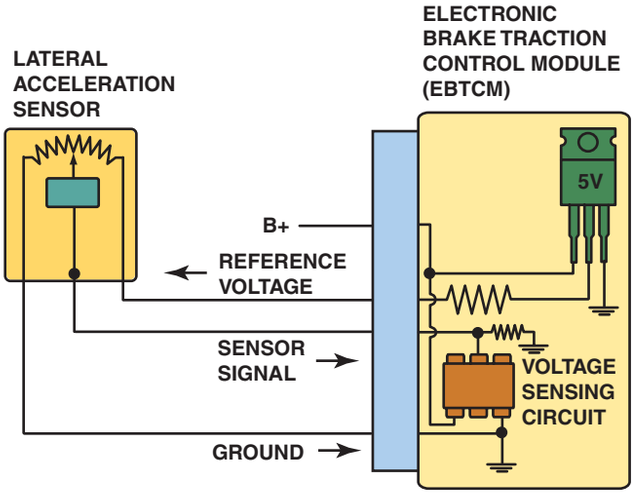

FIGURE 115–13 A schematic showing the lateral acceleration sensor and the EBCM.

FIGURE 115–14 A visual inspection showed a liquid had spilled. This lead to finding the lateral acceleration sensor connector terminals were corrorded.

TECH TIP

A Visual Inspection Is Often the Key to Success.

An ABS amber warning light and a stored U0124 code (lost communications with lateral acceleration sensor) lead to looking at service information for the location of the sensor. It was found to be located under the center console. A visual check of the area showed that a sticky soft drink had likely spilled from the cup holder. ● **SEE FIGURE 115–14.** The liquid had gotten into the electrical connector and caused the fault.

This sensor can be either a stand-alone unit or combined with the lateral accelerometer sensor. Typically, the sensor is mounted in the passenger compartment under the front seat, center console, or on the rear package shelf.

The sensor produces a voltage signal of 0 to 5 volts as the vehicle yaw rate changes. The voltage signal is an input to the EBCM. The yaw rate input to the EBCM indicates the number of degrees that the vehicle deviates from its intended direction.

For example, with a 0-degree yaw rate, the sensor output is 2.5 volts. During an emergency maneuver, the signal will vary above or below 2.5 volts. This sensor does set DTC codes. These codes can be found in service information. ● **SEE FIGURE 115–15.**

DRIVER SELECTOR SWITCH

The **driver selector switch** is a two- or three-mode switch, usually located in the center console, and is an input to the suspension control module.

The switch that is used to select either touring (soft) or performance (firm) ride is found on the **Selectable Ride (SR)** and the **Computer Command Ride (CCR)** systems. The mode select switch status is generally displayed on a scan tool. The three-position switch is used on the Corvette RTD system, and allows the driver to select three modes of operation:

- Tour
- Sport
- Performance

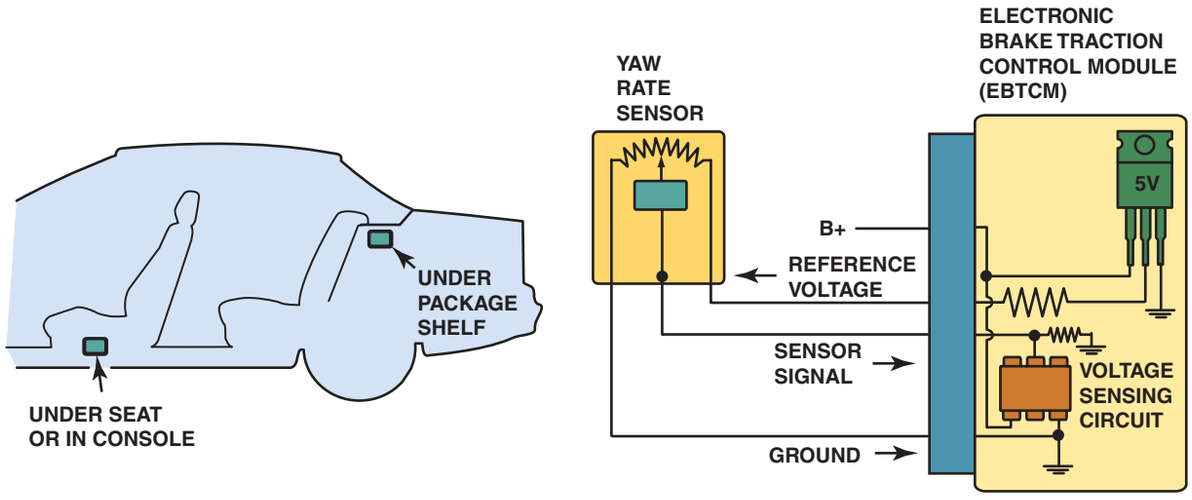

FIGURE 115–15 Yaw rate sensor showing the typical location and schematic.

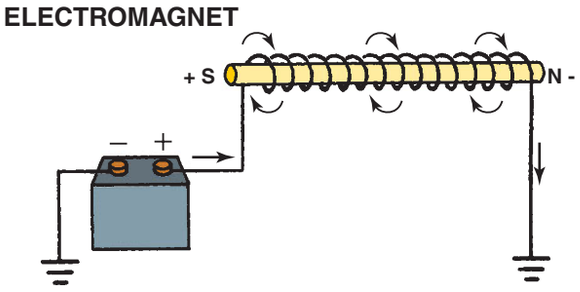

FIGURE 115–16 A magnetic field is created whenever an electrical current flows through a coil of wire wrapped around an iron core.

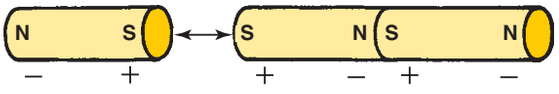

FIGURE 115–17 When magnets are near each other, like poles repel and opposite poles attract.

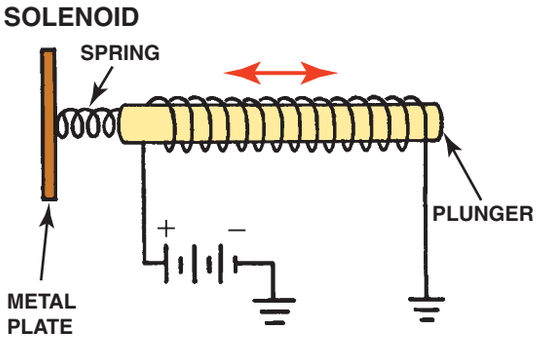

FIGURE 115–18 When electrical current magnetizes the plunger in a solenoid, the magnetic field moves the plunger against spring force. With no current, the spring pushes the plunger back to its original position.

ELECTRONIC SUSPENSION SYSTEM ACTUATORS

PURPOSE AND FUNCTION Each actuator in an electronically controlled suspension system receives output signals from the ECM and responds to these signals, or commands, by performing a mechanical action. Actuators are usually inductive devices that operate using an electromagnetic field. A simple **electromagnet** consists of a soft iron core with a coil of wire, usually copper, wrapped around it. ● **SEE FIGURE 115–16.**

Electrical current traveling through the coiled wire creates a magnetic field around the core. All magnets are polarized; that is, they have a north, or positive, and a south, or negative, pole. When the opposite poles of two magnets are placed near each other—positive-to-negative—the magnets attract each other. Place the same poles together, positive-to-positive or negative-to-negative, and the magnets repel each other. ● **SEE FIGURE 115–17.** Magnets also attract and are attracted to certain types of metals, especially iron and steel.

When an electromagnet has more than one coil, the stronger primary coil can induce voltage into the weaker secondary coil. This inductive transfer occurs even though there is no physical connection between the two coils.

SOLENOIDS In a **solenoid,** the core of the electromagnet also acts as a plunger to open and close a passage or to move a linkage. Solenoids are cylindrically shaped with a metal plate at one end and open at the other end to allow the plunger to move in and out. The electromagnetic coils are placed along the sides of the cylinder. A preload spring forces the plunger toward one end of the device when the solenoid is de-energized, or there is no current in the coil.

When the solenoid is energized, current passes through the coil and magnetizes the core. The magnetized core is attracted to the metal plate and the strength of the magnetic field overcomes spring force to pull the plunger inward. ● **SEE FIGURE 115–18.** When the electrical current switches off, the solenoid de-energizes and spring force returns the plunger to its rest position.

An airflow control valve is an example of a solenoid used in an electronically controlled suspension. ● **SEE FIGURE 115–19.** As the solenoid plunger extends and retracts, it opens and closes air passages between the system air-pressure tank and the air springs. The position of the plunger determines whether the springs receive more pressure or whether pressure bleeds out of them. Increasing the pressure in the air springs lifts the body higher, and decreasing the pressure by bleeding air from the springs lowers the body.

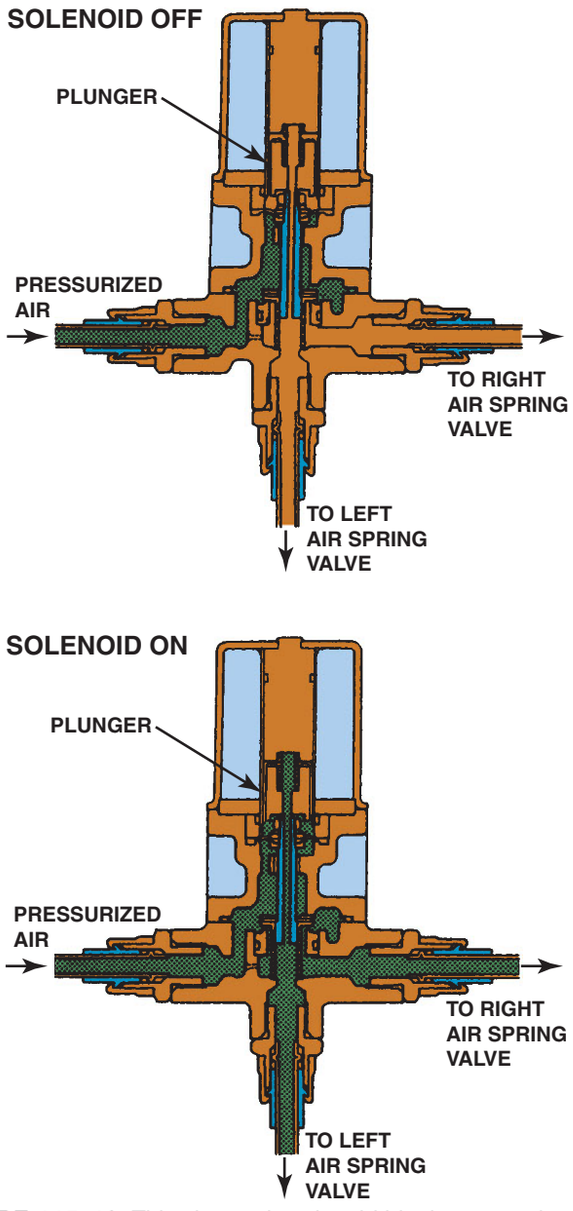

FIGURE 115–19 This air supply solenoid blocks pressurized air from the air spring valves when off. The plunger pulls upward to allow airflow to the air spring valves when the solenoid is energized.

Solenoids are digital devices that are either on or off. However, the ECM can vary the amount a solenoid opens by pulsing the output signal to the coil. If the signal is rapidly switched on and off, spring and magnetic forces do not have enough time to react and effectively move the plunger between the signal changes. The amount of time the current is on compared to the amount of time it is off is called **pulse width,** and the control of a solenoid using this pulsing-on-and-off method is called **pulse-width modulation.**

ACTUATOR MOTORS If a current-carrying conductor is placed in a magnetic field, it tends to move from the stronger field area to the weaker field area. A **motor** uses this principle to convert electrical energy into mechanical movement. Electrical current is directed through the field coils on the motor frame to create a magnetic field within the frame. By applying an electrical current to the **armature,** which is inside the motor frame, the armature rotates from a strong field area to a weaker field area. Armature movement can in turn move another part, such as a gear, pulley, or shaft, attached to it.

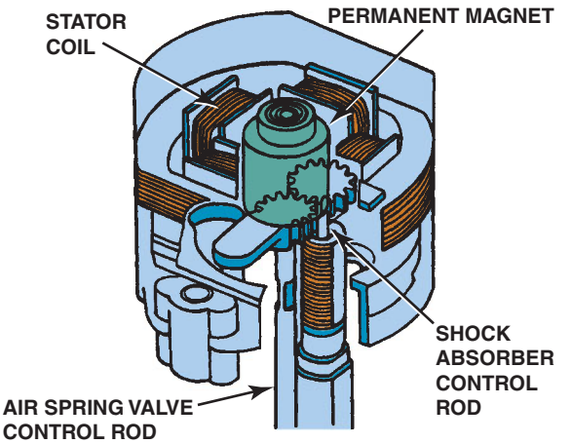

FIGURE 115–20 An actuator motor uses a permanent magnet and four stator coils to drive the air spring control rod.

Located at the top mount of the air spring variable shock assembly of each wheel, the suspension control actuator moves a control rod that regulates air pressure to the spring, which determines ride height. The actuator is an electromagnetic device consisting of four stator coils and a permanent magnet core. ● **SEE FIGURE 115–20.**

The ECM applies current to two stator coils at a time to create opposing magnetic fields around the core, which causes the core to rotate into a new position. Which coils are energized determines how far and in which direction the core rotates. ● **SEE FIGURE 115–21.** By switching current from one pair of coils to the other, the ECM moves the core into a new position, and a third position is available by reversing the polarity of the coils.

A gear at the base of the permanent magnet connects to a rod that operates the air valve to the air spring. The gear also drives another gear, which operates the control rod of the variable shock absorber. Therefore, the three positions of the suspension control actuator motor provide three shock absorber stiffness settings in addition to a variable air spring.

TYPES OF ELECTRONIC SUSPENSION

The types of electronic suspension systems used on General Motors vehicles, as examples, include:

1. Selectable Ride
2. Automatic Level Control
3. Air Suspension
4. Computer Command Ride
5. Real-Time Dampening/Road-Sensing Suspension
6. Vehicle Stability Enhancement System
7. Magneto-Rheological Suspension (F55)

SELECTABLE RIDE (SR) The Selectable Ride (SR) system is the most basic of the electronic systems offered by General Motors. Selectable Ride (SR) allows the driver to choose between two distinct damping levels:

- Firm
- Normal

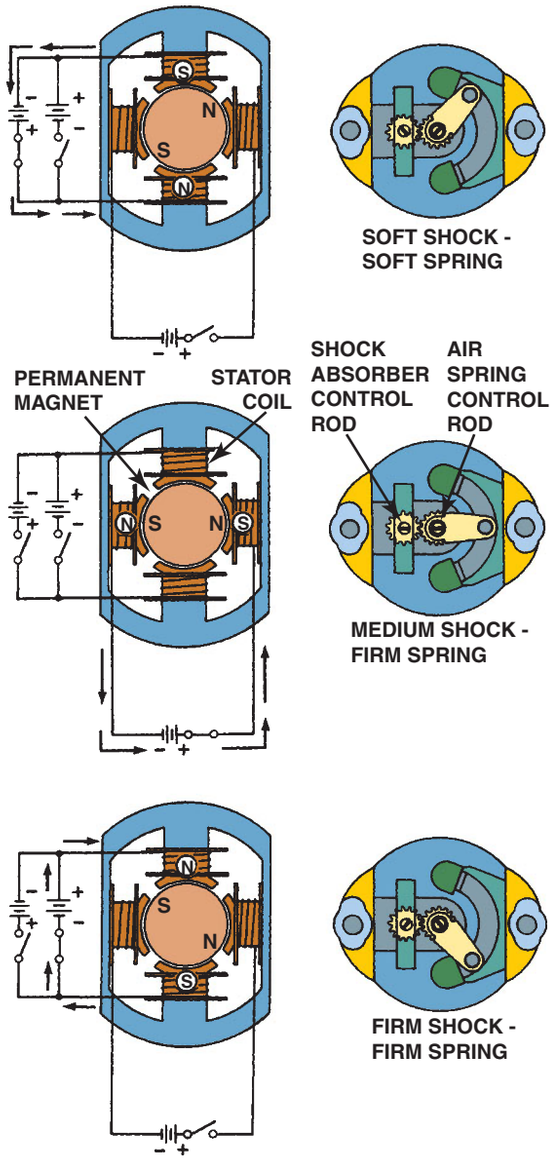

FIGURE 115–21 The stator coils of the actuator are energized in three ways to provide soft, medium, or firm ride from the air springs and shock absorbers.

SR is found on Chevrolet and GMC full-size pickup trucks. ● **SEE FIGURE 115–22.**

A switch is used to control four electronically controlled gas-charged dampers. The **mode select switch** activates the bi-state (two settings) dampers at all four corners of the vehicle, allowing the driver to select vehicle ride characteristics. The system is either energizing or de-energizing the bi-state dampers to provide a firm or normal ride.

AUTOMATIC LEVEL CONTROL

The **Automatic Level Control (ALC)** system automatically adjusts the rear height of the vehicle in response to changes in vehicle loading and unloading. Automatic Level Control is found on many General Motors vehicles. ALC controls rear leveling by monitoring the rear suspension position sensor and energizing the compressor to raise the vehicle or energizing the exhaust valve to lower the vehicle. ALC has several variations across the different platforms. ● **SEE FIGURE 115–23.**

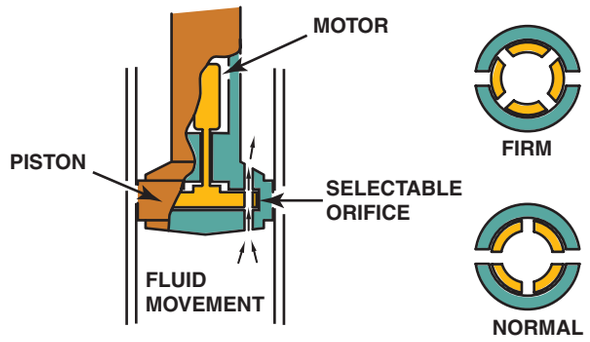

FIGURE 115–22 Selectable Ride as used on Chevrolet and GMC pickup trucks.

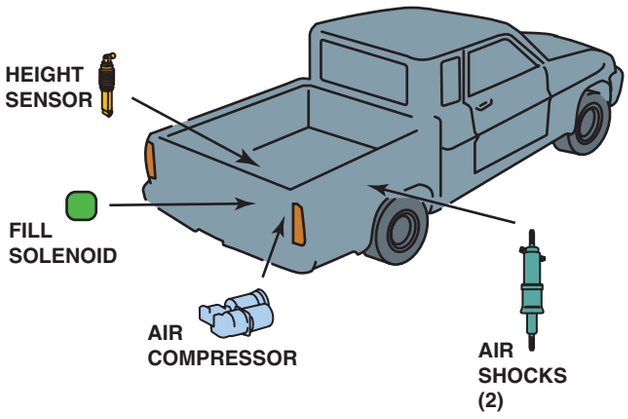

FIGURE 115–23 ALC maintains the same ride height either loaded or unloaded by increasing or decreasing the air pressure in the rear air shocks.

AIR SUSPENSION (AS)

Air Suspension (AS) is a system very similar to the ALC system. The purpose of the AS system includes:

1. Keep the vehicle visually level
2. Provide optimal headlight aiming
3. Maintain optimal ride height

The AS system includes the following components:

- An air suspension compressor assembly
- Rear air springs
- Air suspension sensors

The AS system is designed to maintain rear trim height within 3/16 inch (4 mm) in all loading conditions, and the leveling function will deactivate if the vehicle is overloaded.

The AS system also includes an accessory air inflator found in the rear cargo area. ● **SEE FIGURE 115–24.**

VARIABLE-RATE AIR SPRINGS

In an air spring system with ordinary shock absorbers, the ECM uses the air springs to control trim height and is used on many Ford, Mercury, and Lincoln vehicles.

The three height sensors transmit a signal to the ECM that reflects trim height at each axle. ● **SEE FIGURE 115–25.** The ignition and brake light switches tell the ECM whether the ignition switch is on or off, and if the brake pedal is depressed. The dome light switch indicates whether any doors are open. The on/off switch disables the air spring system to avoid unexpected movement while towing or servicing the vehicle.

CAUTION: Failure to turn off the system will cause the air springs to be vented when the vehicle is hoisted. This will cause the vehicle to drop almost to the ground when the vehicle is lowered. This can cause damage to the air springs and/or to the vehicle. The shut-off switch is usually located in the trunk.

The ECM receives information from the height sensors indicating that the trim height is too high or too low, and it energizes the actuators to add or bleed air from the air springs. The system actuators can still operate for up to an hour after the ignition is switched off.

Any time the ignition is switched to the "run" position, the ECM raises the vehicle, if necessary, within the first 45 seconds. If trim height is too high and the vehicle must be lowered, the ECM delays doing so for 45 seconds after the ignition is switched on.

An air compressor with a regenerative dryer provides the air change required to inflate the air springs on the air suspension system, and a vent solenoid is used to relieve air pressure and deflate the springs. ● **SEE FIGURE 115–26.**

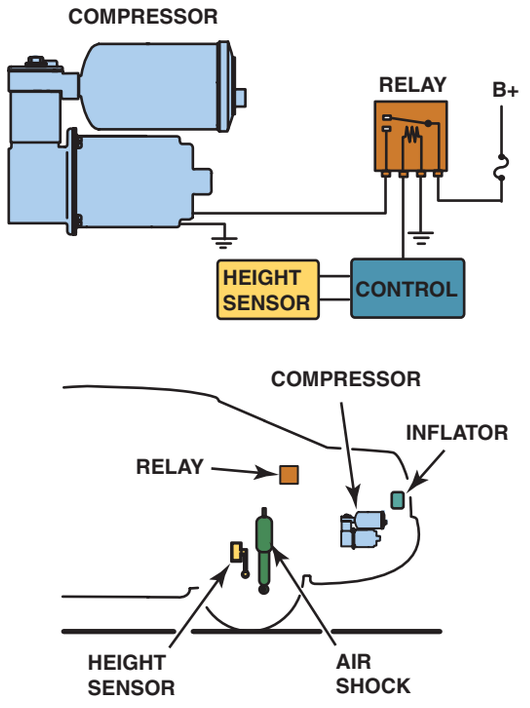

FIGURE 115–24 A typical schematic showing the air suspension compressor assembly and sensor.

By energizing the compressor relay, the ECM directs current to turn on the compressor motor when trim height needs to be raised. The ECM command to lower the vehicle is an electrical signal that opens the vent solenoid to bleed air pressure out of the system. ● **SEE FIGURE 115–27.**

GENERAL MOTORS COMPUTER COMMAND RIDE The General Motors Computer Command Ride (CCR) system controls ride firmness by automatically controlling an actuator in each of the four struts to increase ride firmness as speed increases.

The three damping modes are:

- Comfort
- Normal
- Sport

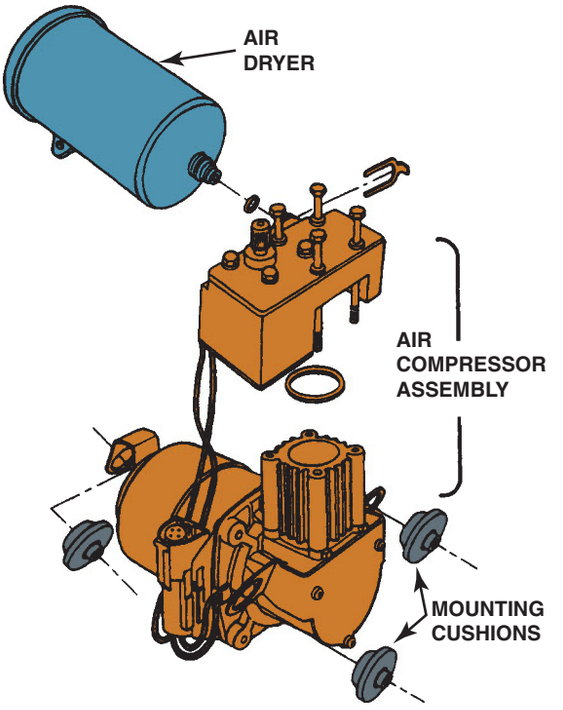

FIGURE 115–26 The air spring compressor assembly is usually mounted on rubber cushions to help isolate it from the body of the vehicle. All of the air entering or leaving the air springs flows through the regenerative air dryer.

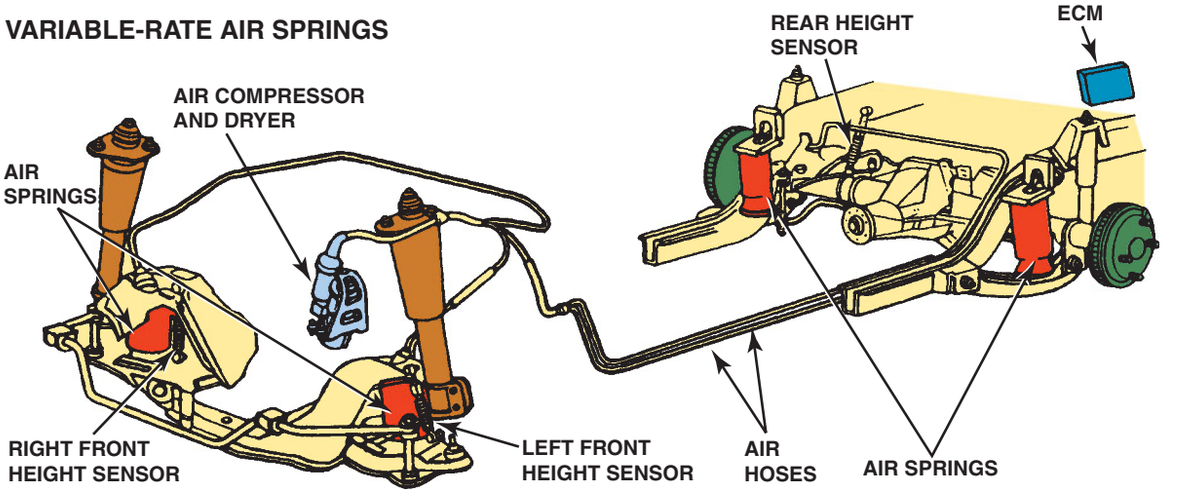

FIGURE 115–25 The typical variable-rate air spring system uses three height sensors, two in the front and one in the rear, to monitor trim height and to provide input signals to the ECM.

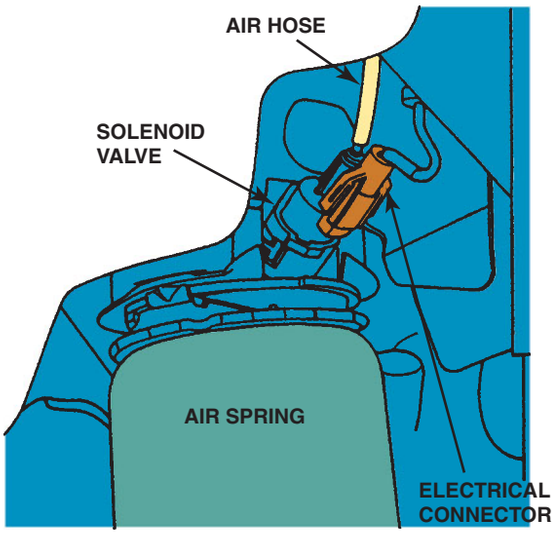

FIGURE 115–27 A solenoid valve at the top of each spring regulates airflow into and out of the air spring.

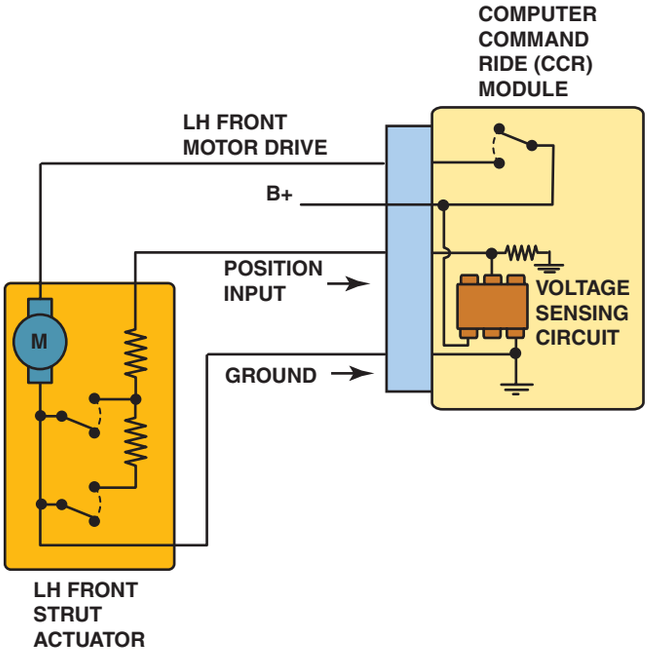

FIGURE 115–28 Schematic showing Computer Command Ride (CCR) system.

Damping mode selection is controlled by the CCR control module according to vehicle speed conditions, driver select switch position, and any error conditions that may exist.

In the **perform ride mode,** the system will place the damping level in the firm mode regardless of vehicle speed.

In the **touring ride mode,** the damping level depends on vehicle speed. ● **SEE FIGURE 115–28.**

REAL-TIME DAMPENING AND ROAD-SENSING SUSPENSION

Real-time dampening (RTD) independently controls a solenoid in each of the four shock absorbers in order to control the vehicle ride characteristics and is capable of making changes within milliseconds (0.001 second).

Road-sensing suspension (RSS), along with ALC, controls damping forces in the front struts and rear shock absorbers in response to various road and driving conditions.

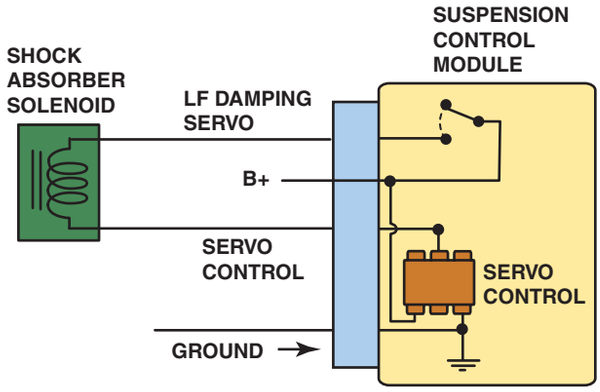

FIGURE 115–29 Schematic showing the shock control used in the RSS system.

TECH TIP

Check the RPO Code

Whenever working on the suspension system check the **RPO (regular production option)** code for the type of suspension used. For example, the F55 RPO may be called by a different name depending on the make and model of vehicle. Also, service procedures will be different on the same vehicle depending on whether it is equipped with an F45 or an F55 system. The General Motors vehicle RPO codes are on a sticker on the spare tire cover in the trunk or in the glove compartment.

RTD and RSS incorporate the following components:

- An electronic suspension control module,
- Front and rear suspension position sensors,
- Bi-state dampers,
- A ride select switch, and
- An air compressor is used on some models.

● **SEE FIGURES 115–29 AND 115–30.**

BI-STATE AND TRI-STATE DAMPERS

The bi-state damper is also known as a **solenoid controlled damper.** Bi-state dampers are found on the RTD, RSS, and SR systems. Each of the suspension dampers used in these systems have an integral solenoid. The solenoid valve provides various amounts of damping by directing hydraulic damping fluid in the suspension shock absorber or strut. ● **SEE FIGURE 115–31.**

The General Motors version of ESC is called the vehicle stability enhancement system (VSES) and includes an additional level of vehicle control to the EBCM. VSES is also known as **Stabilitrak.**

The purpose of the vehicle stability enhancement system along with the antilock brake system (ABS) is to provide vehicle stability enhancement during oversteer or understeer conditions.

The pulse-width modulation (PWM) voltage signal from the suspension control module controls the amount of current flow through each of the damper solenoids. With a low PWM signal de-energized, more hydraulic damping fluid is allowed to bypass the main suspension damper passage, resulting in a softer damping mode.

As the PWM signal increases, or is energized, the damping mode becomes more firm. ● **SEE FIGURE 115–32.**

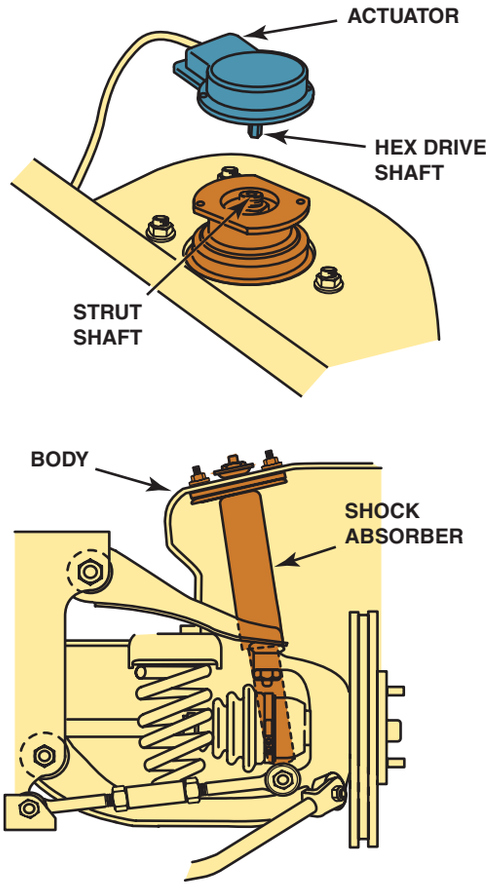

FIGURE 115–30 Bi-state dampers (shocks) use a solenoid to control fluid flow in the unit to control compression and rebound actions.

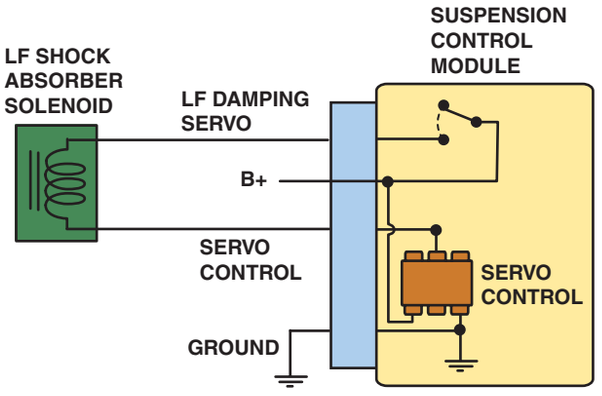

FIGURE 115–31 Solenoid valve controlled shock absorber circuit showing the left front (LF) shock as an example.

NOTE: If the suspension module does not control the shock absorber solenoid, a full soft damping mode results. In some system malfunctions, the module may command one or all of the damper solenoids to a full soft damping.

The main difference between a tri-state damper and a bi-state damper is that the tri-state damper uses an electrical actuator, whereas the bi-state damper is solenoid controlled.

The three damping modes include:

- Comfort
- Normal
- Sport

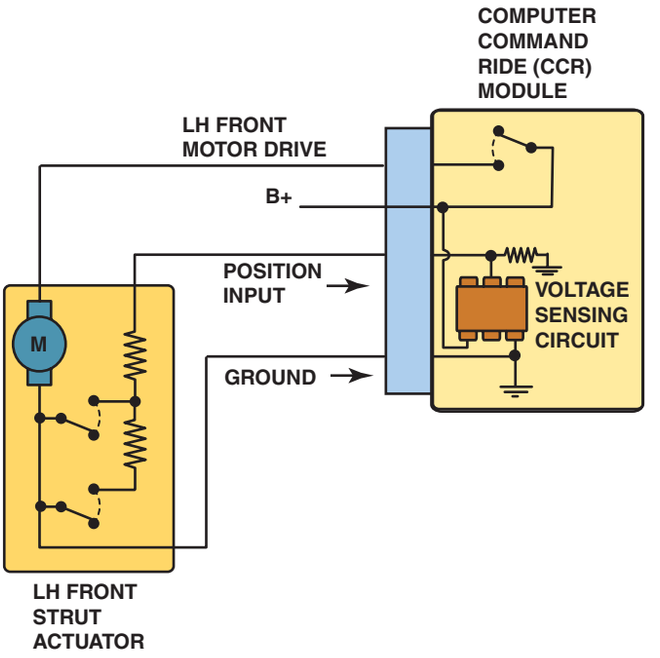

FIGURE 115–32 A typical CCR module schematic.

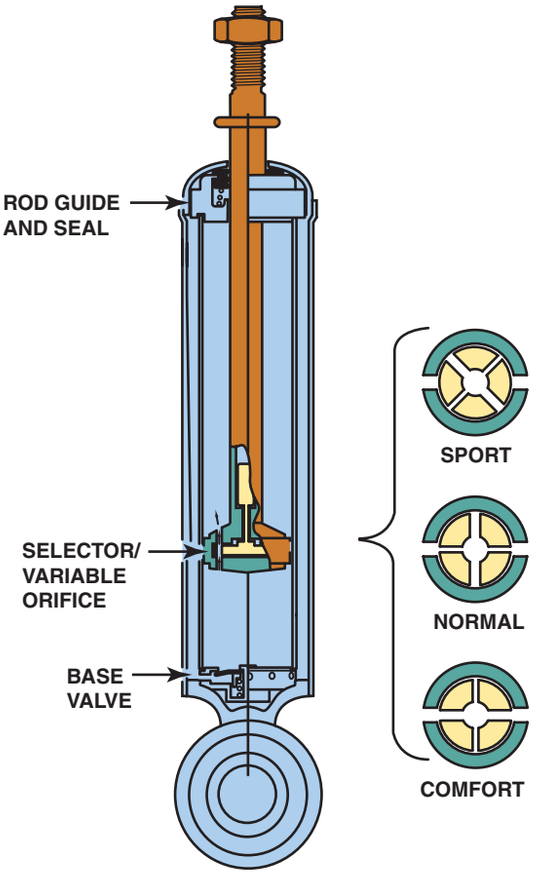

FIGURE 115–33 The three dampening modes of a CCR shock absorber.

A tri-state damper has an integral electrical strut actuator that rotates a selector valve to change the flow of hydraulic damping fluid. ● **SEE FIGURE 115–33.**

The CCR module controls the operation of the strut actuators to provide the three damping modes.

The strut position input provides feedback to the CCR module. The strut position input is compared to the commanded actuator position to monitor system operation. ● **SEE FIGURE 115–34.**

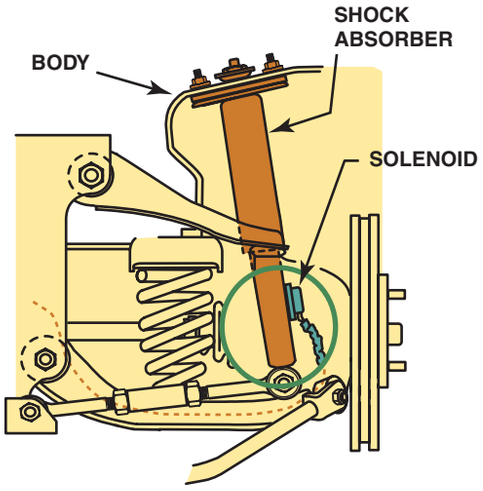

FIGURE 115–34 Integral shock solenoid.

FREQUENTLY ASKED QUESTION

What Are Self-Leveling Shocks?

A German company, ZF Sachs, supplies a self-leveling shock absorber to several vehicle manufacturers, such as Chrysler for use on the rear of minivans, plus BMW, Saab, and Volvo. The self-leveling shocks are entirely self-contained and do not require the use of height sensors or an external air pump. ● **SEE FIGURE 115–35.**

The shock looks like a conventional shock absorber but contains the following components:

- Two reservoirs in the outer tube
- An oil reservoir (low-pressure reservoir)
- A high-pressure chamber

Inside the piston rod is the pump chamber containing an inlet and an outlet valve. When a load is placed in the rear of the vehicle, it compresses the suspension and the shock absorber. When the vehicle starts to move, the internal pump is activated by the movement of the body. Extension of the piston rod causes oil to be drawn through the inlet valve into the pump. When the shock compresses, the oil is forced through the outlet valve into the high-pressure chamber. The pressure in the oil reserve decreases as the pressure in the high-pressure chamber increases. The increasing pressure is applied to the piston rod, which raises the height of the vehicle.

When the vehicle's normal height is reached, no oil is drawn into the chamber. Because the shock is mechanical, the vehicle needs to be moving before the pump starts to work. It requires about 2 miles of driving for the shock to reach the normal ride height. The vehicle also needs to be driven about 2 miles after a load has been removed from the vehicle for it to return to normal ride height.

AUTOMATIC LEVEL CONTROL (ALC)

Vehicles that have an air inflator system as part of the ALC system also have an air inflator switch. The air inflator switch is an input to the ALC and AS system. The inflator switch is used to control the air inflator system operation and provides a signal to the ALC or AS module to initiate compressor activation.

FIGURE 115–35 A typical ZF Sachs self-leveling shock, as used on the rear of a Chrysler minivan.

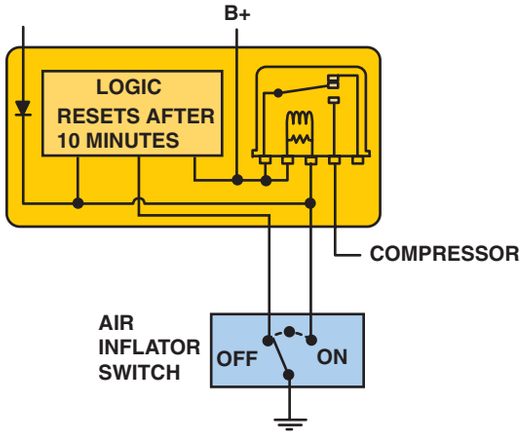

FIGURE 115–36 Schematic of the ALC system.

With the ignition on, the driver can turn the system to ON. The switch will command the compressor to run for up to 10 minutes, allowing time to inflate a tire or other items requiring air.

NOTE: There are no DTCs associated with compressor assembly.

INFLATOR OR COMPRESSOR RELAY The suspension control module energizes the relay to activate the compressor motor. This adjusts the rear trim height as needed. The suspension control module controls the compressor relay for normal operation or for the accessory air inflator.

To avoid compressor overheating, the timer within the suspension control module limits the compressor run time to 10 minutes. ● **SEE FIGURE 115–36.**

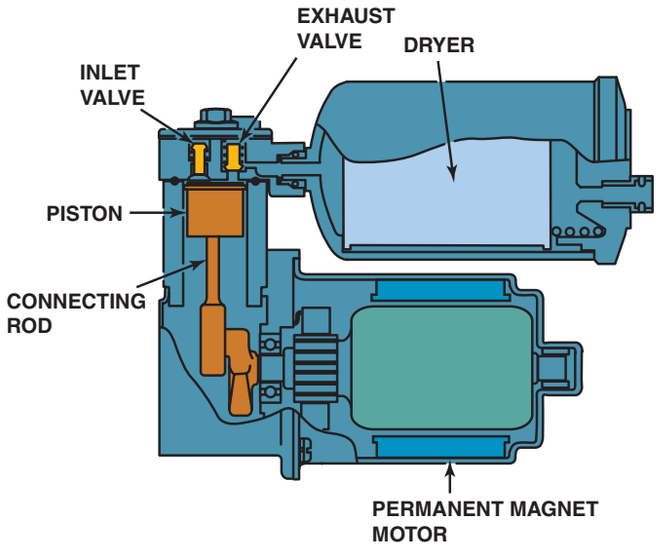

FIGURE 115–37 Air compressor assembly can be located at various locations depending on the vehicle.

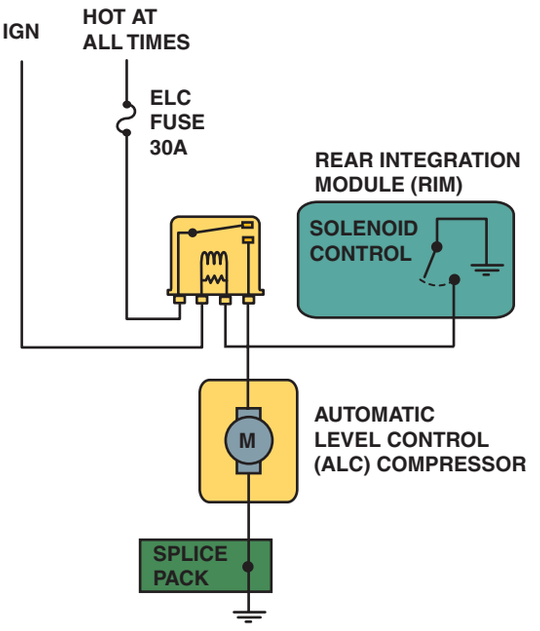

FIGURE 115–39 Schematic showing the rear integration module (RIM) and how it controls the ALC compressor.

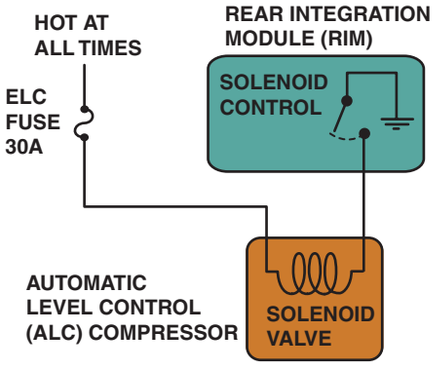

FIGURE 115–38 The exhaust solenoid is controlled by the rear integration module (RIM).

On RTD or RSS systems with a compressor, the scan tool may display DTCs associated with compressor relay operation. On some vehicle applications, the scan tool will display data relating to relay operation and can be used to command the relay to verify proper operation.

COMPRESSOR The compressor is a positive-displacement air pump and can generate up to 150 lbs. of pressure per square inch (PSI). The compressor is found on the ALC, AS, RTD, and RSS systems. A 12-volt permanent magnet motor drives the compressor. The compressor supplies compressed air to the rear air shock absorbers or struts to raise the vehicle. ● **SEE FIGURE 115–37.**

AIR DRYER. Within the compressor is an air dryer. The air dryer is responsible for removing moisture from the compressor system. Improper air dryer operation can cause a premature failure in the system if an air line restriction occurs due to excessive moisture build-up. A dryer on the output side of the compressor contains silica gel **desiccant,** which removes moisture from the discharge air before it travels through the nylon air hoses to the air chamber of the rear shocks.

EXHAUST SOLENOID. The exhaust solenoid, which is located on the compressor, relieves pressure in the system. The ground-side switched exhaust solenoid has three main functions:

1. It releases compressed air from the shock absorbers or air springs to lower the vehicle body.
2. It relieves compressor head pressure. By exhausting air, it protects compressor start-up from high head pressure, which can possibly cause fuse failure.
3. The solenoid acts as a pressure relief valve, which limits overall system pressure.

The special functions on many scan tools can be used to command the solenoid and to verify its operation. ● **SEE FIGURES 115–38 AND 115–39.**

MAGNETO-RHEOLOGICAL (MR) SUSPENSION

MR fluid shocks use a working fluid inside the shock that can change viscosity rapidly depending on electric current sent to an electromagnetic coil in each device. The fluid is called **magneto-rheological (MR)** and is used in monotube-type shock absorbers. This type of shock and suspension system is called the **magneto-rheological real-time damping (MRRTD)** or **chassis continuously variable real-time dampening magneto-rheological suspension (CCVRTMR).**

Under normal operating conditions, the fluid flows easily through orifices in the shock and provides little dampening. When a large or high-frequency bump is detected, a small electrical current is sent from the chassis controller to an electromagnetic coil in each shock and the iron particles in the fluid respond within 3 milliseconds (ms), aligning themselves in fiberlike strands. ● **SEE FIGURES 115–40 AND 115–41.**

FIGURE 115–40 Vehicles that use magneto-rheological shock absorbers have a sensor located near each wheel, as shown on this C6 Corvette.

FIGURE 115–41 The controller for the magneto-rheological suspension system on a C6 Corvette is located behind the right front wheel.

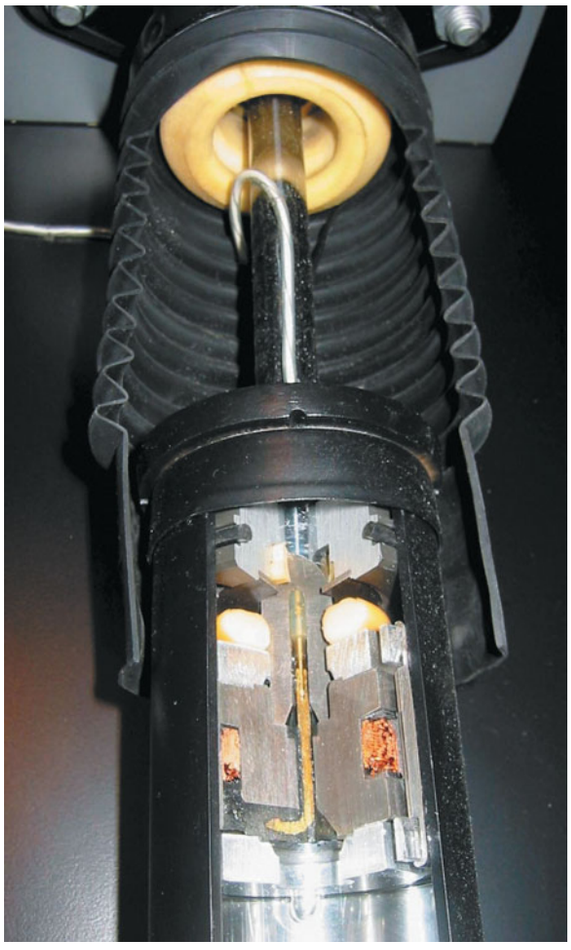

FIGURE 115–42 A cutaway of a magneto-rheological shock absorber as displayed at the Corvette Museum in Bowling Green, Kentucky.

This causes the MR fluid to become thick like peanut butter and increases the firmness of the shock. This type of shock absorber is used to control squat during acceleration and brake dive as well as to reduce body roll during cornering by the chassis controller. ● **SEE FIGURE 115–42.**

? FREQUENTLY ASKED QUESTION

Can Computer-Controlled Shock Absorbers and Struts Be Replaced with Conventional Units?

Maybe. If the vehicle was manufactured with or without electronic or variable shock absorbers, it may be possible to replace the originals with the standard replacement units. The electrical connector must be disconnected, and this may cause the control system to store a diagnostic trouble code (DTC) and/or turn on a suspension fault warning light on the dash. Some service technicians have used a resistor equal in resistance value of the solenoid or motor across the terminals of the wiring connector to keep the controller from setting a DTC. All repairs to a suspension system should be done to restore the vehicle to like-new condition, so care should be exercised if replacing electronic shocks with nonelectronic versions.

TROUBLESHOOTING REAR ELECTRONIC LEVELING SYSTEMS

The first step with any troubleshooting procedure is to check for normal operation. Some leveling systems require that the ignition key be on (run), while other systems operate all the time. Begin troubleshooting by placing approximately 300 lb (135 kg) on the rear of the vehicle. If the compressor does not operate, check to see if the sensor is connected to a rear suspension member and that the electrical connections are not corroded.

Also check the condition of the compressor ground wire. It must be tight and free of rust and corrosion where it attaches to the vehicle body. If the compressor still does not run, check to see if 12 volts are available at the power lead to the compressor. If

necessary, use a fused jumper wire directly from the positive (+) of the battery to the power lead of the compressor. If the compressor does not operate, it must be replaced.

If the ride height compressor runs excessively, check the air compressor, the air lines, and the air shocks (or struts) with soapy water for air leaks. Most air shocks or air struts are not repairable and must be replaced. Most electronic leveling systems provide some adjustments of the rear ride height by adjusting the linkage between the height sensor and the rear suspension. ● **SEE FIGURE 115–43.**

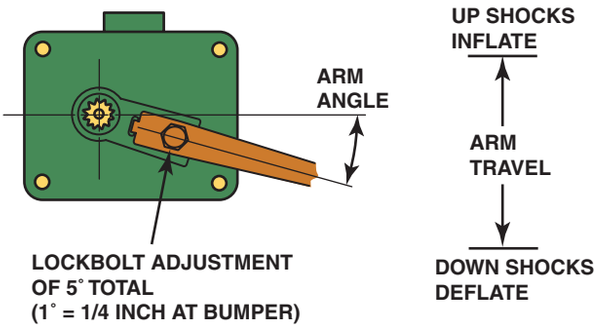

FIGURE 115–43 Most electronic level-control sensors can be adjusted, such as this General Motors unit.

REVIEW QUESTIONS

1. What type of sensor is usually used on electronically controlled suspensions to sense the height of the vehicle?
2. Why is the vehicle speed sensor used as input for many electronic suspension systems?
3. What is a lateral accelerometer sensor and why is it used?
4. Why does the output side of the suspension air compressor contain a desiccant?

CHAPTER QUIZ

1. What type of sensor is used as a height sensor on vehicles equipped with an electronically controlled suspension?
   a. Hall-effect
   b. Photo cell
   c. Potentiometer
   d. All of the above
2. Which sensors do most vehicles use if equipped with electronic suspension?
   a. Height sensors
   b. Steering wheel position sensors
   c. Lateral accelerometer sensors
   d. All of the above
3. A lateral acceleration sensor is used to provide the suspension control module with feedback regarding _____ force.
   a. Cornering
   b. Acceleration
   c. Braking
   d. All of the above
4. A steering wheel position sensor is being discussed. Technician A says that the sensor is used to determine the direction the steering wheel is turned. Technician B says that the sensor detects how fast the steering wheel is turned. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. Technician A says that an electronic control module used in the suspension system is the same as that used for engine control. Technician B says that most electronically controlled suspension systems use a separate electronic control module. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
6. What type of actuator is used on electronically controlled suspensions?
   a. Solenoid
   b. Electric motor
   c. Either a or b
   d. Neither a nor b
7. Why is the typical rear load-leveling system connected to the ignition circuit?
   a. To keep the system active for a given time after the ignition is switched off
   b. To prevent the system from working unless the ignition key is on
   c. To keep the compressor from running for an extended period of time
   d. All of the above
8. Which sensor can be tested by unbolting the sensor and with the ignition on, engine off (KOEO), looking at the scan tool data?
   a. "G" sensor
   b. Wheel speed sensor
   c. Vehicle speed sensor
   d. Suspension sensor
9. The *firm* setting is usually selected by the electronic suspension control module whenever which of the following occurs?
   a. High speed
   b. Rapid braking
   c. Rapid acceleration
   d. All of the above
10. Which of the following is the *least likely* sensor to cause an electronic suspension fault?
    a. Yaw sensor
    b. Throttle position (TP) sensor
    c. Steering wheel position sensor
    d. Vehicle speed sensor

chapter 116

STEERING COLUMNS AND GEARS

OBJECTIVES: After studying Chapter 116, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "A" (Steering System Diagnosis and Repair). • Discuss steering columns and intermediate shafts. • Explain how a recirculating ball-nut and worm gear steering gear system works. • Describe how a rack-and-pinion steering gear works.

KEY TERMS: Collapsible column 1360 • Flexible coupling 1360 • Gear lash 1367 • Inflator module 1358 • Kickback 1369 • Lock plate 1363 • Overcenter adjustment 1367 • Pinion torque 1369 • Pitman arm 1363 • Pitman shaft 1363 • Preload 1366 • Rack and pinion 1367 • Rack support 1369 • Sector gear 1363 • Sector shaft 1363 • Steering shaft 1359 • Stub shaft 1361 • Telescoping steering column 1361 • Tilt steering column 1361 • Universal joint 1359 • Variable ratio 1364 • Worm gear 1363

STEERING WHEELS

The steering wheel, which consists of a rigid rim and a number of spokes connecting the rim to a center hub, attaches to the top of the steering shaft at its center. Most steering wheel hubs have internal splines that fit over external splines on the steering shaft. A bolt or nut at the center of the hub secures the wheel to the shaft. The steering wheel may also contain controls for the cruise control and audio controls, as well as the driver's airbag.

HORN OPERATION The horn circuit is in a series circuit in which electricity has one path that it can follow when the circuit is complete. A normally open switch in an electrical circuit is inside the horn button. When the driver pushes the horn button, the contacts on the switch close, allowing electrical current through the circuit to operate the horn. ● **SEE FIGURE 116–1.** A relay circuit is a more common method of wiring the horn. In a relay, closing a switch in a low-current series circuit triggers the high-current circuit that powers the horn.

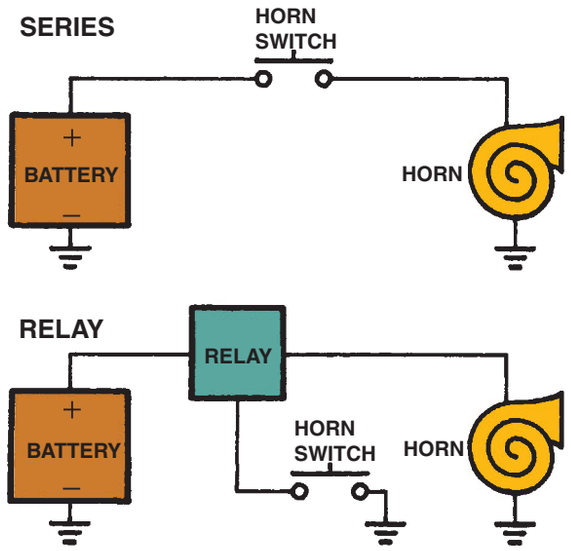

FIGURE 116–1 Most steering columns contain a horn switch. The horn button is a normally open (NO) switch. When the button is depressed, the switch closes, which allows electrical current to flow from the battery to sound the horn. Most horn circuits use a relay to conduct the horn current.

AIRBAGS An airbag is a device made of nylon cloth that is covered with neoprene. The airbag is folded and stored in the front center of the steering wheel. In a front-end collision, the airbag inflates in a fraction of a second to provide a cushion between the driver and the steering wheel and dashboard. ● **SEE FIGURE 116–2.** The part of the steering wheel where the airbag is stored is called the **inflator module.** The module also contains an igniter, a canister of flammable gas, and a number of sodium azide pellets. The sodium azide pellets burn quickly, and rapidly release nitrogen gas while they burn. The nitrogen gas fills the airbag. As it inflates, the airbag tears open the module cover and spreads out across the steering wheel, windshield, and dashboard. The entire process, from sensor reaction to full airbag deployment, takes 30 to 65 milliseconds. Within a second of inflating, the bag deflates partially as the nitrogen gas escapes through exhaust vents in the side of the airbag. Once deployed, an airbag cannot be reused.

The module fits in front of the nut that secures the steering wheel to the steering shaft. Bolts at the back of the steering wheel fasten the airbag module to the steering wheel. Electrical current is provided to the airbag through the spiral cable, which is also known as a clockspring or coil. The spiral cable connects to the airbag module with two wire leads. The spiral cable is a tightly coiled metal strip that allows steering wheel rotation while maintaining electrical continuity. ● **SEE FIGURE 116–3.**

CAUTION: Whenever working on the steering column, consult service information for the recommended airbag disarming procedure.

STEERING COLUMNS

The steering shaft transmits rotary motion from the steering wheel to the steering gear, while the column jacket that encases it attaches to the vehicle body and offers a stationary mounting

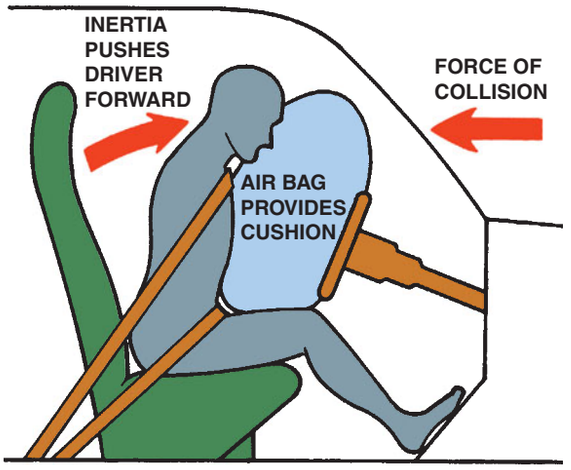

FIGURE 116–2 The airbag inflates at the same time the driver moves toward the steering wheel during a front-end collision and supplements the protection of the safety belt.

point for a number of switches and mechanisms. ● **SEE FIGURE 116–4.**

STEERING SHAFT The **steering shaft** extends from the steering wheel to the steering gear. A bolt or nut secures the shaft to the steering wheel, and a flexible coupling joins it to the steering gear input shaft. The coupling can be a simple rubber or fabric insert, a universal joint (U-joint), or a pot joint. In addition to allowing a directional change of the shaft, a pot joint permits a limited amount of plunging motion. ● **SEE FIGURE 116–5.**

UNIVERSAL JOINT A **universal joint,** or U-joint, consists of two yokes with a steel crosspiece joining them together. ● **SEE FIGURE 116–6.** Universal joints allow changes in the angle between two rotating shafts. In a steering shaft, U-joints allow rotary motion transfer between the steering wheel and the steering gear even though the steering shaft meets the steering gear input shaft at an angle. On

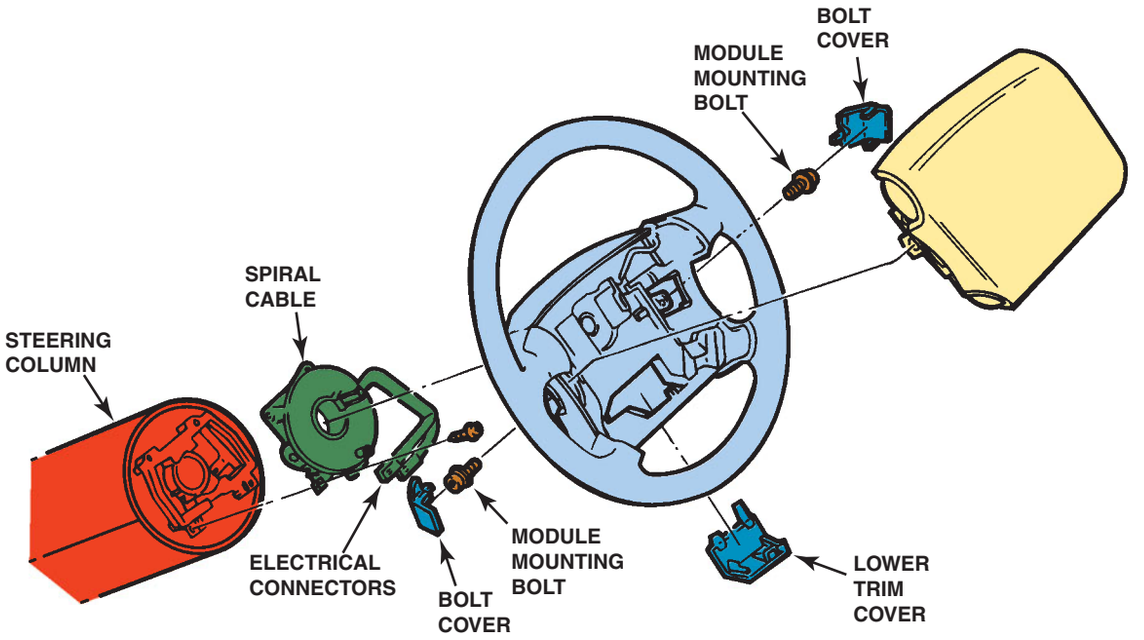

FIGURE 116–3 The airbag module attaches to the steering wheel and is removed as an assembly to service the steering wheel and column.

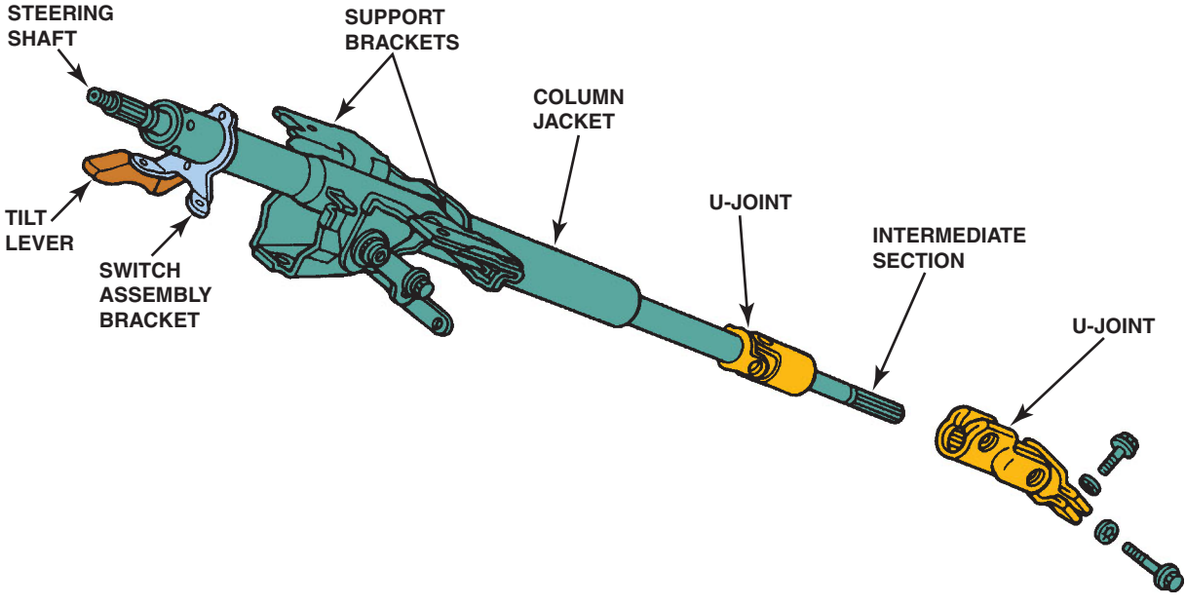

FIGURE 116–4 The steering shaft links the steering wheel to the steering gear while the column jacket, which surrounds part of the shaft, holds support brackets and switches. This steering shaft has a small intermediate section between the main section and the steering gear.

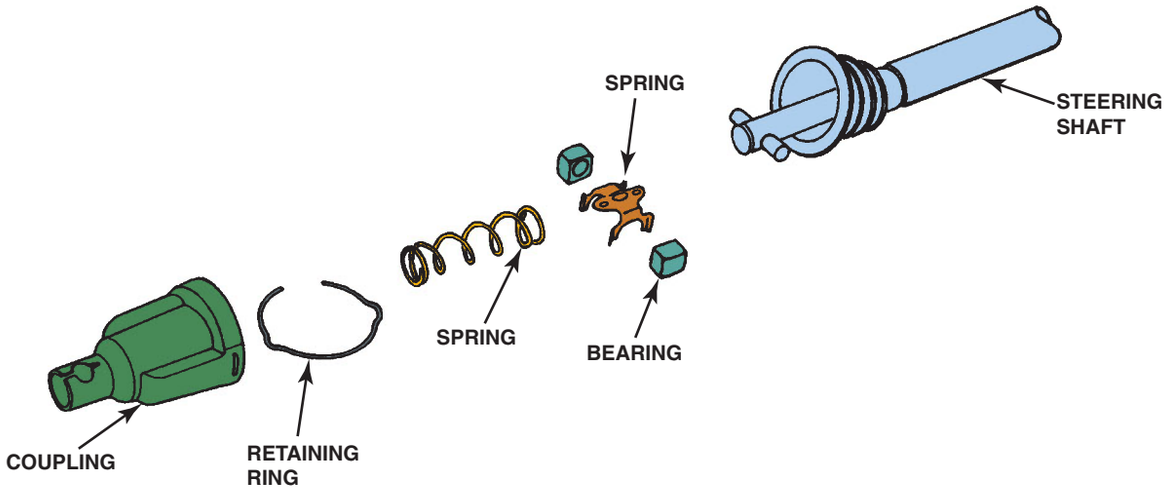

FIGURE 116–5 A pot joint is a flexible coupling used to join two shafts that allow plunging motion.

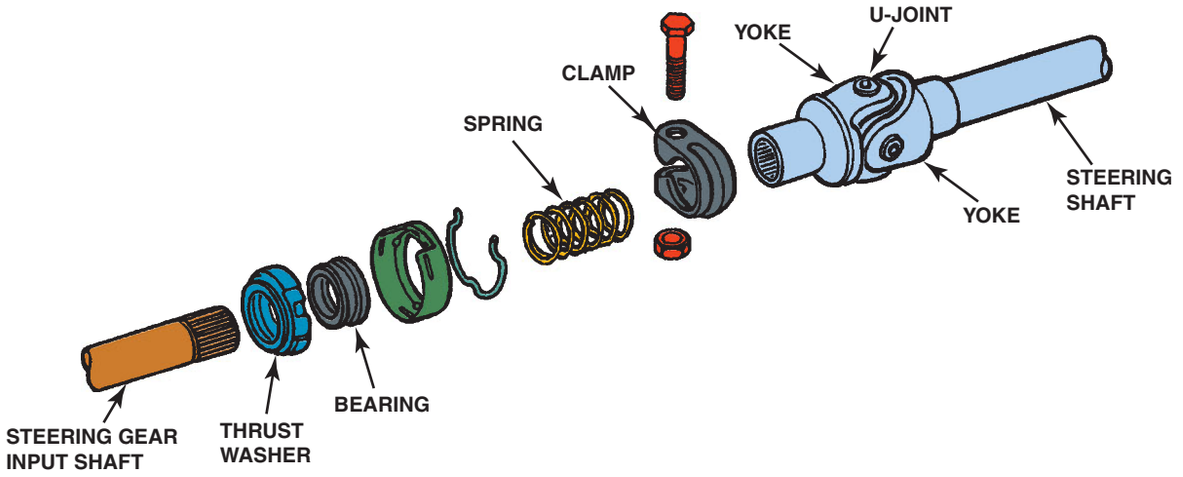

FIGURE 116–6 A typical intermediate steering shaft assembly showing a U-joint and related components.

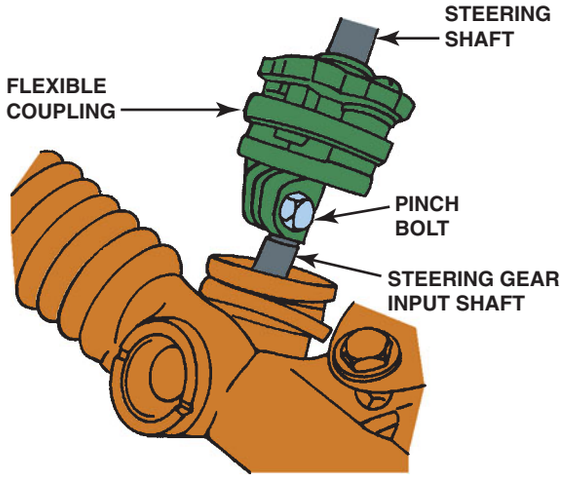

FIGURE 116–7 A flexible coupling is used to isolate road noise and vibration from the steering shaft.

some models the steering shaft itself is assembled in sections that are connected by U-joints. This permits the steering shaft to bend around obstacles between the steering wheel and the steering gear.

FLEXIBLE COUPLING A **flexible coupling** is a simple device made of rubber, or rubber reinforced with fabric, that is placed between two shafts to allow for a change in angle between them. ● **SEE FIGURE 116–7.** The rubber in a steering shaft flexible coupling absorbs vibrations and helps keep the steering wheel from shaking. A fail-safe connection between the steering shaft and the steering gear input shaft keeps the two shafts linked should the rubber coupling wear out or break. This allows the driver to maintain steering control, although the steering feels loose when this happens.

COLUMN COVER To keep the wiring from the jacket-mounted switches out of sight, the part of the steering column that extends into the passenger compartment is shrouded by the column cover. ● **SEE FIGURE 116–8.** The column cover is usually at least two separate pieces, top and bottom. A knee bolster that mounts under the steering column is a safety feature designed to keep the driver from sliding forward during a collision. Knee bolsters are part of the passive restraint system required to meet U.S. federal safety standards on certain vehicles.

COLLAPSIBLE COLUMN Federal law requires that all vehicles sold in the United States have steering columns and shafts that collapse, called **collapsible columns,** during a head-on collision to absorb some of the energy of the crash and lessen the danger of injury to the driver. ● **SEE FIGURE 116–9.** One early method used a section of the steering column constructed out of mesh, which would collapse easily during a crash. Another method is to use a two-piece column. One section of the column has a smaller diameter so that it fits inside the other and rides on a roller bearing. During a

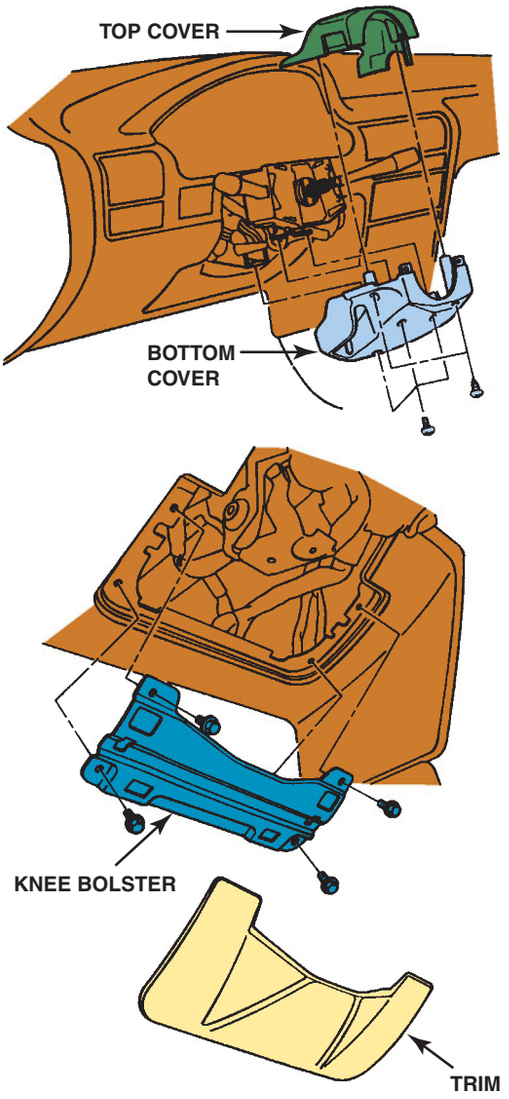

FIGURE 116–8 Steering column covers are often part of the interior trim.

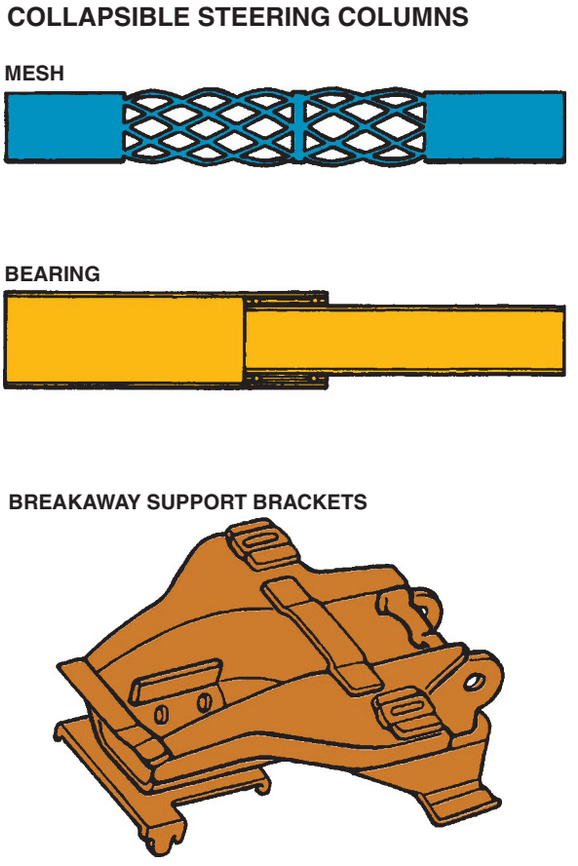

FIGURE 116–9 Collapsible steering columns include a mesh design that crushes easily, a bearing design that allows one section of the column to slide into the other, and a breakaway device that separates the steering column from the body of the vehicle in the event of a front-end collision.

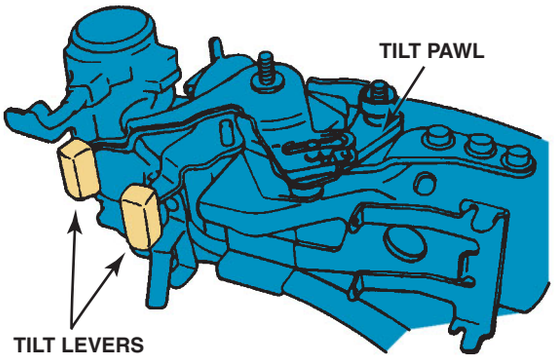
collision, the smaller section slides down into the larger one to collapse like a telescope.

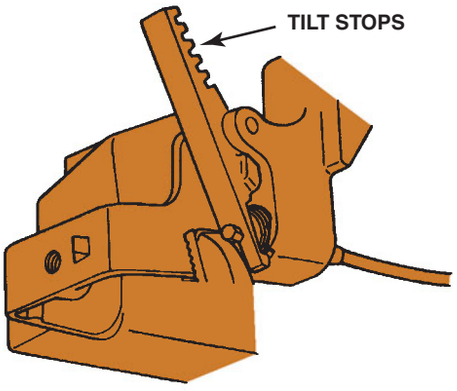
TILT MECHANISMS Many steering columns have tilt mechanisms, which allow the driver to adjust the angle of the steering wheel relative to the steering column. In a typical **tilt steering column,** the steering shaft has a short section at the top joined to the rest of the steering shaft either by a U-joint or gears. Most tilt mechanisms are some sort of ratchet device that enables the driver to lift the steering wheel and the top section of the shaft and place them in the desired position. ● **SEE FIGURE 116–10.** Usually, spring tension locks the steering wheel in place on the ratchet, and a release lever compresses the spring to allow tilt adjustment.

TELESCOPING STEERING COLUMNS Some steering columns are designed to **telescope,** which means that the top of the steering shaft and jacket can be pulled out toward the driver or pushed in toward the dashboard, and then locked into the new position.

STEERING COLUMN CONSTRUCTION The steering shaft is at the center of the steering column. ● **SEE FIGURES 116–11 AND 116–12.** The top end of the steering shaft splines to the center of the steering wheel, and a large nut fastens the steering wheel to the shaft. The lock housing, which contains the ignition lock cylinder, encases the top part of the steering shaft. The steering column jacket covers the shaft under the ignition lock housing, and the gear selector lever housing fits over a portion of the column jacket.



A U-joint connects the lower end of the steering shaft to a small intermediate shaft, often called a **stub shaft.** Because this steering column includes a gear selector lever, the lower end of the column also incorporates an attachment point that connects the shift tube to the gear shift rod. The intermediate shaft extends through a hole in the floor where it is coupled to the steering gear input shaft by a U-joint.



A toe plate bolts to the floor of the passenger compartment to cover the shaft opening and to protect the interior from noise, drafts,

TECH TIP

Do Not Pound on the Steering Column

Always use a steering wheel puller and/or the special tools recommended by the vehicle manufacturer when servicing the steering column. If a hammer is used on the steering shaft in an attempt to remove a steering wheel, the shaft could collapse, requiring the replacement of the entire steering column assembly.

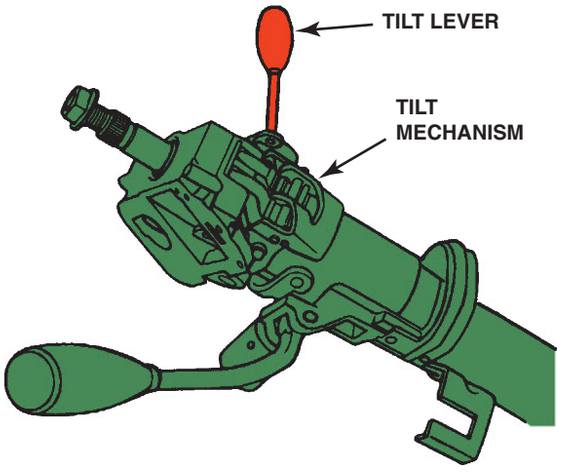


FIGURE 116–10 Tilt mechanisms vary by design and vehicle manufacturer, although most use a ratchet to position the top portion of the steering column.

and dirt. ● **SEE FIGURE 116–13.** The toe plate has a tube for the intermediate shaft, and a seal and silencer fit on top of the tube.

Two sections at the upper end of the steering column house the column-mounted controls. ● **SEE FIGURE 116–14.** The lock housing, seated on top of the column jacket, is the topmost piece and contains the turn signal lever, hazard light control, and ignition lock. The gear selector lever and its housing are just below the lock housing, and the housing encases the top of the steering column jacket.

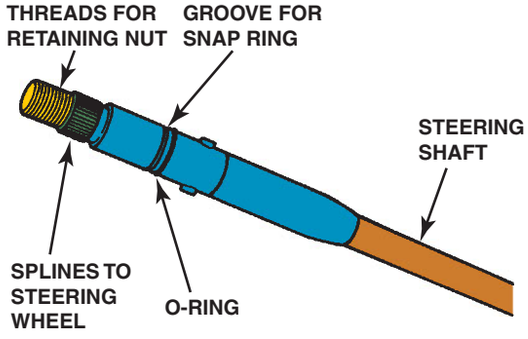

FIGURE 116–12 The steering shaft splines onto the steering wheel.

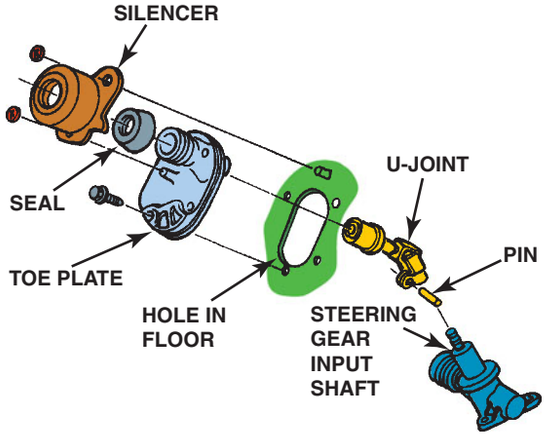

FIGURE 116–13 The toe plate seals the hole from the steering shaft and helps seal out noise and moisture.

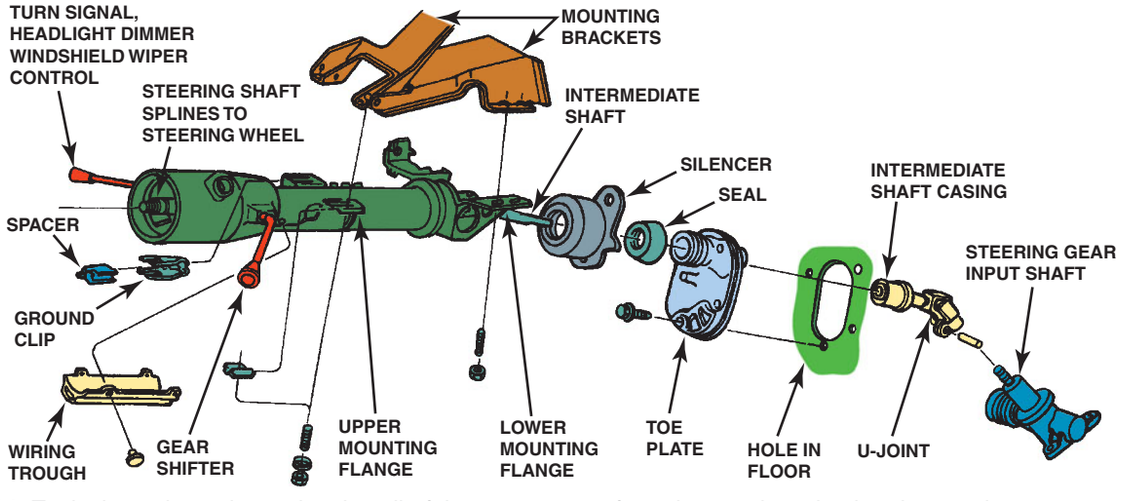

FIGURE 116–11 Typical steering column showing all of the components from the steering wheel to the steering gear.

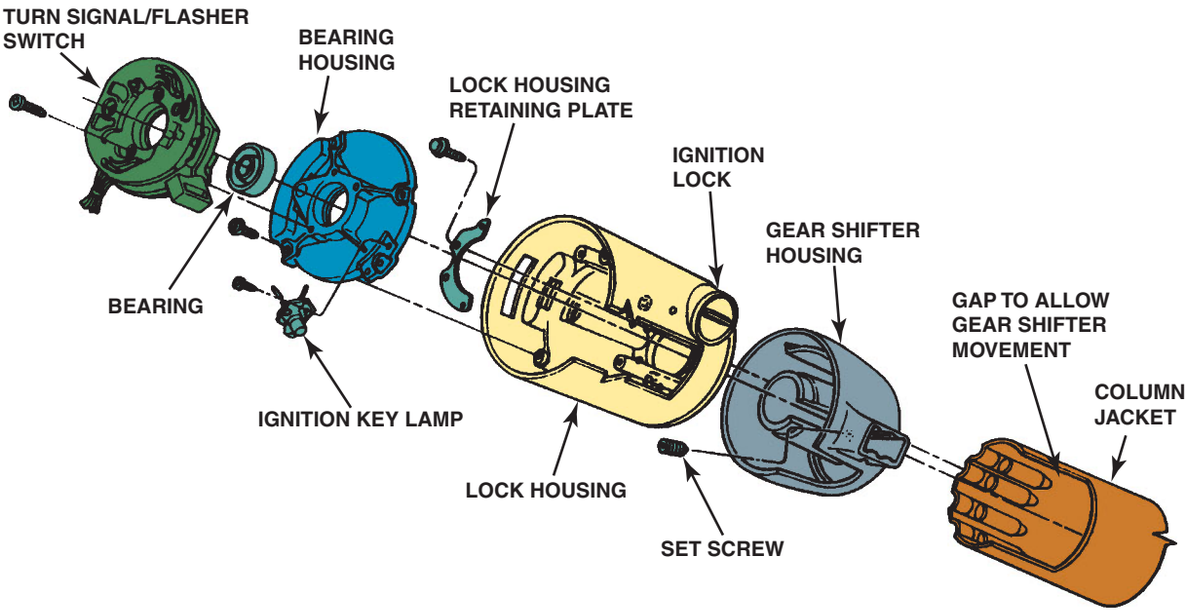

FIGURE 116–14 The upper section of the steering column includes the lock housing and switches.

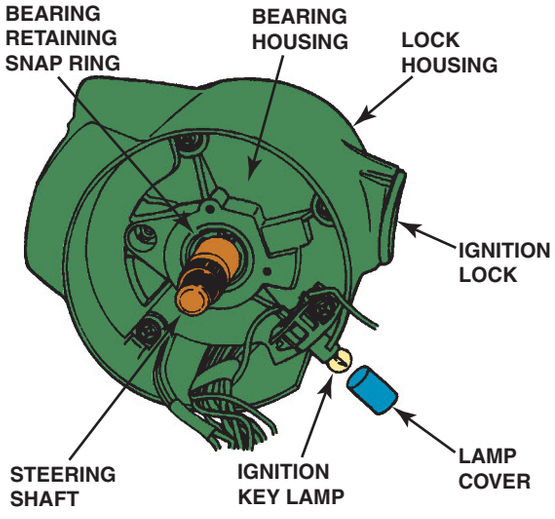

FIGURE 116–15 The upper section of the steering column contains the steering shaft bearing.

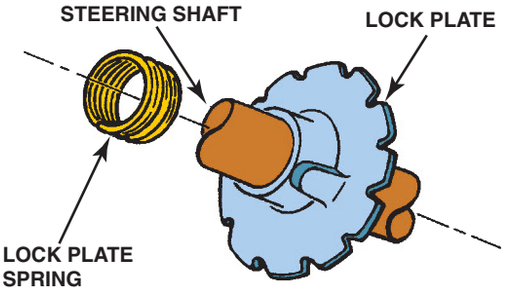

FIGURE 116–16 The lock plate engages an ignition lock pawl to keep the steering wheel in one position when the ignition is off.

The lock housing contains the ignition lock cylinder, several electrical switches, and a steering shaft bearing. Some of the switches have driver-operated controls on the outside of the lock housing.

A multifunction switch operates the turn signals, the windshield wiper and washer switch, and the dimmer switch.

Most steering shafts ride on at least two bearings, one near the top and one near the bottom of the shaft, to allow the shaft to rotate freely without affecting other parts of the steering column. ● **SEE FIGURE 116–15.** A snap ring at the center of the bearing housing rests in a groove on the steering shaft to secure the bearing, and an O-ring on the steering shaft keeps lubricant in the bearing.

Underneath the bearing and housing is a **lock plate** and coil spring that lock the steering shaft into position when the driver removes the ignition key. ● **SEE FIGURE 116–16.** The ignition lock cylinder, which is under the lock plate, moves a bellcrank that in turn operates a spring and lever assembly linked to the ignition switch actuating rod.

CONVENTIONAL STEERING GEARS

PURPOSE AND FUNCTION A conventional steering gear uses steering gear assembly that moves linkages and support arms to steer the vehicle.

All steering gears have an input gear, which transmits rotary movement from the steering wheel into the steering gear, and an output gear, which causes the steering linkage to move laterally. The rotation of the steering wheel is transferred to the front wheels through a steering gear and linkage. The intermediate shaft is splined to a **worm gear** inside a conventional steering gear. Around the worm gear is a nut with gear teeth that meshes with the teeth on a section of a gear called a **sector gear.** The sector gear is part of a **pitman shaft,** also known as a **sector shaft,** as shown in ● **FIGURE 116–17.**

Ball, roller, or needle bearings support the sector shaft and the worm gear shaft, depending on the make and model of the gear assembly.

As the steering wheel is turned, the movement is transmitted through the steering gear to an arm attached to the bottom end of the pitman shaft. This arm is called the **pitman arm.** Whenever the steering wheel is turned, the pitman arm moves.

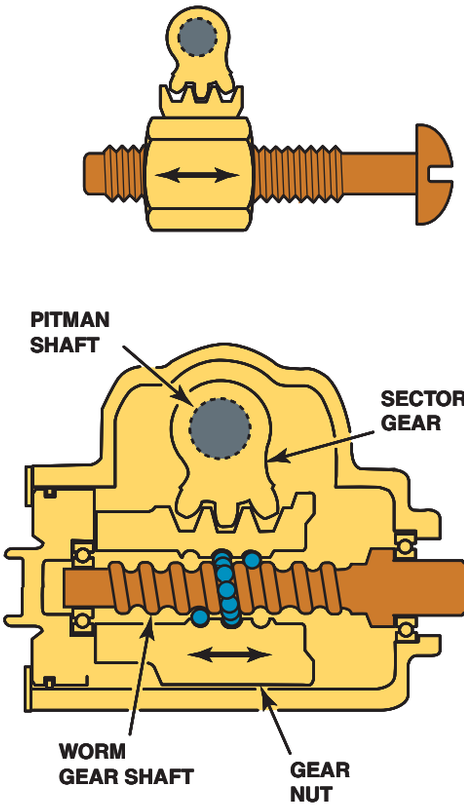

FIGURE 116–17 As the steering wheel is turned, the nut moves up or down on the threads, shown using a bolt to represent the worm gear and the nut representing the gear nut that meshes with the teeth of the sector gear.

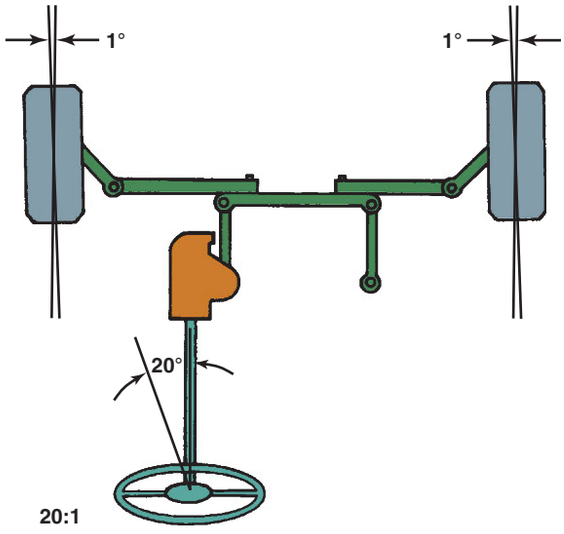

FIGURE 116–18 Steering gear ratio is the ratio between the number of degrees the steering wheel is rotated to the number of degrees the front wheel turns.

STEERING GEAR RATIO When the steering wheel is turned, the front wheels turn on their steering axis. If the steering wheel is rotated 20 degrees and results in the front wheels rotating 1 degree, then the steering gear ratio is 20:1 (read as "20 to 1"). ● **SEE FIGURE 116–18.** The front wheels usually are able to rotate through 60 to 80 degrees of rotation. The steering wheel, therefore, has to rotate 20 times the number of degrees that the wheels move.

FIGURE 116–19 Constant-ratio steering gear sector shaft. Notice that all three gear teeth are the same size.

20 × 60 degrees = 1,200 degrees, or about three full revolutions (360 degrees = 1 full turn) of the steering wheel

20 × 80 degrees = 1,600 degrees, or over four revolutions of the steering wheel

A vehicle that turns three complete revolutions from full left to full right is said to have three turns "lock to lock."

A high ratio, such as 22 to 1 (22:1), means that the steering wheel must be rotated 22 degrees to move the front wheels 1 degree. This high ratio means that the steering wheel is easier to turn than a steering wheel with a lower ratio such as 14:1. The 14:1 ratio is considered to be "faster" than the 22:1 ratio. This fast ratio allows the front wheels to be turned with less movement of the steering wheel, yet more force may be required to turn the wheel. This is considered by some to be more "sporty."

Most steering gears and some rack-and-pinion steering gears feature a **variable ratio.** This feature causes the steering ratio to decrease as the steering wheel is turned from the on-center position. The high on-center ratio (such as 16:1) provides good steering feel at highway speeds while the reduced off-center ratio (13:1) provides fewer steering wheel turns during turning and parking. The ratio is accomplished by changing the length of the gear teeth on the sector gear. ● **SEE FIGURE 116–19** for an example of the teeth of a constant-ratio sector gear.

● **SEE FIGURE 116–20** for an example of the teeth on a variable-ratio sector gear.

The sector gear meshes with the ball nut inside the steering gear, as shown in ● **FIGURE 116–21.**

RECIRCULATING BALL STEERING GEAR

PARTS AND OPERATION A recirculating ball steering gear is the most commonly used conventional steering gear. ● **SEE FIGURE 116–22.**

The end of the steering gear input shaft, or worm shaft, splines to the steering shaft U-joint and provides rotary input to the steering gear. An oil seal prevents fluid leakage where the input shaft enters

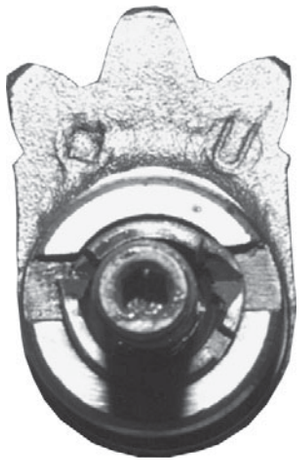

FIGURE 116–20 Variable-ratio steering gear sector shaft. Notice the larger center gear tooth.

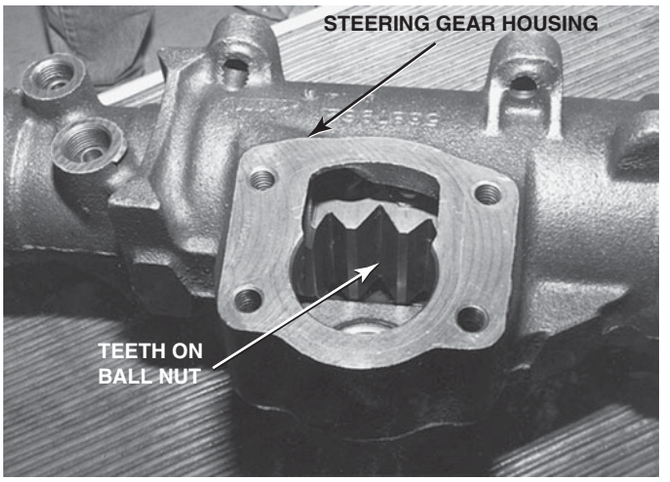

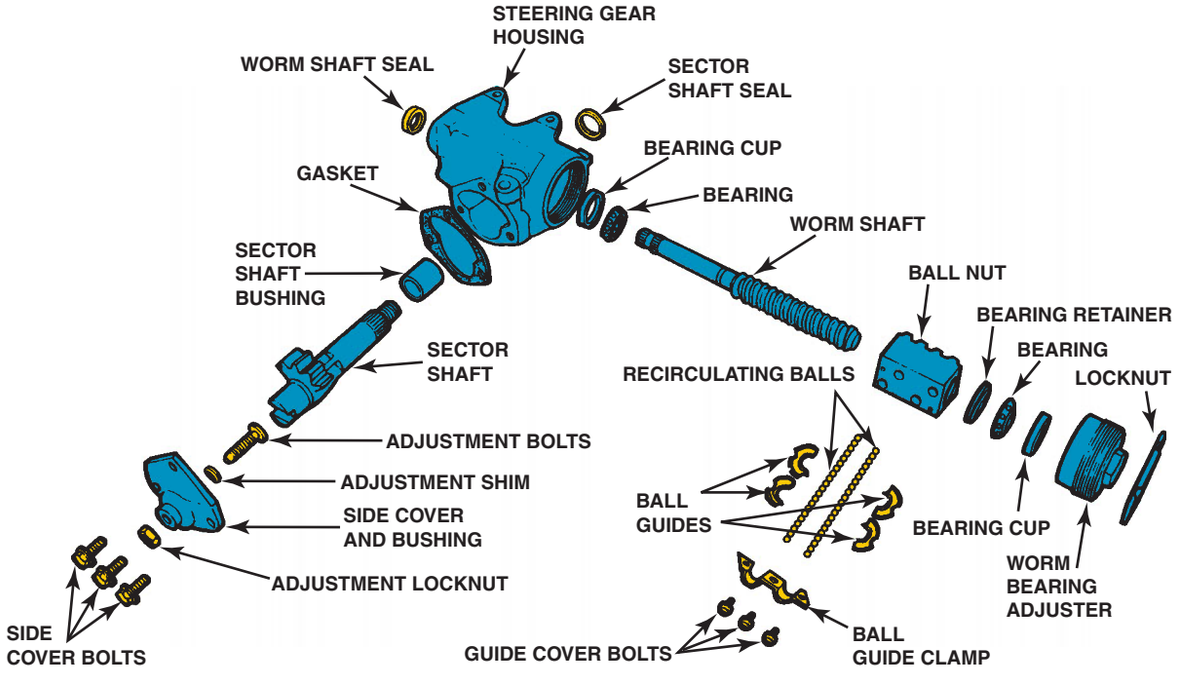

FIGURE 116–21 The sector gear meshes with the gear teeth on the ball nut.

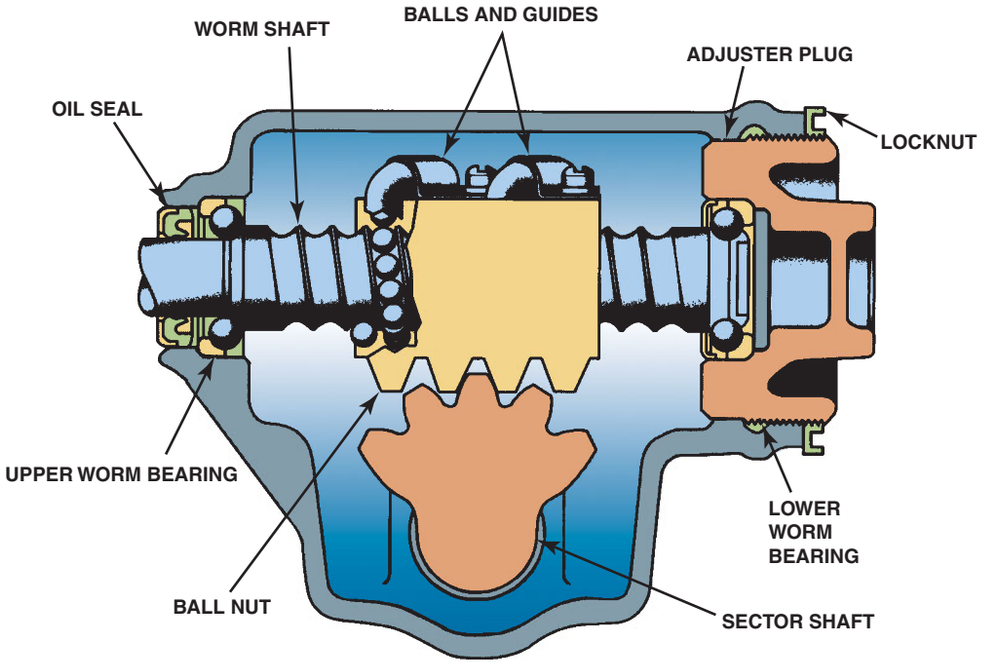

FIGURE 116–22 A typical manual recirculating ball steering gear.

the steering gear housing. At the top and the bottom of the worm gear are the upper and lower thrust bearings. The upper bearing cup seats in the housing, and the lower bearing cup seats in the adjuster plug. The thrust bearings reduce friction between the worm gear and the steering gear housing and control worm endplay.

The adjuster plug at the lower end of the worm gear holds the worm gear, shaft, and bearings inside the steering gear housing.

BALL NUT ASSEMBLY The ball nut, which has internal grooves that match the worm gear thread, fits over the worm gear. Steel balls roll through the tunnels formed by the ball nut grooves and the worm gear thread. Crescent-shaped ball-return guides link the ends of the ball-nut tunnels together, so the balls continuously circulate through the ball nut and worm gear, into the ball-return guides, and back again. These recirculating balls reduce friction and make the steering easier to rotate by the driver. A clamp secured by screws holds the return guides in place on one side of the ball nut. Gear teeth mesh with the teeth of the sector gear machined into the outside of the ball nut on the side opposite the ball-return guides.

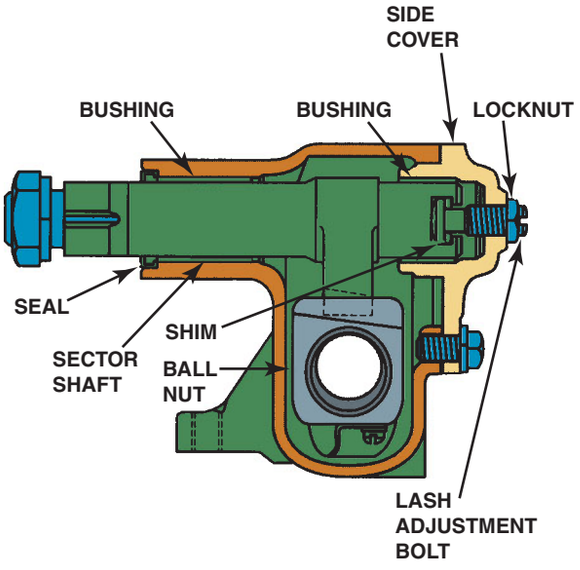

FIGURE 116–23 The sector shaft is supported by bushings, one in the housing and one in the side cover.

SECTOR GEAR The sector gear is an integral part of the sector shaft, which runs through the center of the sector gear, and forms the axis of the gear. One end of the sector shaft extends out of the steering gear housing and splines to the pitman arm. An oil seal prevents lubricant leakage where the sector shaft goes through the opening in the housing. To reduce friction, the sector shaft rides on two bushings. One bushing fits inside the housing and the other is part of the housing side cover. ● **SEE FIGURE 116–23.**

STEERING GEAR ADJUSTMENTS

For the steering gear to operate efficiently, the internal parts must be positioned correctly in relation to the housing and each other. As parts wear, clearances inside the housing and between parts increase, causing looseness and excessive play. The acceptable clearance between any two mechanical parts is called their tolerance. Insufficient tolerance causes binding between parts, increasing steering effort. Excessive tolerance causes delayed reaction to steering input and too much steering wheel freeplay.

Worm bearing preload, also referred to as worm endplay, is a measurement of how much force is required to turn the steering gear input shaft against the force, or **preload,** that the thrust bearings apply to the worm gear and shaft. Worm endplay, which is the distance the worm gear can move end-to-end between the thrust bearings, is directly related to preload. The higher the force the bearings push against the worm gear, the less endplay there is, and the more force it takes to turn the input shaft and worm gear. Worm bearing preload is adjusted by one of two methods: turning an adjustment nut or screw or installing selectively sized shims. Either adjustment method increases or decreases the worm endplay.

Worm endplay is a linear measurement, made in fractions of inches or millimeters, of how far the worm gear and shaft can slide axially. ● **SEE FIGURE 116–24.** Worm bearing preload is a measurement of how much force it takes to overcome bearing pressure in order to turn the input shaft. Preload is a torque, or turning force, measurement made in inch-pounds or Newton-meters. Because endplay and

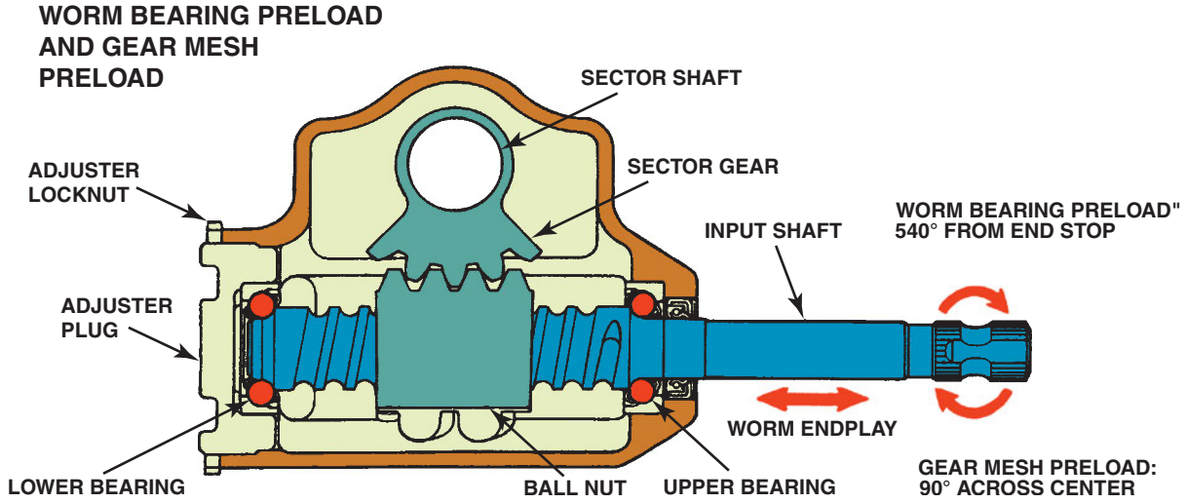

FIGURE 116–24 Worm bearing preload is a turning force measured in in.-lb or N-M, and worm endplay is axial movement measured in fractions of an inch or millimeters.

preload are related, one measurement affects the other. When measuring and adjusting the worm bearing preload, a technician measures preload and adjusts endplay. The endplay is correct when the preload measurement is correct. ● **SEE FIGURES 116–25 AND 116–26.**

Gear mesh preload is a measurement of how closely the teeth of the ball-nut gear and sector gear, or the worm gear and roller, fit together. Gear mesh preload is related to another measurement, called sector lash or **gear lash.**

Gear mesh preload is a measurement of how much turning force must be applied to the input shaft to overcome the resistance of the sector gear and move it. Gear mesh preload is usually measured in a 90-degree turn across the center of the input shaft movement. General Motors calls this adjustment the **overcenter adjustment.** Gear mesh preload (overcenter adjustment) determines how sensitive the steering gear is to small steering wheel movements during straight-ahead driving. Insufficient preload contributes to steering wander.

If there is too much gear lash, the steering becomes unresponsive because the steering gear does not transmit small steering wheel movements to the linkage. Insufficient lash makes the gears bind, offering too much resistance to steering wheel movement. ● **SEE FIGURE 116–27.**

Sector shaft endplay is a measurement of how much room the sector shaft has to slide axially. ● **SEE FIGURE 116–28.** If provision is made to measure sector shaft endplay, the measurement is taken in fractions of inches or millimeters. Some steering gears provide an external adjusting method, but it is more common for sector shaft endplay to be adjusted by internal shims, if it is adjustable.

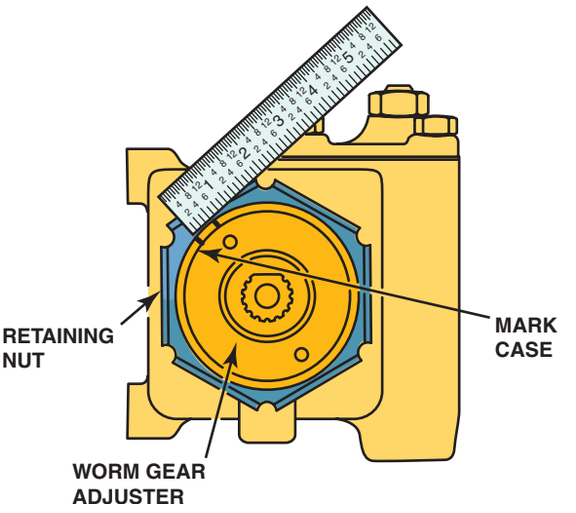

FIGURE 116–26 After the worm gear nut has been tightened, measure 1/2 inch (13 mm) and mark the case. Using the spanner wrench, rotate the worm gear nut counterclockwise 1/2 inch, align the marks, and then tighten the retaining nut. This procedure gives the proper worm gear endplay.

RACK-AND-PINION STEERING GEAR

PARTS AND OPERATION The term "rack and pinion" is simply a description of the basic design of this type of steering gear. The **rack-and-pinion** steering gear is widely used because it is light in weight and takes less space than a conventional steering gear. The input gear of a rack-and-pinion steering gear is a pinion gear that receives rotary input from the steering shaft. The rack is a rod with gear teeth machined into one side. The pinion gear teeth mesh with the teeth on the rack so that when the pinion gear turns, it pushes the rack from side to side. ● **SEE FIGURE 116–29.** The rack connects directly to the tie rod in the steering linkage to move the linkage back and forth in a straight line.

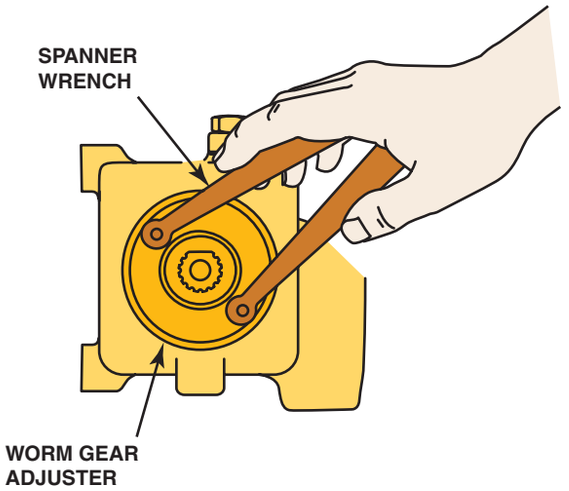

FIGURE 116–25 The first step to adjust worm gear freeplay is to bottom the worm gear nut, using a spanner wrench designed to fit into the two holes in the nut.

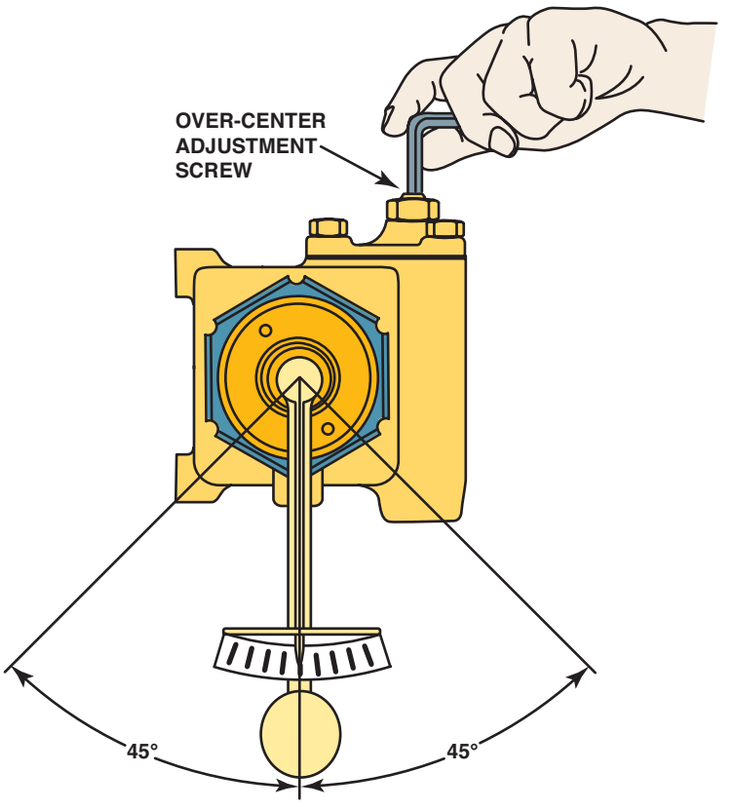

FIGURE 116–27 Performing an overcenter adjustment requires the use of a beam-type inch-lb torque wrench. After the worm bearing preload procedure has been completed, use the torque wrench to measure the rotating torque, which should be 6 to 15 lb-in. If the rotating torque is within the specified range, adjust the overcenter adjustment screw until you achieve 6 to 10 lb-in. additional rotating torque and then tighten the retaining nut.

The steering gear input shaft is splined to the steering shaft U-joint. ● **SEE FIGURE 116–30.** At the end of the steering gear input shaft, which extends into the rack housing, is the pinion gear. Two ball bearings reduce friction between the shaft and the steering gear housing. The upper bearing is a press-fit on the input shaft, and the lower bearing installs inside the housing at the bottom of the pinion gear. A cover, which fits around the shaft and threads into the housing, seats on top of the upper ball bearing to preload it and close the top of the steering gear housing. An oil seal between the top cover and the input shaft keeps lubricant from leaking out of the housing. A lock nut holds the top cover in position.

The teeth of the pinion gear mesh with the teeth of the rack. The teeth are at one end of the rack and the pinion is offset at one side of the housing.

The rack is encased in the long, tubular steering gear housing with a mounting flange on the pinion end. Rubber bushings fit into the mounting flange bolt holes to absorb vibration and isolate the assembly from the frame.

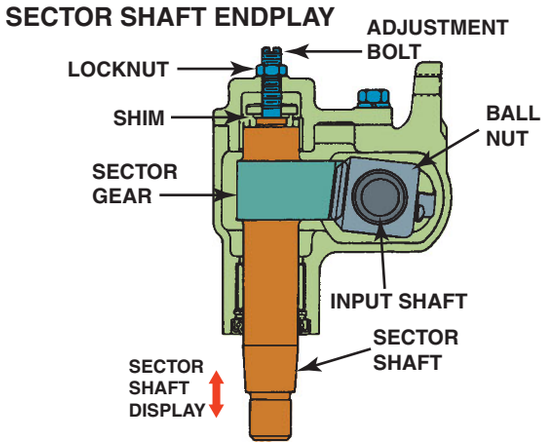

FIGURE 116–28 Sector shaft endplay is the measurement of how far the sector shaft can move axially and is measured in fractions of an inch or millimeters.

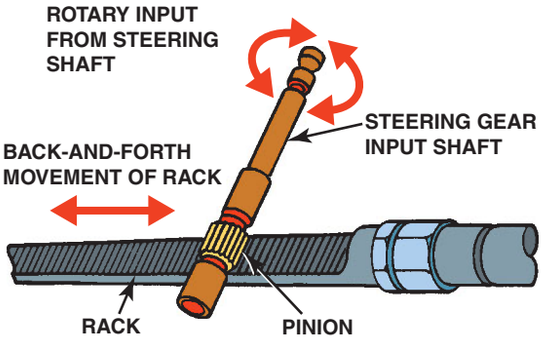

FIGURE 116–29 Rack-and-pinion steering gear operation is simple, direct, and the rack is in a straight line to the front wheels.

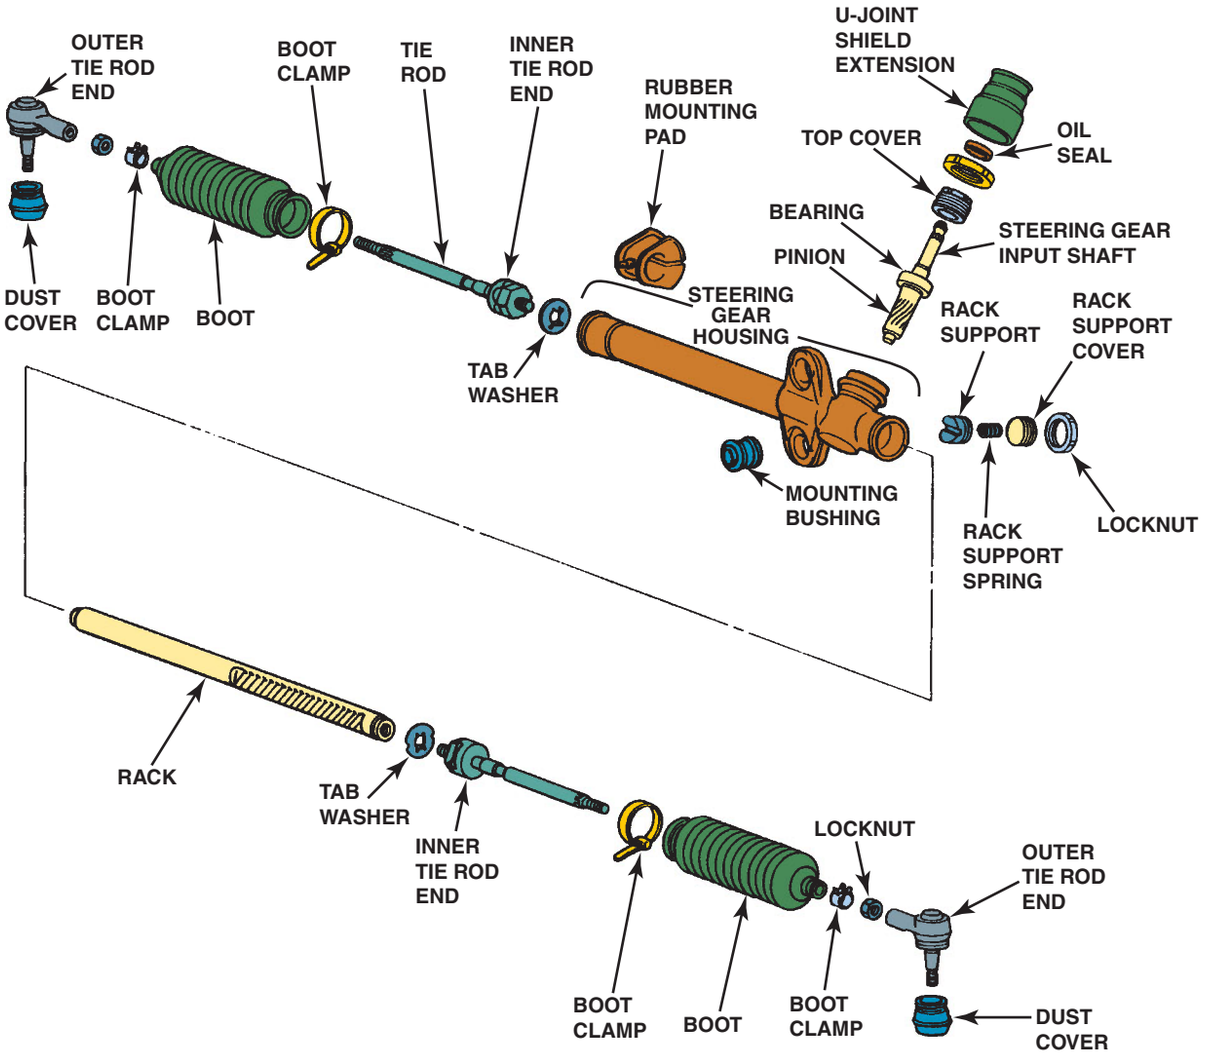

FIGURE 116–30 A typical manual rack-and-pinion steering gear used in a small front-wheel-drive vehicle.

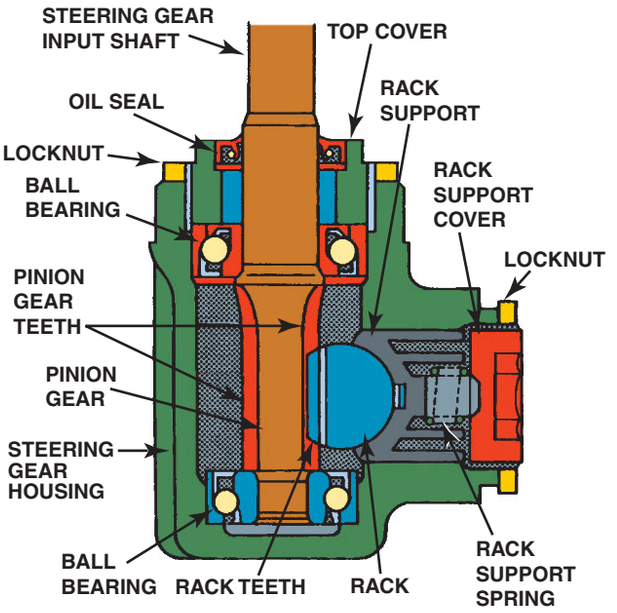

FIGURE 116–31 The spring-loaded rack support positions the rack to keep it from rubbing against the housing and establishes the pinion torque.

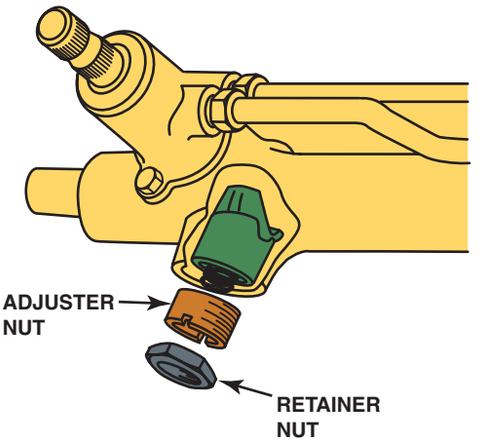

FIGURE 116–32 To adjust the rack-and-pinion gear preload, loosen the retaining nut and tighten the adjuster nut until it bottoms. Then loosen 60 degrees (one "flat" of the six-sided retainer). Tighten retaining nut.

A spring-loaded **rack support** and related hardware install through a hole at the back of the steering gear housing to position the rack. ● **SEE FIGURE 116–31.** The face of the rack support curves to match the back of the rack, which rests on it and slides back and forth across it. A spring behind the rack support cushions the rack from vibration and shocks. While the rack support provides a sliding surface to reduce friction at the pinion end of the rack, the rack rides in a bushing pressed into the steering gear housing at the opposite end to reduce friction.

To adjust the rack-and-pinion gear preload, always check service information for the exact procedure to follow. The specified procedure usually includes these steps. ● **SEE FIGURE 116–32:**

1. Loosen the adjuster plug lock nut.
2. Turn the adjuster plug clockwise until the adjuster plug bottoms in the gear assembly.
3. Turn the adjuster plug back 50 degrees to 70 degrees (approximately one flat).

Most rack-and-pinion units use a small metal tube running along the outside of the housing to connect the two boots and transfer air from one to the other. ● **SEE FIGURE 116–33.** If there were no means for air displacement between the boots, they might collapse as they expanded or explode as they compressed.

Internal threads on each end of the rack allow attachment of the externally threaded tie rods.

A rubber boot at each side of the steering gear housing covers the end of the rack and the inner tie rod end to prevent dirt, water, and other contaminants from entering the assembly. Band clamps fasten the ends of the boots to the housing and tie rods. The tie rods move back and forth with the rack and connect it to the wheels through the steering linkage.

The housing generally bolts to either a flange on the firewall or to the subframe or engine cradle. ● **SEE FIGURE 116–34.** The mounting points have rubber cushions to isolate the steering gear from shock and vibration. If the driver can feel vibration and road shocks through the steering wheel, the condition is called **kickback.** Kickback is most noticeable when driving into a curbed driveway.

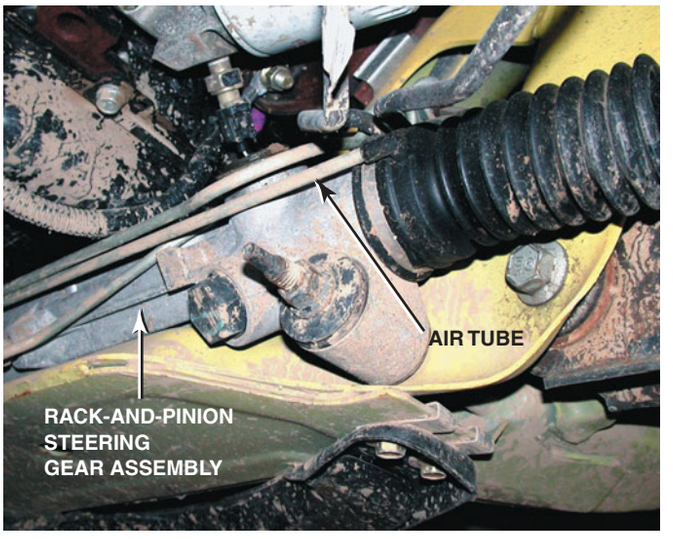

FIGURE 116–33 A small air tube is used to transfer air between the boots as they extend and compress during turns.

RACK-AND-PINION ADJUSTMENTS

PURPOSE Some rack-and-pinion steering gears can be adjusted. **Pinion torque** is a measurement of how much turning force is needed at the input shaft for the pinion to overcome the resistance of the rack and move it. ● **SEE FIGURE 116–35.** The measurement gives an indication of how closely meshed the pinion teeth and the rack teeth are. Like gear mesh preload in a standard steering gear, pinion torque indicates steering system responsiveness. The adjustment method is to thread the rack support cover farther into the steering gear housing to reduce gear lash, or thread it out to increase gear lash. Manufacturers specify an acceptable range of pinion torque in inch-pounds or Newton-meters. Because the middle teeth on the rack wear before the teeth at either end, pinion torque should be checked

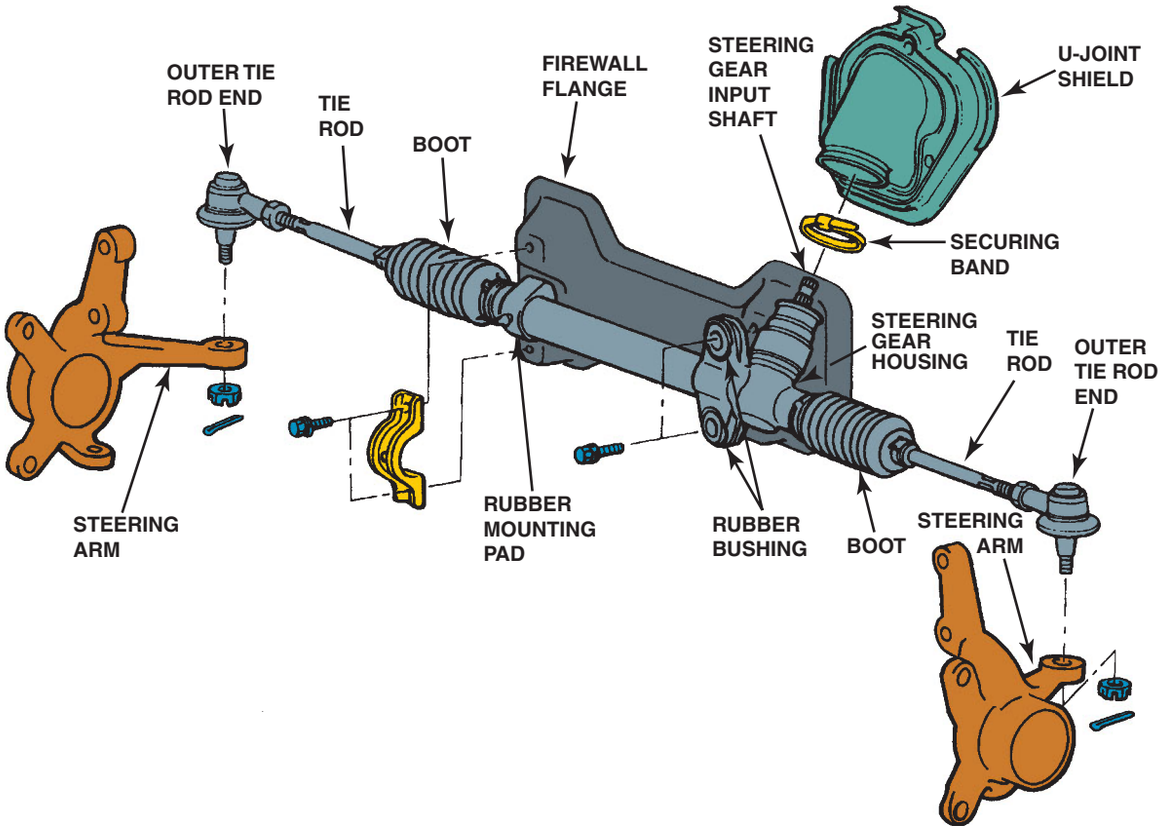

FIGURE 116–34 This manual rack-and-pinion steering gear mounts to the bulkhead (firewall), whereas others mount to the engine cradle or frame of the vehicle.

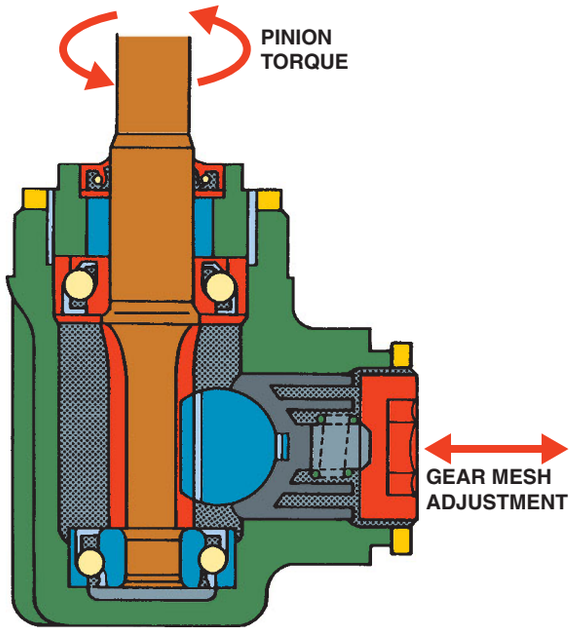

FIGURE 116–35 Pinion torque is a turning torque force measured in inch-pounds or Newton-meters. Tightening the rack support against the rack increases the pinion torque.

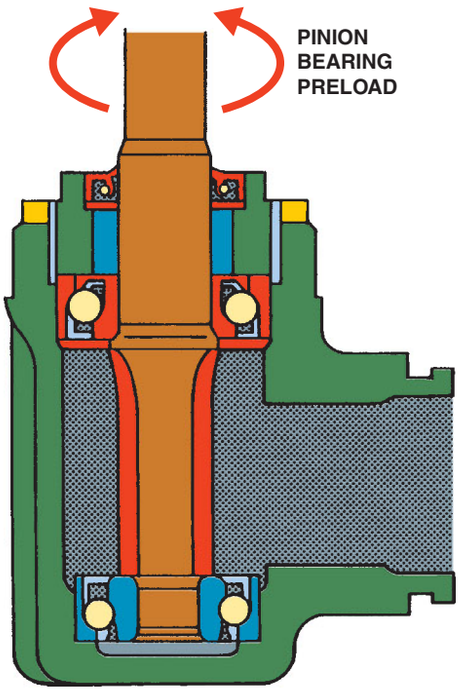

FIGURE 116–36 Pinion bearing preload is a measurement of the turning force required to overcome the resistance of the pinion shaft bearings.

across the whole stroke of the rack. Otherwise, reducing gear lash to a very close tolerance in the middle may cause binding as the pinion travels toward the end of the rack.

BEARING PRELOAD PROCEDURE Pinion bearing preload in a rack-and-pinion steering gear is the same concept as worm bearing preload in a standard steering gear. That is, it is a measurement of how much force is required to turn the steering gear input shaft against the force, or preload, that the bearings apply to the pinion gear and shaft. ● **SEE FIGURE 116–36.** To provide adjustable pinion bearing preload, there may be a threaded adjustment mechanism or selectively sized shims that install behind a shim cover.

? FREQUENTLY ASKED QUESTION

What Is a Center-Take-off Rack?

A center-take-off rack is a rack and pinion steering gear that uses long tie rods and which connect to the center of the rack rather than at the ends of the rack. Instead of using a ball and socket type of connection at the end of the rack, a center take-off rack assembly simply bolts the inner ends of the tie rods to the rack. Check service information for the exact procedures to follow when working with a center-take-off rack and pinion gear assembly.

REVIEW QUESTIONS

1. What components are included in a typical steering column assembly?
2. When the driver turns the steering wheel, how is the motion transferred to the front wheels through a conventional steering gear?
3. Why are recirculating balls used in the recirculating ball steering gear?
4. What steering gear adjustments are possible on a conventional recirculating-ball-type steering gear?
5. What steering gear adjustments are possible on a typical rack-and-pinion steering gear?

CHAPTER QUIZ

1. The circuit to the airbag inflation module is connected from the steering column to the steering wheel through what component?
   a. Slip ring and carbon brushes
   b. Clockspring (coil)
   c. Magnetic field sensor
   d. Hall-effect switch
2. Which part in the steering column allows for changes in the angle between the upper and lower shafts?
   a. Flexible coupling **c.** Universal joint
   b. Column cover **d.** Collapsible section
3. The rotation of the steering wheel causes which part to move the actual steering linkage in a conventional steering gear?
   a. Sector shaft **c.** Worm gear
   b. Pitman arm **d.** Gear nut
4. The pitman shaft is also called the _____.
   a. Sector **c.** Worm
   b. Input **d.** Spline
5. The driver rotates the steering wheel one-half of one revolution (180 degrees) on a vehicle equipped with a steering gear with a 20:1 gear ratio. How many degrees will the front wheels be rotated?
   a. 9 degrees **c.** 90 degrees
   b. 0.1 degree **d.** 11.1 degrees
6. What causes a variable-ratio steering gear to be able to change the ratio as the steering wheel is turned?
   a. Using two or three different sector gears depending on design
   b. Using a variable-length pitman arm
   c. Changing the number of teeth on the worm gear
   d. Changing the length of the teeth on the sector gear
7. Recirculating steel balls are used in most conventional steering gears because they _____.
   a. Provide for a variable ratio
   b. Keep the steering wheel centered
   c. Reduce friction
   d. Help provide feedback to the driver regarding the road surface
8. Which conventional steering gear adjustment should be the first performed?
   a. Worm bearing preload
   b. Tolerance adjustment
   c. Gear mesh preload
   d. Sector shaft endplay
9. The two rack-and-pinion steering gear adjustments include _____.
   a. Worm bearing preload and tolerance adjustment
   b. Pinion bearing preload and rack support
   c. Sector shaft and stub shaft preload
   d. Stub shaft endplay and sector shaft preload
10. A driver of a vehicle equipped with a rack-and-pinion steering gear complains that the steering wheel jerks whenever the vehicle is being driven into a curbed driveway approach at an angle. Technician A says that the rack-and-pinion gears may have too little clearance between the teeth of the gears. Technician B says that a lack of lubrication of the rack-and-pinion is the most likely cause. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 117

STEERING LINKAGE AND SERVICE

OBJECTIVES: After studying Chapter 117, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "A" (Steering System Diagnosis and Service). • Identify steering linkage components. • Describe how the movement of the steering wheel causes the front wheels to turn. • Describe how to perform a dry park test to determine the condition of steering system components. • Perform an under-the-vehicle inspection of the steering system components. • List the service procedures for under-the-vehicle steering system service. • Explain how to replace steering linkage parts.

KEY TERMS: Articulation test 1384 • Ball socket assembly 1373 • Center link 1372 • Center take-off rack 1374 • Cross-steer linkage 1372 • Dry park test 1379 • Front steer 1375 • Grease fitting 1373 • Opposite-phase steering 1375 • Parallelogram linkage 1372 • Pitman arm 1372 • RBS 1373 • Rear steer 1375 • Same-phase steering 1375 • Steering dampener 1372 • Steering stops 1378 • SWPS 1377 • Tie rods 1372 • Zerk fitting 1373

STEERING LINKAGE

PARTS AND OPERATION

The steering linkage relays steering forces from the steering gear to the front wheels. Most conventional steering gear linkages use the **parallelogram**-type design. A parallelogram is a geometric box shape where opposite sides are parallel and equal distance. A parallelogram-type linkage uses four **tie rods,** two inner and two outer (left and right), a **center link** (between the tie rods), and an idler arm on the passenger side and a **pitman arm** attached to the steering gear output shaft (pitman shaft). ● **SEE FIGURE 117–1.**

As the steering wheel is rotated, the pitman arm is moved. The pitman arm attaches to a center link. At either end of the center link are inboard (inner) tie rods, adjusting sleeves, and outboard (outer) tie rods connected to the steering arms which moves the front wheels. The passenger side of all these parts is supported and held horizontal by an idler arm that is bolted to the frame. The center link may be known by several names, including the following:

- Center link
- Connecting link
- Connecting rod
- Relay rod
- Intermediate rod
- Drag link (usually a truck term only)

Other types of steering linkages often used on light trucks and vans include the **cross-steer linkage.** ● **SEE FIGURE 117–2** for a comparison of parallelogram and cross-steer-type steering linkage arrangements.

NOTE: Many light trucks, vans, and some luxury cars use a steering dampener attached to the linkage. A steering dampener is similar to a shock absorber, and it absorbs and dampens sudden motions in the steering linkage. ● **SEE FIGURE 117–3.**

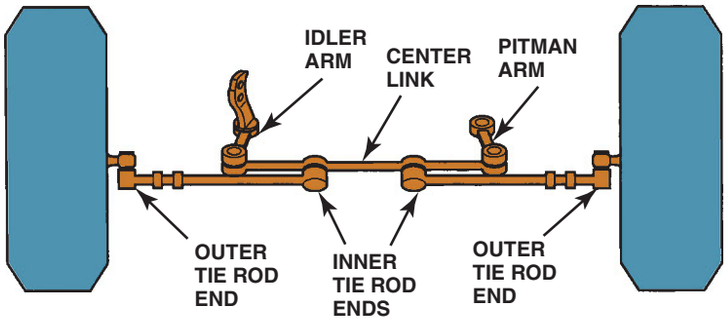

FIGURE 117–1 Steering movement is transferred from the pitman arm that is splined to the sector shaft (pitman shaft), through the center link and tie rods, to the steering knuckle at each front wheel. The idler arm supports the passenger side of the center link and keeps the steering linkage level with the road. This type of linkage is called a parallelogram-type design.

FREQUENTLY ASKED QUESTION

Why Is a Grease Fitting Sometimes Called a Zerk Fitting?

In 1922 the *zerk* fitting was developed by Oscar U. Zerk, an employee of the Alemite Corporation, a manufacturer of pressure lubrication equipment. A zerk or grease fitting is also known as an *Alemite fitting.*

Connections between all steering component parts are constructed of small ball-and-socket joints. These joints allow side-to-side movement to provide steering of both front wheels, and allow the joints to move up and down, which is required for normal suspension travel.

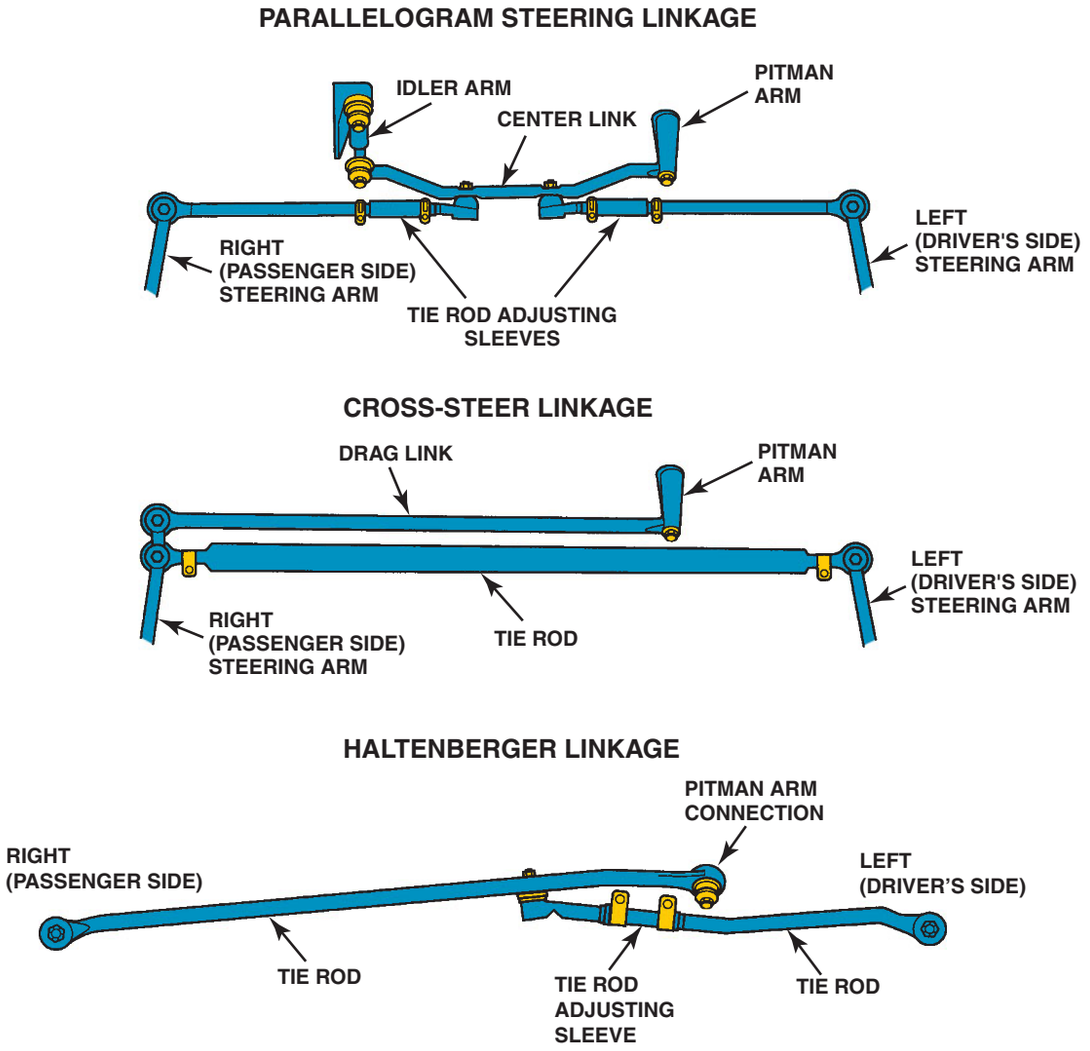

FIGURE 117–2 The most common type of steering is the parallelogram. The cross-steer and Haltenberger linkage designs are used on some trucks and vans.

FIGURE 117–3 Typical steering dampener used on a Hummer H2.

It is important that all of these joints be lubricated with chassis grease through a **grease fitting,** also called a **zerk fitting,** at least every six months or per the vehicle manufacturer's specifications.

Most vehicles come equipped with sealed joints and do not require periodic servicing. Some vehicles come from the factory with plugs that need to be removed and replaced with grease fittings and then lubricated.

TIE ROD ENDS Tie rod ends connect the steering linkage to the steering knuckles and to other steering linkage components. Conventional tie rod ends use a hardened steel ball stud assembled into a hardened steel and thermoplastic bearing. An internal preload spring limits the ball stud endplay and helps compensate for ball-and-socket wear. ● **SEE FIGURE 117–4** for two designs of tie rod ends.

For many years, Ford Motor Company used tie rod ends that included a rubber-bonded steel ball stud. Because there is no sliding friction inside the tie rod end, no lubrication was needed. This type of tie rod end is called **RBS (rubber-bonded socket).** ● **SEE FIGURE 117–5.**

RACK-AND-PINION INNER TIE ROD ENDS

TERMINOLOGY Inner tie rod end assemblies used on rack-and-pinion steering units require special consideration and often special tools. The inner tie rod end is also called a **ball socket assembly.**

The inner tie rod assemblies are attached to the end of the steering rack by one of several methods. ● **SEE FIGURE 117–6.**

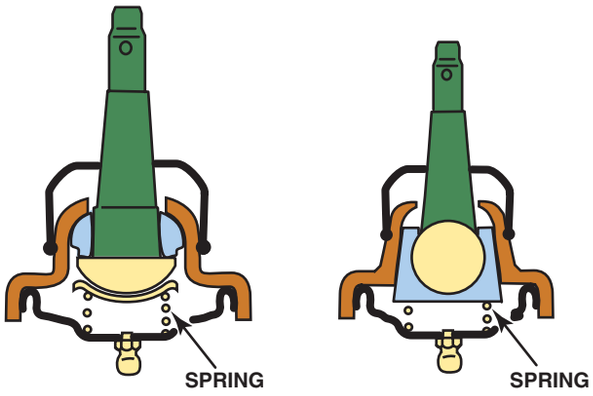

FIGURE 117–4 (a) A dual bearing design with a preload spring. The use of two bearing surfaces allows for one surface for rotation (for steering) and another surface for pivoting (to allow for suspension up-and-down movement). (b) The nylon wedge bearing type allows for extended lube intervals. Wear is automatically compensated for by the tapered design and spring-loaded bearing.

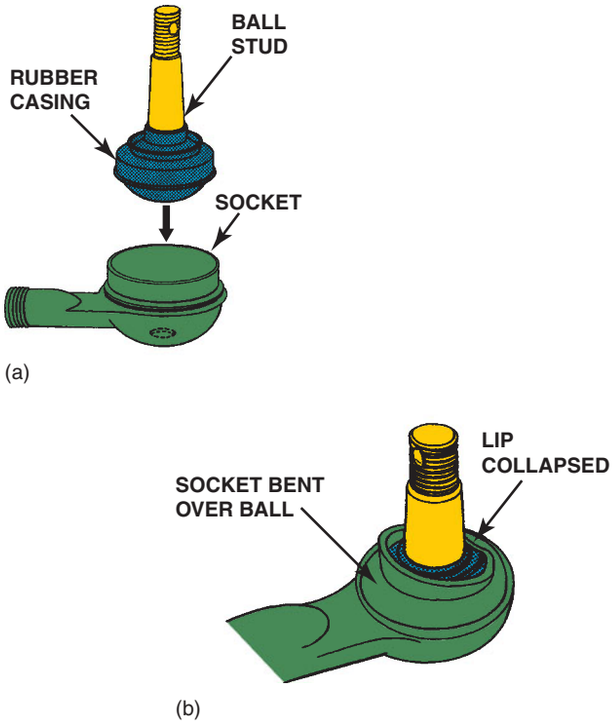

FIGURE 117–5 (a) A rubber-bonded socket is constructed of a rubber casing surrounding the ball stud, which is then inserted into the socket of the tie rod end. The hole in the socket allows air to escape as the ball stud is installed and there is not a place for a grease fitting. (b) The socket is crimped over the ball so that part of the socket lip retains the stud.

STAKED This method is common on Saginaw-style rack-and-pinion steering units found on General Motors vehicles.

The flange around the outer tie rod must be restaked to the flat on the end of the rack.

RIVETED OR PINNED This method is commonly found on Ford vehicles. Some roll pins require a special puller, or the pin can be drilled out. Many styles use an aluminum rivet. A special, very deep socket or a large open-end wrench can usually be used to shear the aluminum rivet by unscrewing the socket assembly from the end of the rack while the rack-and-pinion unit is still in the vehicle. ● **SEE FIGURE 117–7.**

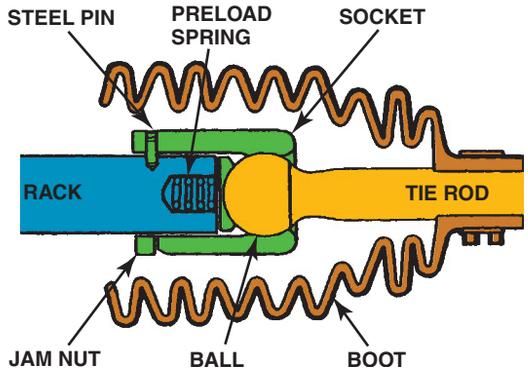

FIGURE 117–6 Rack-and-pinion steering systems use a ball-and-socket-type inner tie rod end.

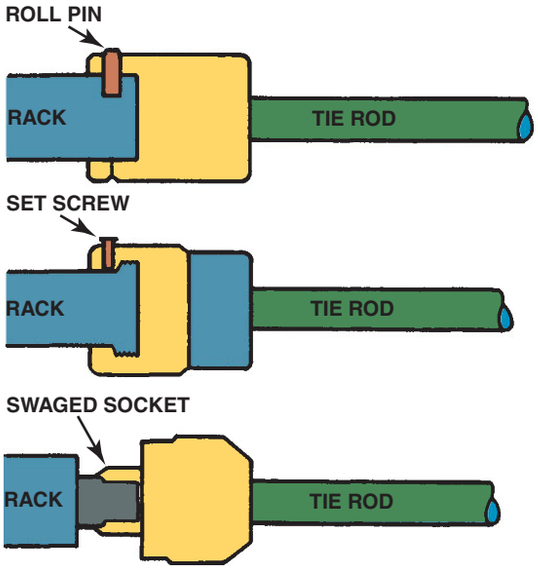

FIGURE 117–7 A variety of methods are used to secure the inner tie rod end socket assembly to the end of the rack.

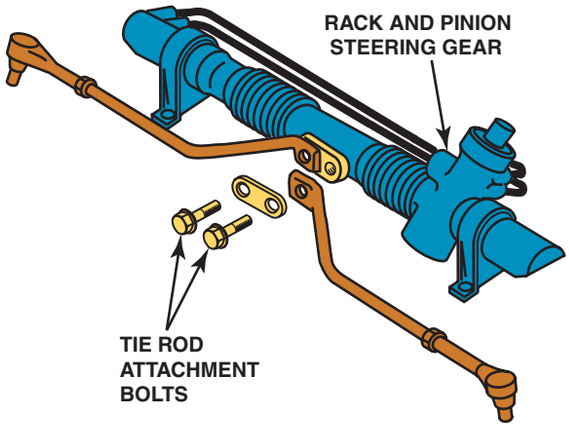

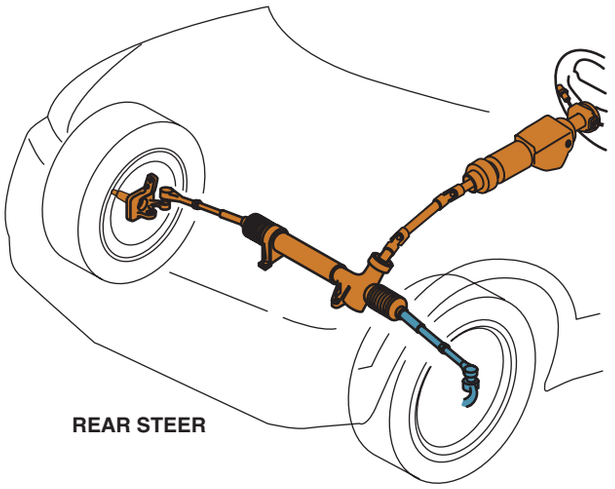

FIGURE 117–8 Exploded view of a center-take-off-style rack-and-pinion steering gear assembly.

CENTER TAKE-OFF RACKS For the **center take-off racks,** use bolts to secure the inner tie rods to the rack, as shown in ● **FIGURE 117–8.**

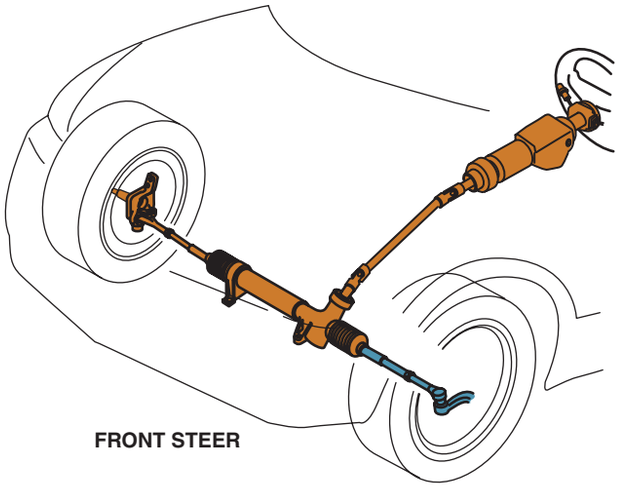

FIGURE 117–9 In a rear-steer vehicle, the steering linkage is behind the centerline of the front wheels, whereas the linkage is in front on a front-steer vehicle.

FRONT STEER VERSUS REAR STEER

Front steer, also called *forward steer,* is the term used to describe a vehicle that has the steering gear in front of the front wheel centerline. Having the steering gear located in this position improves handling and directional stability, especially when the vehicle is heavily loaded.

Front-steer vehicles usually produce an understeer effect that makes the vehicle feel very stable while cornering. If the steering gear linkage is located behind the wheels, it is called **rear steer** and the cornering forces are imposed on the steering in the direction of the turn. This is an oversteer effect. It tends to make the steering easier and makes the vehicle feel less stable.

Most front-wheel-drive vehicles are rear steering, with the rack-and-pinion steering unit attached to the bulkhead or subframe behind the engine. ● **SEE FIGURE 117–9.**

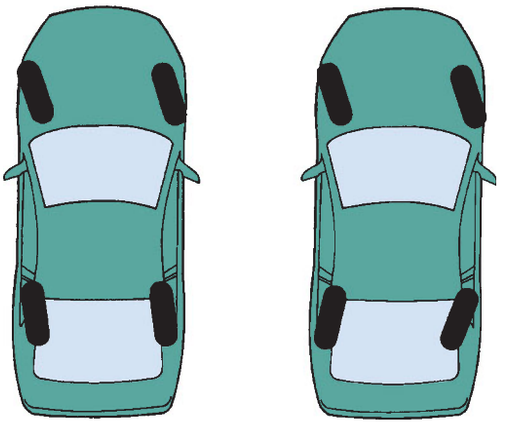

FIGURE 117–10 Opposite-phase four-wheel steer is usually used only at low vehicle speed to help in parking maneuvers. Same-phase steering helps at higher speeds and may not be noticeable by the average driver.

FOUR-WHEEL STEERING SYSTEMS

Some vehicles were equipped with a system that steers all four wheels. Two terms are commonly used when discussing four-wheel steering:

1. **Same-phase steering.** Same-phase steering means that the front and rear wheels are steered in the same direction. Same-phase steering improves steering response, especially during rapid-lane-change-type maneuvers.
2. **Opposite-phase steering.** Also called *negative-phase mode,* opposite-phase steering is when the front wheels and rear wheels are steered in the opposite direction. ● **SEE FIGURE 117–10.** Opposite-phase steering will quickly change the vehicle's direction, but may cause a feeling of oversteering.

Opposite-phase steering is best at low speeds; same-phase steering is best for higher-speed handling and lane-change maneuvers.

QUADRASTEER Quadrasteer™ is a four-wheel steering system that dramatically enhances low-speed maneuverability, high-speed stability, and towing capability. ● **SEE FIGURE 117–11.**

The system is an electrically powered rear wheel steering system comprised of the following components:

- A steerable, solid rear axle
- A heavy-duty wiring harness and fuse
- A programmable control module
- A power relay in the control module
- A rack-and-pinion-style steering actuator mounted on the rear differential cover
- An electric motor assembly on top of the rear steering actuator
- Three Hall-effect switches in the motor assembly
- A shorting relay in the motor assembly
- A rear wheel position sensor located under a cover on the bottom of the actuator, below the motor assembly

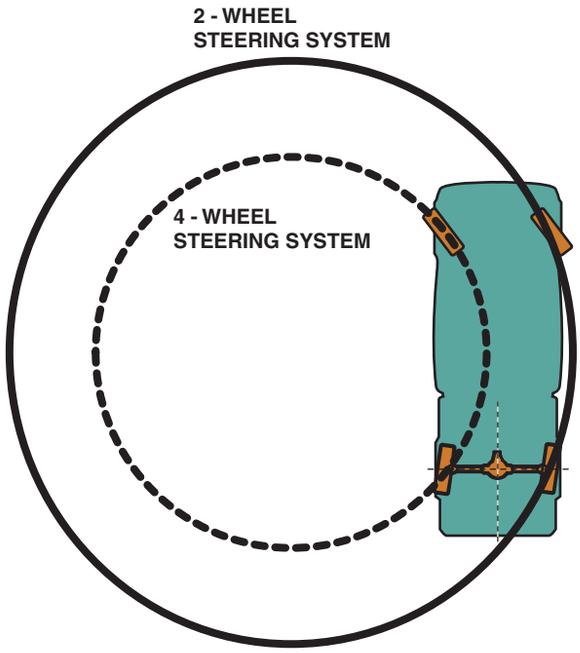

FIGURE 117–11 Being equipped with four-wheel steer allows a truck to make shorter turns than would otherwise be possible.

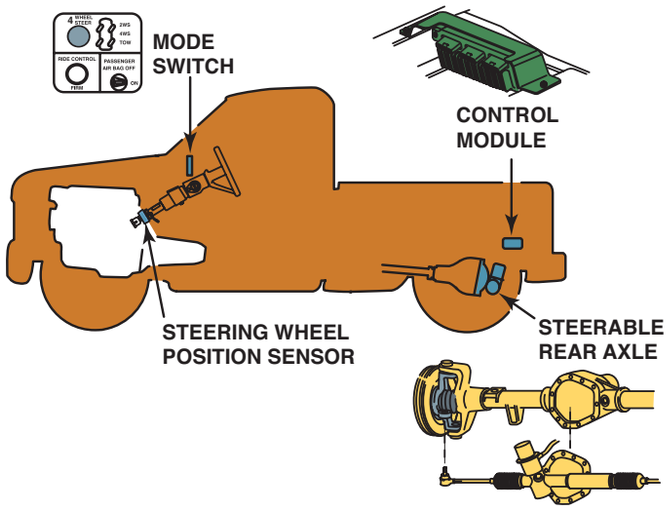

FIGURE 117–12 The Quadrasteer system includes many components that all work together.

- A steering wheel position sensor located at the base of the steering column
- A mode select switch on the dash

● **SEE FIGURE 117–12** for an overall view of the components of the Quadrasteer system.

The rear wheel steering control module has the following inputs:

- Battery voltage
- Switched battery voltage
- Class 2 serial data
- Steering wheel position sensor analog signal, via class 2 message from the body control module (BCM)
- Steering wheel position sensor phase A
- Steering wheel position sensor phase B

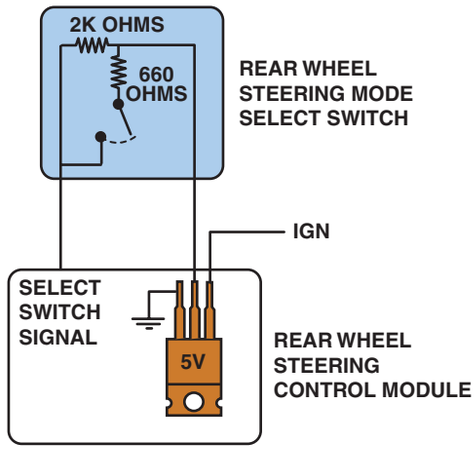

FIGURE 117–13 Rear steer select switch schematic.

- Steering wheel position sensor marker pulse
- Rear wheel position sensor position 1
- Rear wheel position sensor position 2
- Rear wheel steering motor Hall sensor A
- Rear wheel steering motor Hall sensor B
- Rear wheel steering motor Hall sensor C
- Vehicle speed signal from the instrument panel cluster (IPC)
- Rear wheel steering mode switch signal

● **SEE FIGURE 117–13.**

The system operates in three principal modes, as follows:

- **Two-wheel steer mode.** Normal steering operation—the rear wheels are held in a centered position and rear wheel steering is disabled while in this mode.
- **Four-wheel steer mode.** The four-wheel steering mode provides three principal phases of steering: negative phase, neutral phase, and positive phase. Negative phase occurs at low speeds and the rear wheels turn opposite of the front wheels. In the neutral phase, the rear wheels are centered and do not turn. Positive phase occurs at higher speeds and the rear wheels turn in the same direction as the front wheels.
- **Four-wheel steer tow mode.** The four-wheel steer tow mode provides more positive-phase steering than the normal four-wheel steering at high speed. During low-speed driving, the four-wheel steer tow mode provides similar negative-phase steering as it does in the normal four-wheel steering mode.

REAR WHEEL STEERING CONTROL MODULE

The rear wheel steering control module controls all functions of the rear wheel steering system. The module has a dedicated power feed line from an underhood fuse holder, via a 125-amp mega fuse. The module is located in the rear of the vehicle on the underbody. The module uses the inputs listed earlier to determine when and how far to turn the rear wheels. The module uses the Hall switches in the motor assembly, a shorting relay, and a motor control relay to monitor and control the direction and speed of the motor. The module also controls the duty cycle of the phase leads to the motor. The motor control relay is part of the rear wheel steering control module and is not serviceable.

The control module allows the vehicle rear wheels to turn a maximum of 12 degrees left or right. When the vehicle is operated in reverse, the maximum rear wheel steering angle is 5 degrees left or right. When the vehicle is sitting still in the test mode, the system will move a maximum of 5 degrees left or right.

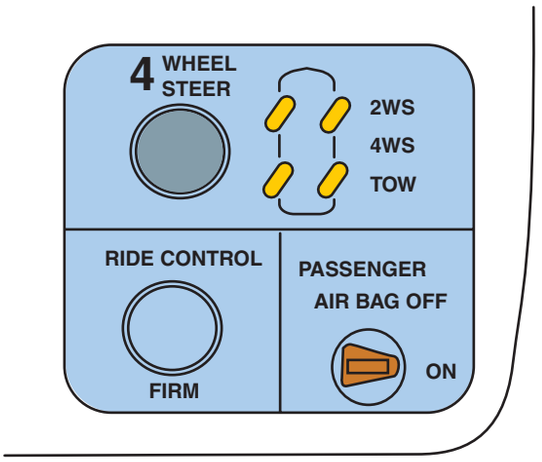

FIGURE 117–14 The dash-mounted select switch showing the three positions for the four-wheel steer system.

REAR WHEEL STEERING MODE SWITCH

The mode switch located in the instrument panel allows the driver the option of selecting two-wheel steering, four-wheel steering, or four-wheel steering tow modes of operation. The mode switch has indicators that show which mode the rear wheel steering system is in. When all indicators are lit the rear wheel steering control module has lost its memory settings and the scan tool must be used to recalibrate the rear wheel steering control module. During a mode change, the indicator for the selected mode will flash until the mode change is complete. The rear wheel steering control module will wait for the steering wheel to pass the center position before entering the selected mode. The indicators on the mode switch are LEDs; the switch is also back lit. ● **SEE FIGURE 117–14.**

REAR WHEEL STEERING MOTOR ASSEMBLY. The rear wheel steering motor assembly is a three-phase, six-pole, brushless DC motor. The motor assembly is located on the top of the rear steering actuator, and transmits its power through a planetary gearset inside the actuator. There are three Hall switches inside the assembly: Hall A, Hall B, and Hall C. The rear wheel steering control modules uses the Hall switch inputs to monitor the position, speed, and direction of the motor.

STEERING WHEEL POSITION SENSOR. The **steering wheel position sensor (SWPS)** provides one analog signal and three digital signals. The digital signals—Phase A, Phase B, and marker pulse—are direct inputs to the rear wheel steering control module. The analog signal is input to the body control module (BCM) and is sent via a class 2 message to the rear wheel steering control module. Battery voltage is supplied to the sensor from the cruise fuse to operate the digital portion of the sensor. A 12-volt reference is provided by the rear wheel steering control module to the Phase A, Phase B, and marker pulse circuits of the SWPS. The module monitors each circuit as it remains high or is pulled low by the SWPS. The scan tool displays the Phase A and Phase B data parameters as either high or low when the steering wheel is being rotated. Each change from high to low, or low to high, represents 1 degree of steering wheel rotation. When observing with the scan tool, the parameters for Phase A and Phase B will not always display the same value at the same time. The marker pulse is a digital pulse signal that is displayed as high by the scan tool with the steering wheel angle between +10 degrees and −10 degrees. At greater than 10 degrees steering wheel angle in either direction, the marker pulse data will be displayed as low. The BCM provides the 5-volt reference and low reference for the analog portion of the SWPS. The BCM reads the SWPS analog signal in voltage, which is typically 2.5 volts with the steering wheel on center.

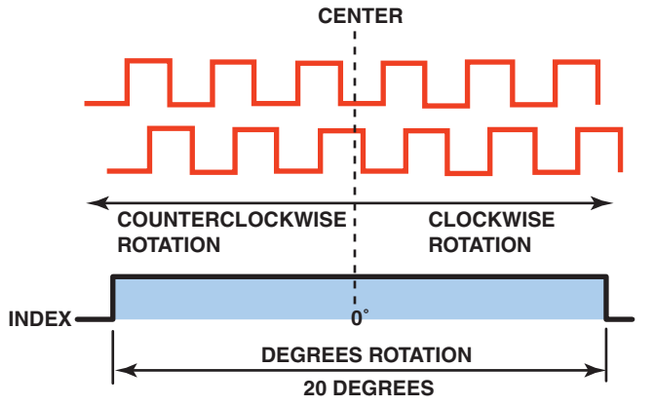

FIGURE 117–15 The output of the handwheel sensor digital signal.

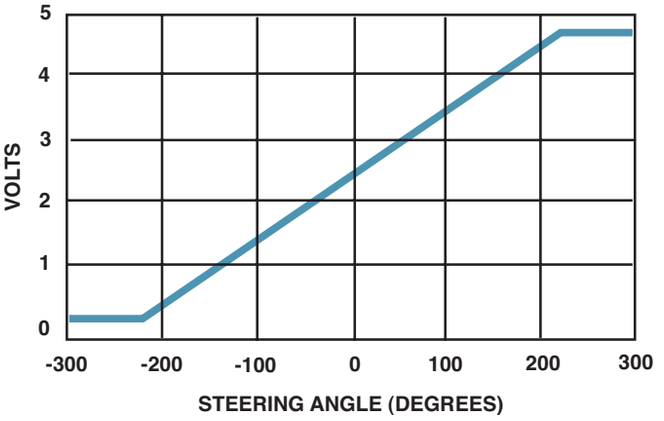

FIGURE 117–16 Handwheel analog signal.

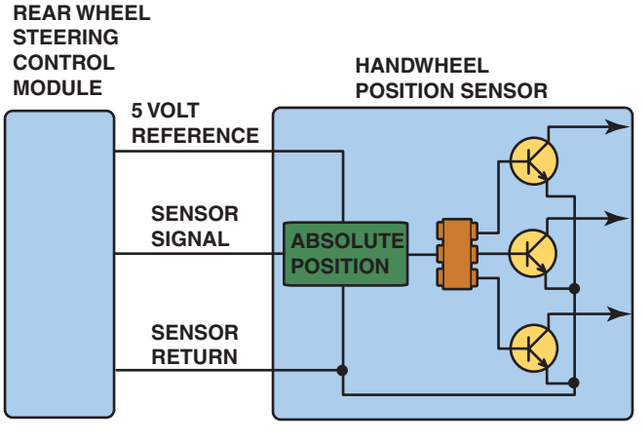

FIGURE 117–17 Handwheel position sensor analog signal to control module.

The voltage ranges from 0.25 volts at approximately one full turn left to 4.75 volts at approximately one full turn right. The voltage will then remain at that level for the remainder of steering wheel travel. This voltage can be monitored in BCM data display on a scan tool. The sensor may also be utilized by other optional systems. ● **SEE FIGURES 117–15 THROUGH 117–18.**

REAR WHEEL POSITION SENSOR. The rear wheel position sensor has two signal circuits: position 1 and position 2. Position 1 is a linear measurement of voltage per degree. The voltage range for position 1 is from 0.25 to 4.75 volts, and the angular measurement range is from −620 degrees to +620 degrees. At 0.25 volts the steering wheel has been rotated −600 degrees past center. At 4.75 volts

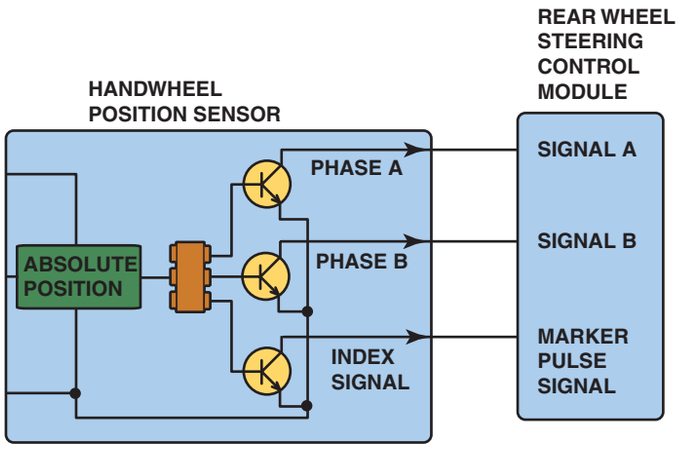

FIGURE 117–18 Handwheel position sensor digital signal to control module.

FIGURE 117–19 A Quadrasteer system showing all of the components. The motor used to power the rear steering rack can draw close to 60 amperes during a hard turn and can be monitored using a Tech 2.

the steering wheel has been rotated +600 degrees past center. The position 2 circuit is a linear measurement of voltage per degree. The voltage for position 2 increases or decreases from 0.25 to 4.75 volts every 180 degrees. When the steering wheel is 0 degrees center, the position 1 and position 2 output signals each measure 2.5 volts.

STEERABLE REAR AXLE. The steerable rear axle has a rack-and-pinion-style actuator mounted to the differential cover, specially designed axle shafts, and movable hub and bearing assemblies mounted by upper and lower ball joints. The actuator housing is part of the differential cover. In the event of a system malfunction, the actuator returns the rear wheels to the center position through internal springs. The actuator has specially designed inner and outer tie rod ends. There are inner tie rod boots to prevent contaminants from entering the actuator. The actuator has the rear wheel steering motor assembly attached to the upper housing. There are shields and a skid plate on the rear axle to protect the actuator. There are no internal adjustments to the actuator. ● **SEE FIGURE 117–19.**

STEERING LINKAGE LUBRICATION

Keeping all joints equipped with a grease fitting properly greased is necessary for long life and ease of steering. ● **SEE FIGURE 117–20.**

FIGURE 117–20 Greasing a tie rod end. Some joints do not have a hole for excessive grease to escape, and excessive grease can destroy the seal.

FIGURE 117–21 Part of steering linkage lubrication is applying grease to the steering stops. If these stops are not lubricated, a grinding sound may be heard when the vehicle hits a bump when the wheels are turned all the way one direction or the other. This often occurs when driving into or out of a driveway that has a curb.

During a chassis lubrication, do not forget to put grease on the *steering stop,* if so equipped. **Steering stops** are the projections or built-up areas on the control arms of the front suspension designed to limit the steering movement at full lock. ● **SEE FIGURE 117–21.**

When the steering wheel is turned as far as it can go, the steering should *not* stop inside the steering gear! Forces exerted by the power steering system can do serious damage to the steering gear if absorbed by the steering gear rather than the steering stop.

NOTE: Many rack-and-pinion steering units are designed with a rack-travel-limit internal stop and do not use an external stop on the steering knuckle or control arm.

Most steering stops are designed so that the lower control arm hits a small section of the body or frame when the steering wheel is turned to the full "lock" position. Steering stops should be lubricated to prevent a loud grinding noise when turning while the vehicle is going over a bump. This noise is usually noticeable when turning into or out of a driveway.

FREQUENTLY ASKED QUESTION

What Is "Goofy Mode"?

Trucks that are equipped with the Quadrasteer system have a three-position switch on the dash:

1. 2WS
2. 4WS
3. Tow

The Quadrasteer module then determines the right amount of rear steer and in which direction based on vehicle speed and steering wheel angle. If trailer towing mode is selected and the truck is *not* towing a trailer, the computer will adjust the steering as if there is a trailer and will slightly delay the rear steering action when changing lanes and other maneuvers. As a result, when the steering wheel is turned the front wheels will of course turn in direct proportion to the input from the steering wheel; however, the rear wheels will be delayed in their action to allow the trailer to track properly. If, however, a trailer is not being towed, this delay feels "goofy" and could result in customer concerns about the proper operation of the Quadrasteer system. Be sure that the control switch is placed in the off or normal modes unless a trailer is in fact being towed.

DRY PARK TEST

PURPOSE Since many steering (and suspension) components do *not* have exact specifications for replacement purposes, it is extremely important that the beginning service technician work closely with an experienced veteran technician. While most technicians can determine when a steering component such as a tie rod end is definitely in need of replacement, marginally worn parts are often hard to spot and can lead to handling problems. One of the most effective, yet easy to perform, steering component inspection methods is called the **dry park test.**

Excessive play in the steering wheel can be caused by worn or damaged steering components. Looseness in the steering components usually causes freeplay in the steering wheel. Freeplay refers to the amount of movement of the steering wheel required to cause movement of the front wheels. The exact cause of freeplay in the steering should be determined if the freeplay exceeds 2 in. (5 cm) for parallelogram-type steering linkages, or 3/8 in. (1 cm) for rack-and-pinion steering. ● **SEE FIGURE 117–22.**

PROCEDURE This simple test is performed with the vehicle on the ground or on a drive-on ramp-type hoist, moving the steering wheel back and forth *slightly* while an assistant feels for movement at each section of the steering system. The technician can start checking for any looseness in the steering linkage starting either at the outer tie rod ends and working toward the steering column, or from the steering column toward the outer tie rod ends. It is important to check each and every joint and component of the steering system, including the following:

1. The intermediate shaft and flexible coupling.
2. All steering linkage joints, including the inner tie rod end ball socket. ● **SEE FIGURE 117–23**.
3. Steering gear mounting and rack-and-pinion mounting bushings.

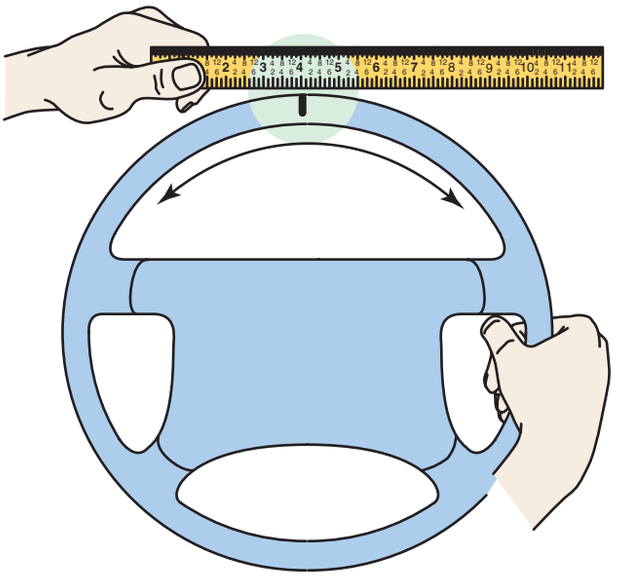

FIGURE 117–22 Checking for freeplay in the steering.

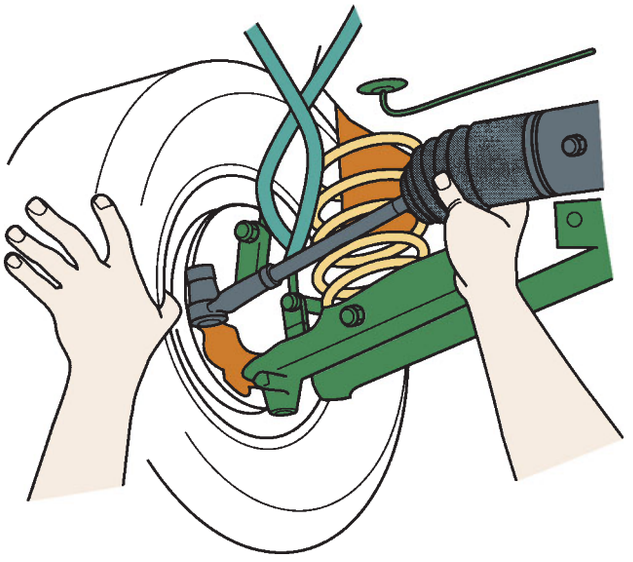

FIGURE 117–23 All joints should be felt during a dry park test. Even inner tie rod ends (ball socket assemblies) can be felt through the rubber bellows on many rack-and-pinion steering units.

FREQUENTLY ASKED QUESTION

Why Do Only a Few Vehicles Use Grease Fittings?

Many years ago, all vehicles were equipped with grease fittings, while today very few vehicles are so equipped. The reasons for this, as given by engineers, include the following:

- It has been determined that the use of the wrong type of grease can cause more harm than good.
- If a grease fitting is used to allow grease to enter the suspension or steering joint, then water can also get inside the joint.
- Grease fittings are often ignored or the greasing of the joint is not performed by the service technician.
- Low-friction joints do not require routine service like the older metal-to-metal joints required.

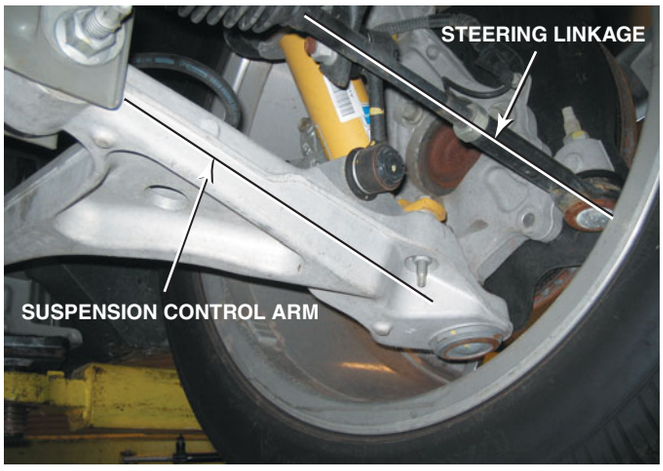

FIGURE 117–24 The steering and suspension control arms must remain parallel to prevent the up-and-down motion of the suspension from causing the front wheels to turn inward or outward.

TECH TIP

Jounce/Rebound Test

All steering linkage should be level and "work" at the same angle as the suspension arms, as shown in ● **FIGURE 117–24.** A simple test to check these items is performed as follows:

1. Park on a hard, level surface with the wheels straight ahead and the steering wheel in the *unlocked* position.
2. Bounce (jounce) the vehicle up and down at the front bumper while watching the steering wheel.

The steering wheel should *not* move during this test. If the steering wheel moves while the vehicle is being bounced, look for a possible bent steering linkage, suspension arm, or steering rack. ● **SEE FIGURE 117–25.**

COMMON WEAR ITEMS

On a vehicle equipped with a conventional steering gear and parallelogram linkage, as shown in ● **FIGURE 117–26,** typical items that wear first, second, and so on include the following:

Steering Component	Estimated Mileage to Wear Out*
1. Idler arm	40,000–60,000 miles (60,000–100,000 km)
2. Outer tie rod ends (replaced in pairs only)	60,000–100,000 miles (100,000–160,000 km)
3. Inner tie rod ends	80,000–120,000 miles (130,000–190,000 km)
4. Center link	90,000–130,000 miles (140,000–180,000 km)
5. Pitman arm	100,000–150,000 miles (160,000–240,000 km)

*Mileage varies greatly due to different road conditions and levels of vehicle maintenance. This chart should be used as a guide only.

Note that there are overlapping mileage intervals for several components. Also note that the mileage interval for an idler arm is such that by the time other components are worn, the idler arm may need to be replaced a second time.

For vehicles that use rack-and-pinion-type steering systems, the list is shorter because there are fewer steering components and the forces exerted on a rack-and-pinion system are in a straight line. The first to wear is usually the outer tie rod ends (one or both) followed by the inner tie rod ball-and-socket joints, usually after 60,000 miles (100,000 km) or more. Intermediate shaft U-joints usually become worn and can cause steering looseness after 80,000 miles (130,000 km) or more.

NOTE: Experienced front-end technicians can often guess the mileage of a vehicle simply by careful inspection of the steering linkage. For example, if the idler arm is a replacement part and again needs to be replaced, and the outer tie rods also need replacement, then the vehicle probably has at least 60,000 miles and usually more! When inspecting a used vehicle for possible purchase, perform a careful steering system inspection. This is one area of the vehicle where it is difficult to hide long or hard service.

PARALLELISM

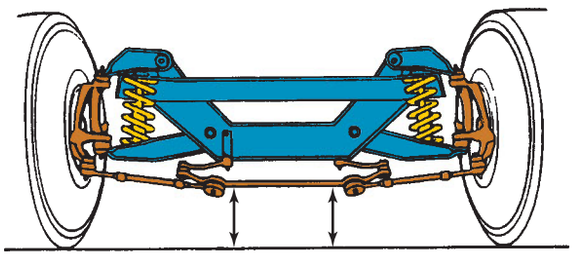

FIGURE 117–25 The center link should be parallel to the ground.

TECH TIP

Wear and Nonwear Center Links

Some center links are equipped with ball-and-socket joints, which can wear. Other center links are manufactured with holes for ball joint studs only. ● **SEE FIGURE 117–27.** Generally, the center links that do not use joints are unlikely to need replacement unless a joint becomes loose and wears the tapered stud hole. Knowing which style of center link is used will help determine the most likely location to check for excessive steering linkage play.

UNDER-VEHICLE INSPECTION

After checking the steering system components as part of a dry park test, hoist the vehicle and perform a thorough part-by-part inspection:

1. Inspect each part for damage due to an accident or bent parts due to the vehicle's hitting an object in the roadway.

CAUTION: Never straighten a bent steering linkage; always replace with new parts.

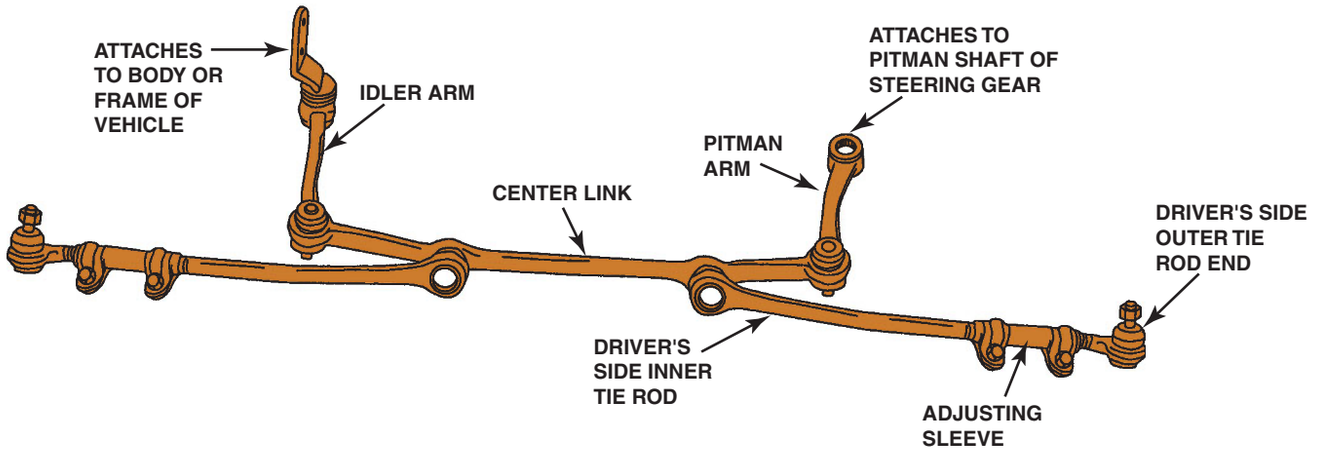

FIGURE 117–26 Typical parallelogram steering linkage. The center link can also be named the relay rod, drag link, or connecting link.

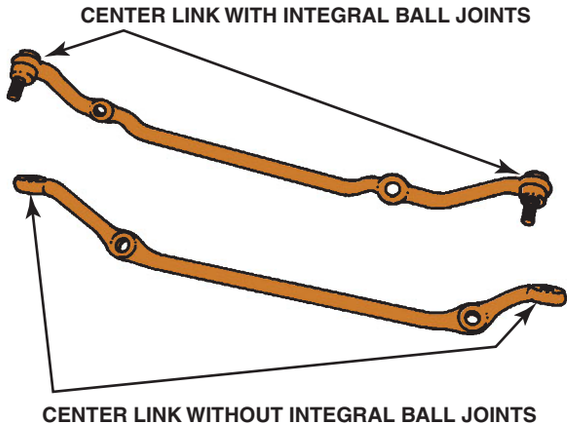

FIGURE 117–27 Some center links have ball joints while others have tapered socket holes to accept ball joints on the pitman arm, idler arm, and inner tie rod ends.

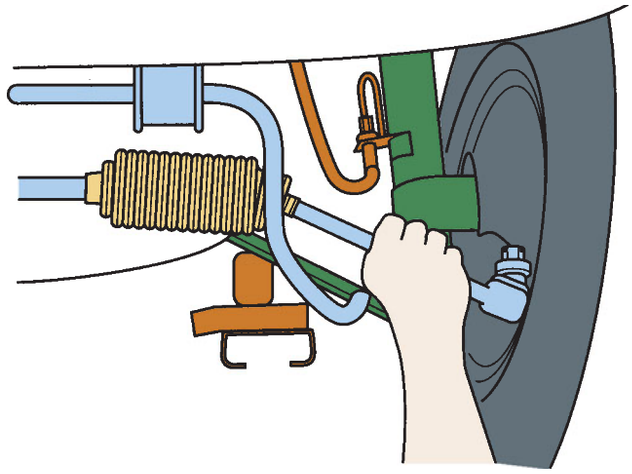

FIGURE 117–29 Steering system component(s) should be replaced if any noticeable looseness is detected when moved by hand.

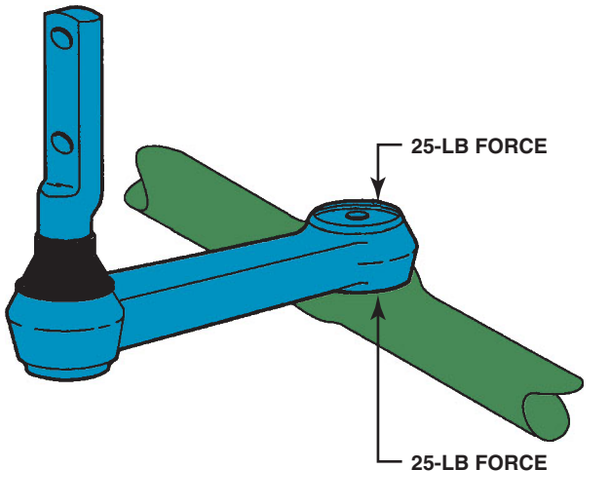

FIGURE 117–28 To check an idler arm, most vehicle manufacturers specify that 25 pounds of force be applied by hand up and down to the idler arm. The idler arm should be replaced if the total movement (up and down) exceeds 1/4 in. (6 mm).

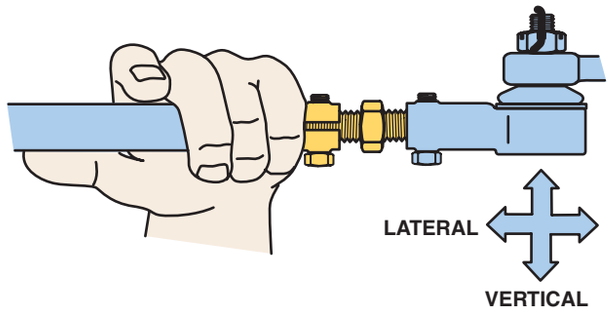

FIGURE 117–30 All joints should be checked by hand for any lateral or vertical play.

2. Idler arm inspection is performed by using *hand* force of 25 lb (110 N-m) up and down on the arm. If the *total* movement exceeds 1/4 in. (6 mm), the idler arm should be replaced. ● **SEE FIGURE 117–28.**
3. All other steering linkage should be tested *by hand* for any vertical or side-to-side looseness. Tie rod ends use ball-and-socket joints to allow for freedom of movement for suspension travel and to transmit steering forces to the front wheels. It is therefore normal for tie rods to rotate in their sockets when the tie rod sleeve is rocked. **Endplay in any tie rod should be zero.** Many tie rods are spring loaded to help keep the ball-and-socket joint free of play as the joint wears. Eventually, the preloaded spring cannot compensate for the wear, and endplay occurs in the joint. ● **SEE FIGURES 117–29 AND 117–30.**
4. All steering components should be tested with the wheels in the straight-ahead position. If the wheels are turned, some apparent looseness may be noticed due to the angle of the steering linkage.

REAL WORLD FIX

Bump Steer

Bump steer, or *orbital steer,* is used to describe what happens when the steering linkage is not level: The front tires turn inward or outward as the wheels and suspension move up and down. (Automotive chassis engineers call it *roll steer.*) The vehicle's direction is changed *without moving the steering wheel* whenever the tires move up and down over bumps, dips in the pavement, or even over gentle rises!

This author experienced bump steer once and will never forget the horrible feeling of not having control of the vehicle. After replacing an idler arm and aligning the front wheels, everything was OK until about 40 mph (65 km/h); then the vehicle started darting from one lane of the freeway to another. Because there were no "bumps" as such, bump steer was not considered as a cause. Even when holding the steering wheel perfectly still and straight ahead, the vehicle would go left, then right. Did a tie rod break? It certainly felt exactly like that's what happened. I slowed down to below 30 mph and returned to the shop.

After several hours of checking everything, including the alignment, I discovered that the idler arm was not level with the pitman arm. This caused a pull on the steering linkage whenever the suspension moved up and down. As the suspension compressed, the steering linkage pulled inward on the tie rod on that side of the vehicle. As the wheel moved inward (toed in), it created a pull just as if the wheel were turned by the driver.

This is why all steering linkages must be parallel with the lower control. The reason for the bump steer was that the idler arm was bolted to the frame, which was slotted vertically. I didn't pay any attention to the location of the original idler arm and simply bolted the replacement to the frame. After raising the idler arm back up where it belonged (about 1/2 in. [13 mm]), the steering problem was corrected.

Other common causes of bump steer are worn or deteriorated rack mounting bushings, a noncentered steering linkage, or a bent steering linkage. If the steering components are not level, any bump or dip in the road will cause the vehicle to steer one direction or the other. ● **SEE FIGURE 117–31.**

Always check the steering system carefully whenever a customer complains about any "weird" handling problem.

TECH TIP

The Killer Bs

The "three Bs" that can cause steering and suspension problems are bent, broken, or binding components. Always inspect each part under the vehicle for each of the killer Bs.

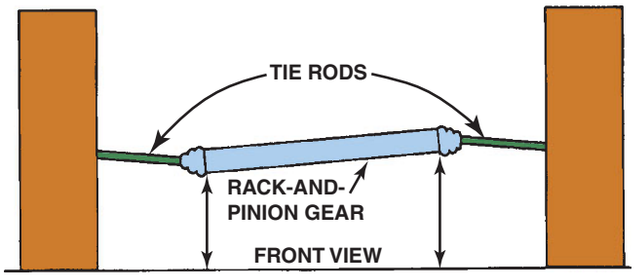

FIGURE 117–31 If a rack-and-pinion or any other steering linkage system is not level, the front tires will be moved inward and/or outward whenever the wheels of the vehicle move up or down.

CAUTION: Do not turn the front wheels of the vehicle while suspended on a lift to check for looseness in the steering linkage. The extra leverage of the wheel and tire assembly can cause a much greater force to be applied to the steering components than can be exerted by hand alone. This extra force may cause some apparent movement in good components that may not need replacement.

STEERING LINKAGE REPLACEMENT

PARALLELOGRAM TYPE

When replacing any steering system component, it is best to replace all defective and marginally good components at the same time. Use the following guidelines.

Parts that can be replaced *individually* include the following:

Idler arm

Center link

Pitman arm

Intermediate shaft

Intermediate shaft U-joint

Parts that should be replaced in *pairs only* include the following:

Outer tie rod ends

Inner tie rod ends

Idler arm (if there are two on the same vehicle, such as GM's Astro van)

Replacing steering system components involves these steps:

STEP 1 Hoist the vehicle safely with the wheels in the straight-ahead position. Remove the front wheels, if necessary, to gain access to the components.

STEP 2 Loosen the retainer nut on tapered components, such as tie rod ends. Use a tie rod removal puller (also called a *taper breaker),* as shown in ● **FIGURE 117–32**, or use hammers to slightly deform the taper, as shown in ● **FIGURE 117–33**.

CAUTION: Vehicle manufacturers often warn not to use a tapered pickle-fork tool to separate tapered parts. The wedge tool can tear the grease seal and damage both the part being removed and the adjoining part.

Pitman arms require a larger puller to remove the pitman arm from the splines of the pitman shaft. ● **SEE FIGURES 117–34 AND 117–35**.

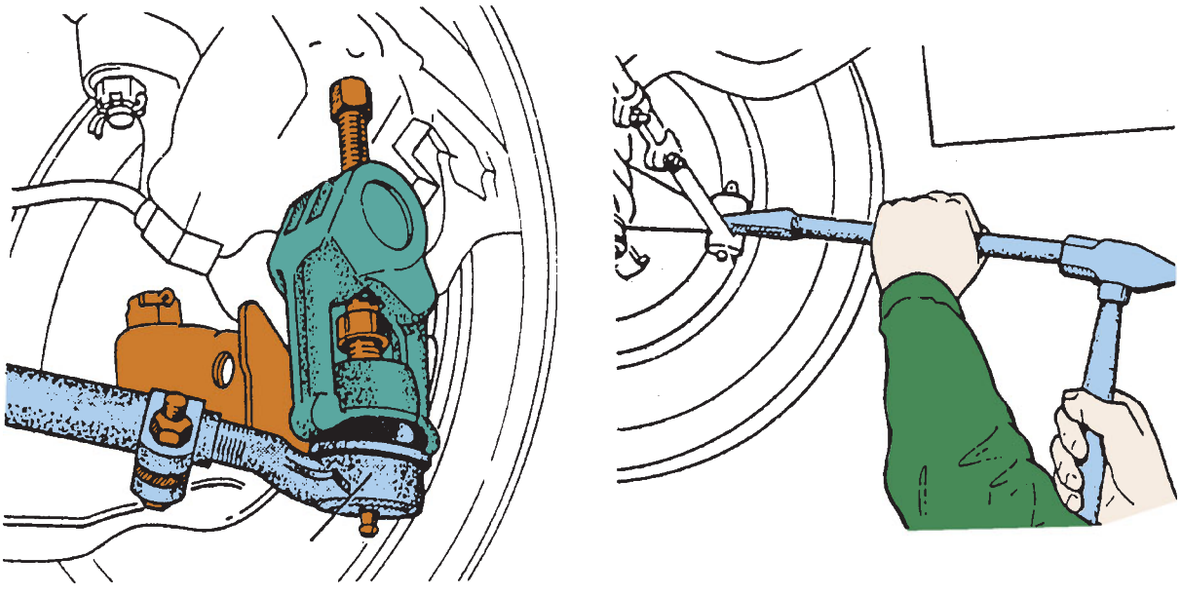

FIGURE 117–32 The preferred method for separating the tie rod end from the steering knuckle is to use a puller such as the one shown. A pickle-fork-type tool should only be used if the tie rod end is going to be replaced. A pickle-fork-type tool can damage or tear the rubber grease boot.

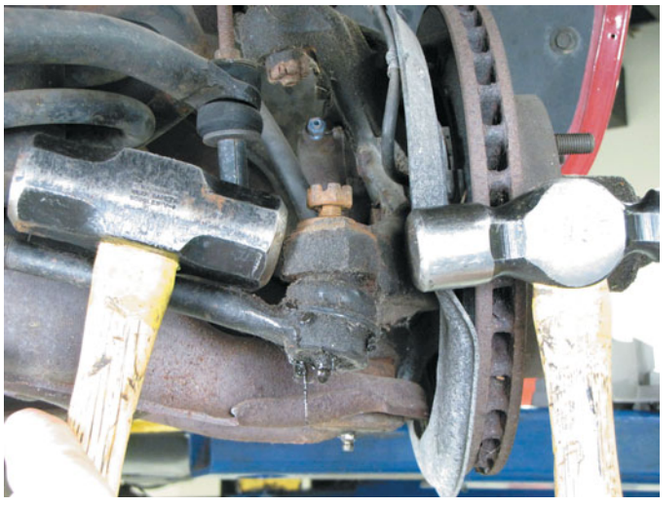

FIGURE 117–33 Two hammers being used to disconnect a tie rod end from the steering knuckle. One hammer is used as a backing for the second hammer. Notice that the attaching nut has been loosened, but not removed. This prevents the tie rod end from falling when the tapered connection is knocked loose.

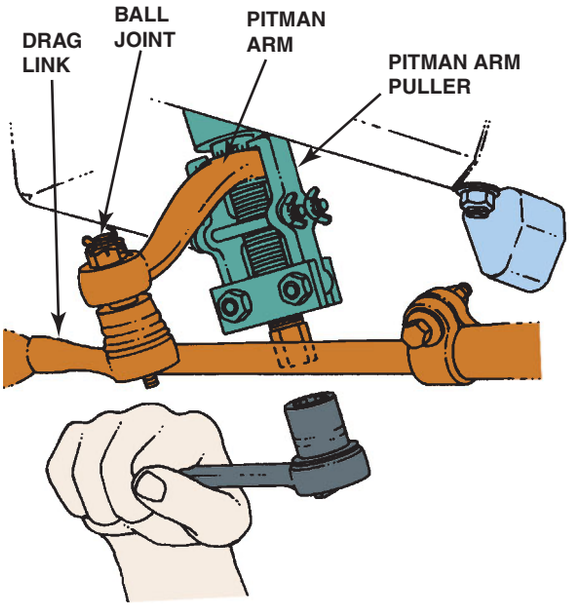

FIGURE 117–34 A pitman arm puller is used to remove the pitman arm from the pitman shaft.

STEP 3 Replace the part using the hardware and fasteners supplied with the replacement part. *Do not reuse the precrimped torque prevailing nuts used at the factory as original equipment on many tie rod ends.*

CAUTION: Whenever tightening the nuts of tapered parts such as tie rods, *DO NOT* loosen after reaching the proper assembly torque to align the cotter key hole. If the cotter key does not fit, *tighten* the nut farther until the hole lines up for the cotter key. ● SEE FIGURE 117–36. Always use a new cotter key.

When replacing tie rod ends, use the adjusting sleeve to adjust the total length of the tie rod to the same position and length as the original. Measure the original length of the tie rods and assemble the replacement tie rod(s) to the same overall length. ● **SEE FIGURE 117–37.**

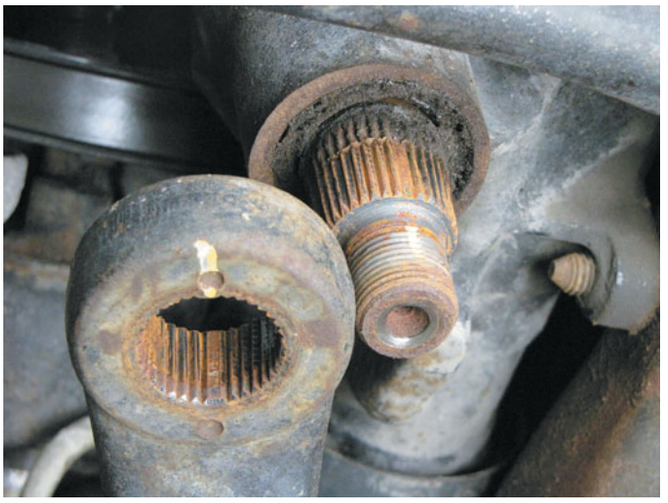

FIGURE 117–35 Pitman arm and pitman shaft indexing splines.

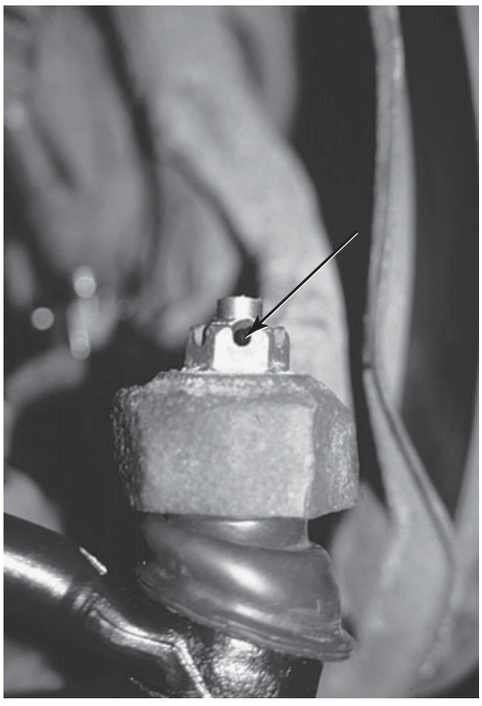

FIGURE 117–36 Align the hole in the tie rod end with the slot in the retaining nut. If the holes do not line up, always tighten the nut farther (never loosen) until the hole lines up.

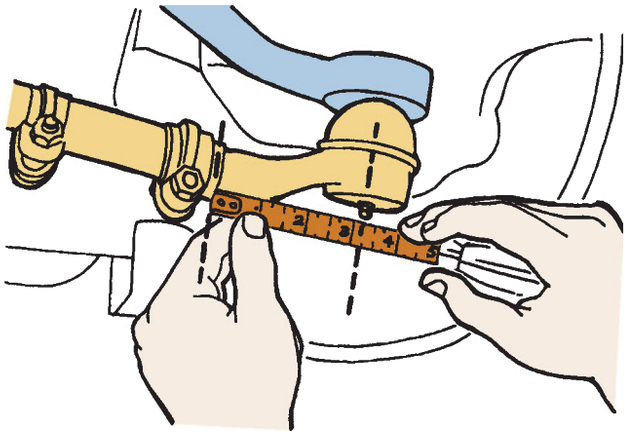

FIGURE 117–37 Replacement tie rods should be of the same overall length as the originals. Measure from the edge of the tie rod sleeve to the center of the grease fitting. When the new tie rod is threaded to this dimension, the toe setting will be close to the original.

When positioning the tie rod end(s), check that the stud is centered in the socket, as shown in ● **FIGURE 117–38.** This permits maximum steering linkage movement without getting into a bind if the steering linkage is pivoted beyond the angle the tie rod end can move in the socket.

NOTE: To ensure proper wheel alignment, install the adjusting sleeve with an equal number of threads showing at each end of the sleeve. Some manufacturers also specify a *minimum* of three threads showing at each end. If the sleeve itself is corroded or bent, it should be replaced along with either or both of the tie rod ends (inner and outer). ● **SEE FIGURE 117–39.**

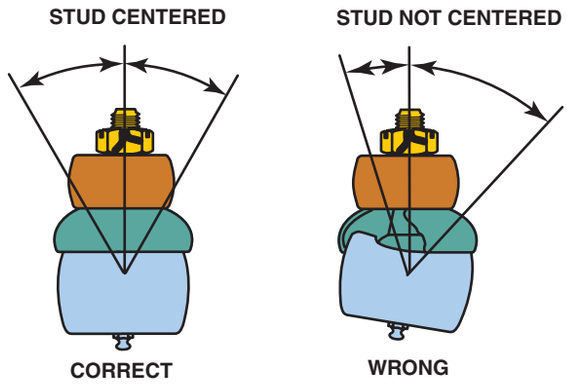

FIGURE 117–38 All tie rod ends should be installed so that the stud is in the center of its operating range, as shown.

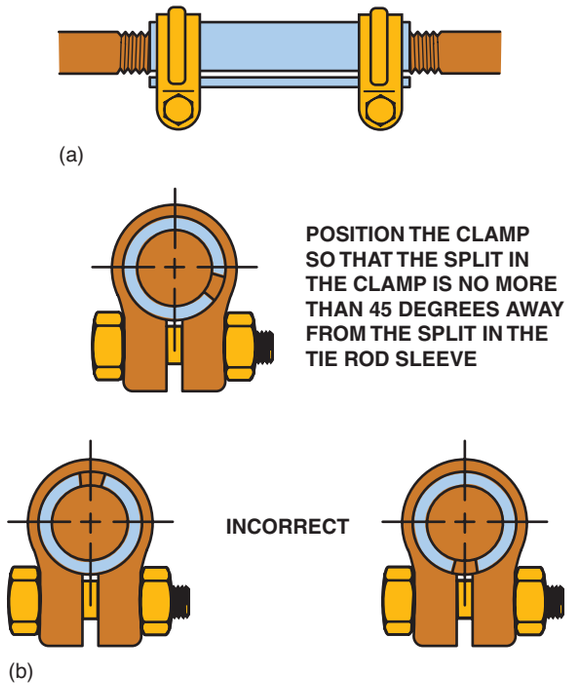

FIGURE 117–39 (a) Tie rod adjusting sleeve. (b) Be sure to position the clamp correctly on the sleeve.

SERVICE OF BALL SOCKET ASSEMBLIES

Inner tie rod end assemblies used on rack-and-pinion steering units require special consideration and often special tools. The inner tie rod end, also called a ball socket assembly, should be replaced whenever there is any noticeable freeplay in the ball-and-socket joint. Another test of this joint is performed by disconnecting the outer tie rod end and measuring the effort required to move the tie rod in the socket, as shown in ● **FIGURE 117–40.** This is called the **articulation test.**

NOTE: The articulation test is to be used on metal-to-metal ball socket assemblies. Low-friction joints (polished ball and plastic liner-type joints) may require less effort to move and still be serviceable.

The inner tie rod assemblies are attached to the end of the steering rack by one of several methods.

Removing a ball socket assembly usually requires the use of two wrenches or a special tool. ● **SEE FIGURE 117–41.**

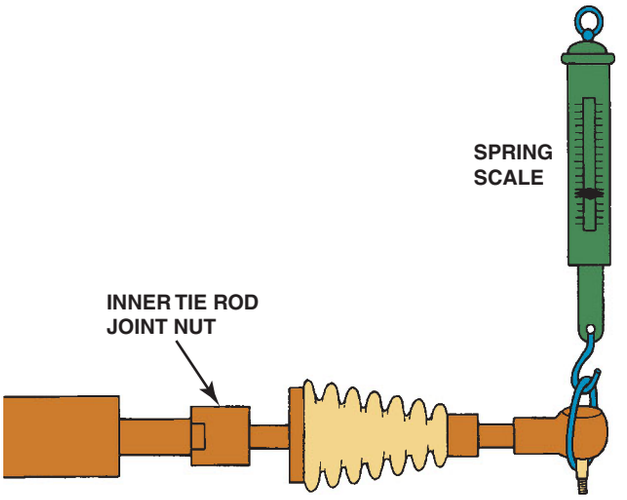

FIGURE 117–40 An articulation test uses a spring scale to measure the amount of force needed to move the tie rod in the ball socket assembly. Most manufacturers specify a minimum of 1 lb (4.4 N) of force and a maximum of 6 lb (26 N).

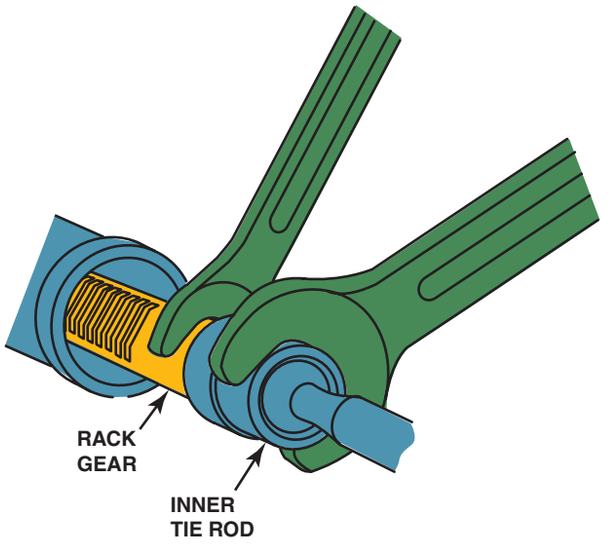

FIGURE 117–41 Removing a staked inner tie rod assembly requires two wrenches—one to hold the rack and the other to unscrew the joint from the end of the steering rack.

The flange around the outer tie rod must be restaked to the flat shoulder on the end of the rack, as shown in ● **FIGURE 117–42.**

Always follow the instructions that come with the replacement part(s). ● **SEE FIGURE 117–43.**

NOTE: When replacing a rack-and-pinion assembly, specify an entire replacement rack and pinion assembly if possible. A short rack does not include the bellows (boots) or inner tie rod ends (ball socket assemblies). The labor and cost required to exchange or replace these parts usually make it easier and less expensive to replace the entire steering unit.

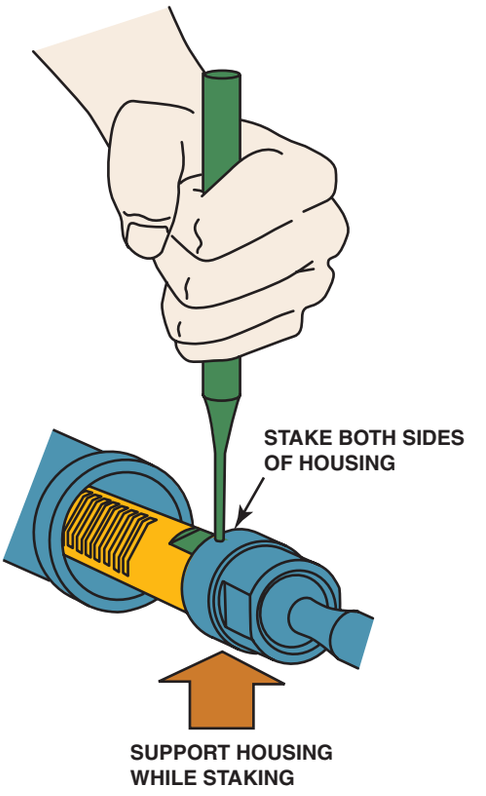

FIGURE 117–42 When the inner tie rod end is reassembled, both sides of the housing must be staked down onto the flat shoulder of the rack.

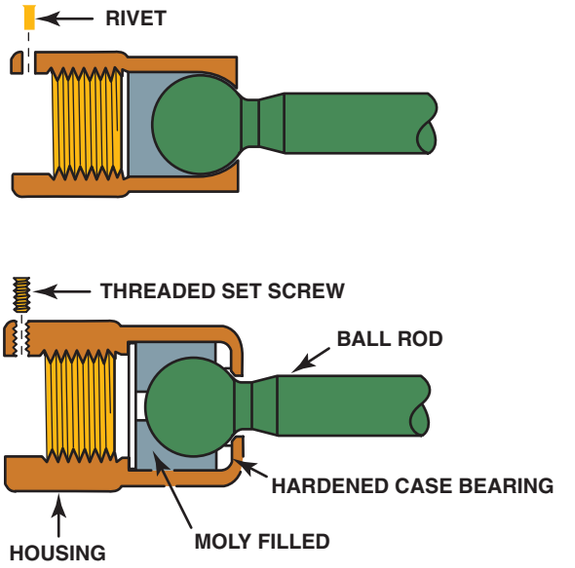

FIGURE 117–43 After replacing an inner tie rod end, the socket assembly should be secured with a rivet or set screw depending on the style of the replacement part.

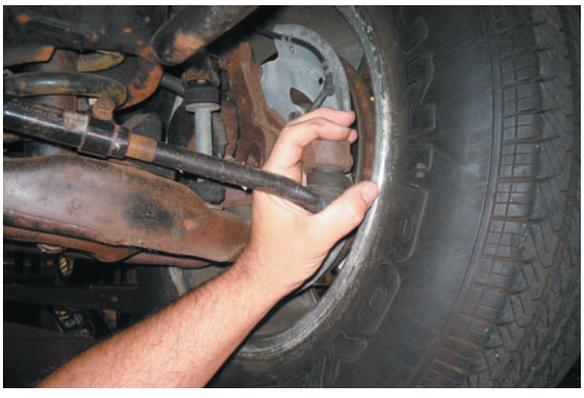
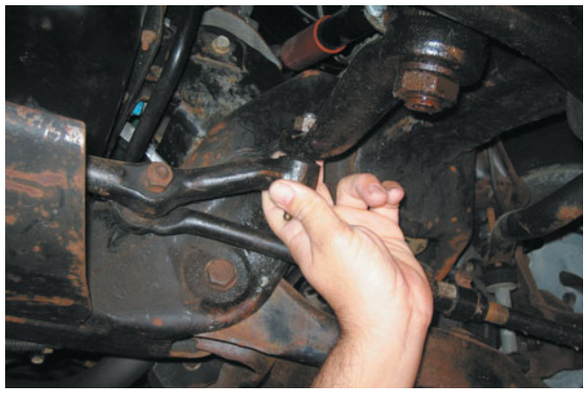
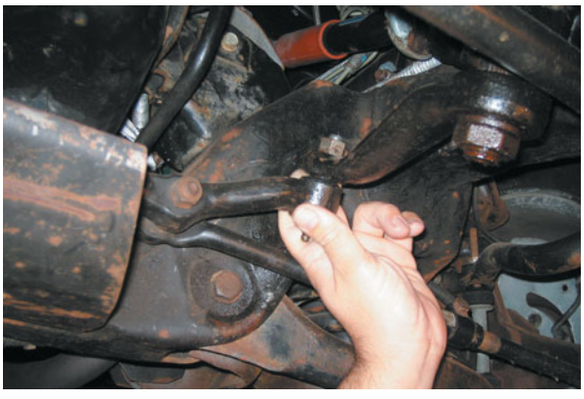


DRY PARK TEST



1 Drive the vehicle onto a drive-on-type hoist and have an assistant gently rotate the steering wheel back and forth about 2 inches (50 mm).



2 Perform a visual inspection of the steering and suspension system, looking for damage from road debris or other faults.

3 As the assistant wiggles the steering wheel, grasp the joint at the outer tie rod end on the driver's side to check for any movement.

4 Next, check for any freeplay at the pitman arm.

5 Check the joint between the left inner tie rod end and the center link for play.

6 Move to the passenger side and check for any looseness at the joint between the center link and the right-side inner tie rod end.

7 Check for looseness at the idler arm connector to the center link and the idler arm at the frame mount.

8 Check for looseness at the passenger-side outer tie rod end. After the inspection, record the results on the work order.

REVIEW QUESTIONS

1. Describe how to perform a dry park test.
2. List the steering parts that should be replaced in pairs.
3. What test procedure can be used to check that the steering linkage is straight and level?
4. What is the difference between a wear and nonwear center link?

CHAPTER QUIZ

1. A "dry park" test to determine the condition of the steering components and joints should be performed with the vehicle _____.
   a. On level ground or on a drive-on lift
   b. On turn plates that allow the front wheels to move
   c. On a frame contact lift with the wheels off the ground
   d. Lifted off the ground about 2 in. (5 cm)
2. Two technicians are discussing bump steer. Technician A says that an unlevel steering linkage can be its cause. Technician B says that if the steering wheel moves when the vehicle is bounced up and down, the steering linkage may be bent. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
3. A vehicle has an excessive amount of freeplay in the steering wheel and it is difficult to keep it traveling straight on a straight and level road. Which is the *least likely* cause?
   a. Worn tie rod ends
   b. Excessive play in the ball socket assemblies
   c. Worn idler arms
   d. Loose pitman arm retaining nut
4. How are the inner tie rods attached to the rack on a center-take-off-type rack-and-pinion steering gear?
   a. Staked **c.** Riveted
   b. Bolted **d.** Pinned
5. What is the *most likely* cause of bump steer?
   a. Worn outer tie rod ends
   b. A worn center link
   c. Worn or oil-soaked rack bushings
   d. A lack of proper lubrication of all ball-and-socket joints
6. How much endplay is usually acceptable in tie rod ends?
   a. Zero **c.** 0.030 to 0.050 in.
   b. 0.0010 to 0.030 in. **d.** 0.050 to 0.100 in.
7. Technician A says that outer tie rod ends should be replaced in pairs, even if only one is worn. Technician B says that inner tie rod ends should be replaced in pairs, even if only one is worn. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
8. Which tool is *not* recommended to be used to separate tapered steering components because it can do harm?
   a. Taper breaker **c.** Tie rod removal puller
   b. Pickle fork **d.** Two hammers
9. Technician A says that torque prevailing nuts can be reused unless damaged. Technician B says that a new cotter key should always be used. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. New tie rods are being installed. Technician A says to tighten the retaining nuts to specification and then loosen, if needed, to align the cotter pin hole. Technician B says to tighten farther to align the cotter key hole. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 118

POWER-ASSISTED STEERING OPERATION AND SERVICE

OBJECTIVES: **After studying Chapter 118, the reader will be able to:** • Prepare for ASE Suspension and Steering (A4) certification test content area "A" (Steering Systems Diagnosis and Repairs). • Discuss the components and operation of power steering pumps. • List the components of a typical power-recirculating-ball-nut steering gear system. • Describe the operation of a power rack-and-pinion steering system. • Discuss how electric power steering works • Describe how to perform a power steering pressure and volume test. • Explain how to flush power steering fluid.

KEY TERMS: BPP 1402 • EHPS 1402 • EPS 1399 • EVO 1397 • Flow control valve 1390 • Force 1388 • Integral reservoir 1389 • Magnasteer 1397 • Pascal's law 1388 • Pressure 1388 • Pressure-relief valve 1391 • PSCM 1400 • PSP 1391 • Remote reservoir 1389 • Rotary control valve 1392 • Self-park 1401 • SPS 1401 • SSS 1397 • TFE 1397 • VES 1396

POWER STEERING HYDRAULIC SYSTEMS

PURPOSE AND FUNCTION Power-assisted steering hydraulically boosts the mechanical steering gear operation so the driver can turn the steering wheel with less effort for the same response. Hydraulic power steering has been available since the 1950s, and many late-model systems are enhanced by electronic controls.

PRINCIPLES INVOLVED Hydraulics is the study of liquids and their use to transmit force and motion. Hydraulic systems transmit force and motion through the use of fluid pressure. **Force** is a push or pull acting on an object and is usually measured in pounds or Newtons. **Pressure** is force applied to a specific area. Pressure is usually measured in force per unit of area, such as pounds per square inch (PSI), or kilopascals (kPa). One PSI is equal to 6.895 kPa.

The Pascal is a unit of measure named after the French scientist Blaise Pascal (1623–1662), who studied the behavior of fluids in closed systems. One of his discoveries, known as **Pascal's law,** was that pressure on a confined fluid is transmitted equally in all directions and acts with equal force on equal areas.

Hydraulic systems can transmit force and motion through liquids because, for all practical purposes, a liquid cannot be compressed. No matter how much pressure is placed on a liquid, its volume remains the same. This allows a liquid to transmit force much like a mechanical lever. ● **SEE FIGURE 118–1.**

The advantage of a liquid over a mechanical lever is that a liquid has volume but does not have a fixed shape. Because it assumes the shape of its container, a liquid can transfer force around obstacles or through pipes and passages of any shape. As explained by Pascal's law, a liquid can also decrease or increase the force it transmits depending on the area of the output surface to which the force is applied. ● **SEE FIGURE 118–2.**

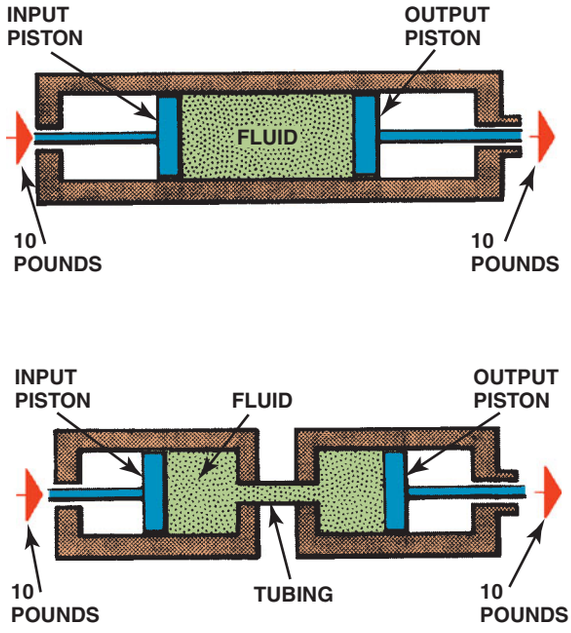


FIGURE 118–1 Hydraulic fluid transmits the same force whether it passes through a single chamber or two chambers connected by a narrow passage.

POWER STEERING PUMP AND RESERVOIR

PURPOSE AND FUNCTION The power steering pump draws fluid from the reservoir, pressurizes it, and delivers it to the power steering system. A power steering pump produces a high-pressure stream of fluid, typically in the 1,500-PSI (10,500 kPa) range. The fluid reservoir may be either integral to (built into) the pump or remotely mounted and connected to the pump by a hose. The power

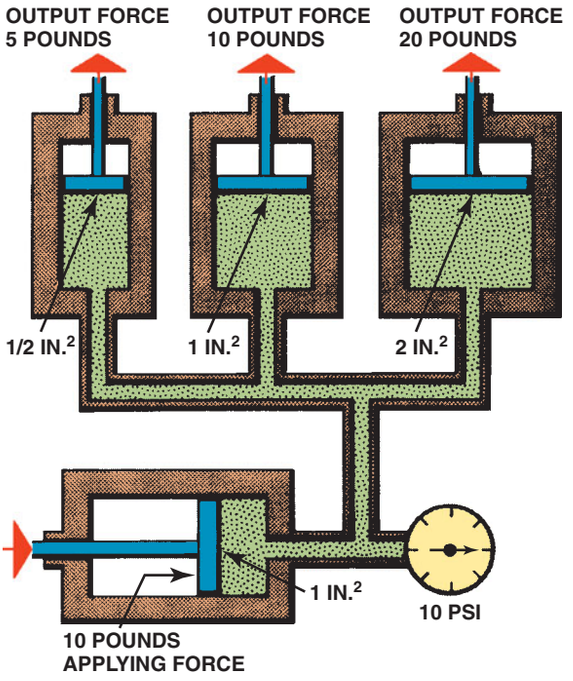

FIGURE 118–2 A fluid applies a force equal to the applied force on a surface that is equal in size to the applying surface. If the surface is half the size, then the fluid exerts half the force: if the surface is twice as large, the fluid exerts twice the force.

steering fluid reservoir is usually made of either plastic or stamped metal, and it includes the fluid filler neck, cap, and dipstick. An **integral reservoir** is part of the pump, and the pump itself operates submerged in power steering fluid. ● **SEE FIGURE 118–3.** Although once common, steering pumps with an integral reservoir have given way to those with a remote reservoir on many current-production vehicles. This is because the remote reservoir allows for a smaller, more compact pump assembly that is better suited to the cramped engine compartment of a modern vehicle.

A **remote reservoir** is a separate assembly from the pump and provides fluid to it through a suction hose. ● **SEE FIGURE 118–4.**

OPERATION

A typical power steering system requires only 2 to 3.5 lb (0.9 to 1.6 kg) of effort to turn the steering wheel.

Most power steering systems use an engine-driven hydraulic pump. Power steering hydraulic pumps are usually belt driven from the front crankshaft pulley of the engine. Pumps come in many sizes and styles. ● **SEE FIGURE 118–5.**

The power steering pump delivers a constant flow of hydraulic fluid to the power steering gear or rack. A typical power steering pump requires less than 1/2 horsepower, which is less than 1% of engine power while driving straight ahead. Even while parking at low speed, the power steering requires only about 3 horsepower while providing high hydraulic pressures. Typical pressures generated by a power steering system include the following.

Straight ahead	less than 150 PSI (1,400 kPa)
Cornering	about 450 PSI (3,100 kPa)
Parking (maximum)	750–1,400 PSI (5,200–10,0000 kPa)

The power steering pump drive pulley is usually fitted to a chrome-plated shaft with a press fit. The shaft is applied to a rotor with vanes that rotate between a thrust plate and a pressure plate. ● **SEE FIGURE 118–6.**

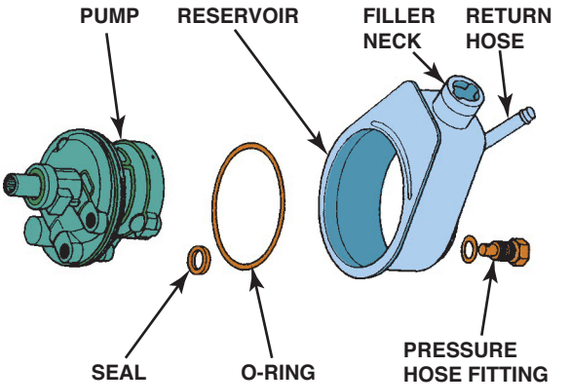

FIGURE 118–3 A typical integral power steering pump when the pump is mounted inside the reservoir.

FIGURE 118–4 Typical remote reservoir.

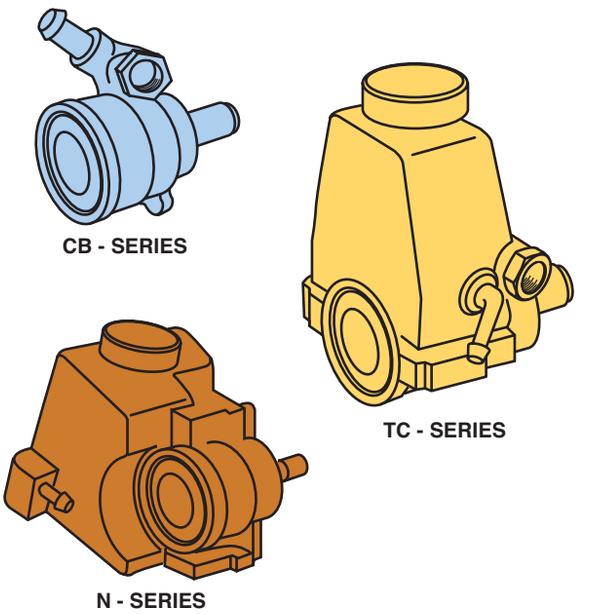

FIGURE 118–5 Typical power steering pump assemblies.

TYPES OF PUMPS

Some power steering pumps are of the slipper or roller design instead of the vane type. When the engine starts, the drive belt rotates the power steering pump pulley and the rotor assembly inside the power steering pump.

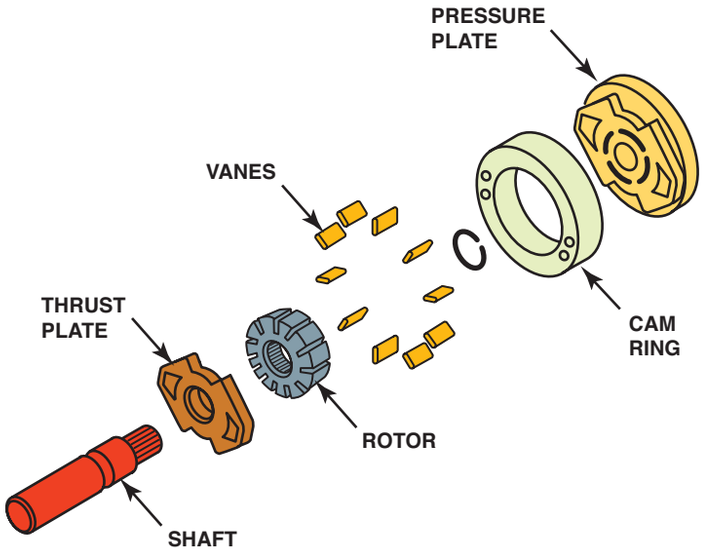

FIGURE 118–6 General Motors vane-type pump.

With a vane-type pump, centrifugal force and hydraulic pressure push the vanes of the rotor outward into contact with the pump ring. The shape of the pump ring causes a change in the volume of fluid between the vanes. As the volume increases, the pressure is decreased in the space between the vanes and draws in fluid from the pump reservoir. When the volume between the vanes decreases, the pressure is increased and flows out the pump discharge port. ● **SEE FIGURES 118–7, 118–8, AND 118–9.**

PRESSURE AND VOLUME CONTROL The pressure outlet hose connects to a fitting that threads into the outlet port of the pump body. A modulator valve, commonly called a **flow control valve,** installs in the same bore as the hose fitting. ● **SEE FIGURE 118–10.**

The modulator valve is a spring-loaded pressure-relief device that bleeds off excess pressure to prevent system damage. When pump output is more than the power steering system requires, the excess pressure overcomes spring force and moves the valve down in its bore. This uncovers an orifice through which the fluid can flow back into the inlet passages. An orifice is a small opening

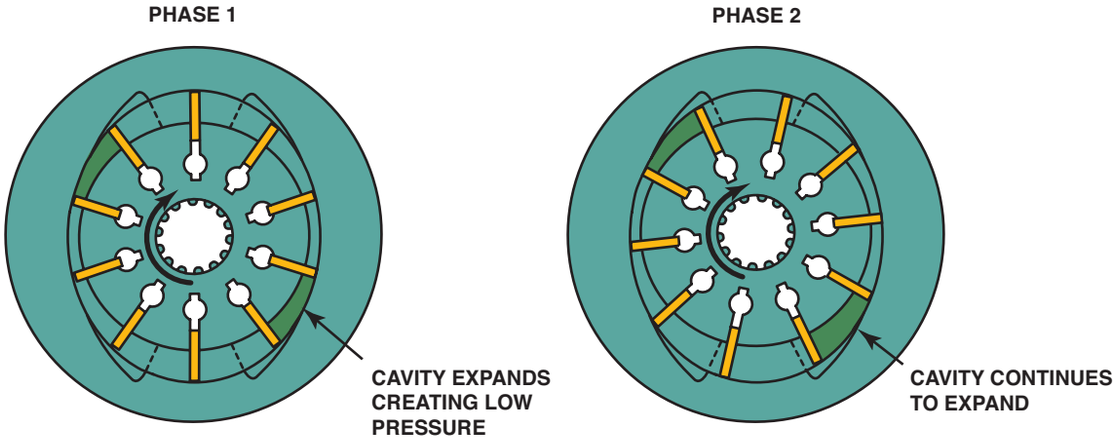

FIGURE 118–7 Vane pump operation. In phase 1, the rotor moves past the opposed suction ports, and the vanes move out to maintain contact with the ring. This creates a low-pressure area, drawing fluid into the cavities formed by the vanes. As the rotor continues to move during phase 2, the vanes follow the contour of the ring. The contour of the ring forms a larger cavity between the vanes. This increases the suction and draws more fluid into the pump.

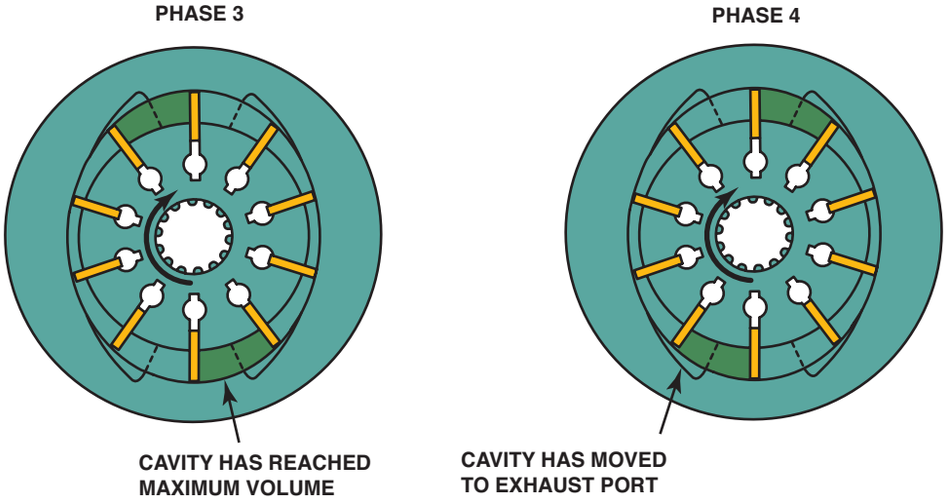

FIGURE 118–8 Vane pump operation—continued. At phase 3, the vanes are at the end of the intake port of the pump and the cavity has reached its maximum volume. In phase 4, the rotor moves into alignment with the opposed discharge ports.

that regulates fluid pressure and flow. It can be a restriction in a fluid line or a hole between two fluid chambers. This particular opening is called a *variable orifice* because the size of the opening varies with the amount of pressure applied to the valve. When fluid pressure is not high, spring force keeps the valve seated so that all of the pressurized fluid flows through the outlet port and into the pressure hose.

Because the engine drives the pump, the power steering pump places a load on the engine whenever the engine is running. Under certain conditions, such as when the steering wheel is turned to or near full stop for more than a few seconds, pressure builds in the system and the pump must work harder to keep up with the demand. As a result, the pump draws more power from the engine. If the engine is running at idle, the extra load can cause it to stall. A pressure switch, known as the **power steering pressure (PSP)** switch, transmits an electronic signal to the powertrain control module (PCM) when the pressure in the system is high enough to increase the load on the engine. In response to the PSP switch signal, the PCM increases the engine idle speed to prevent stalling.

The pressure increases when the steering wheel is turned to its full stop in either direction. To handle the excess pressure, a pressure-relief passage runs from a point near the pressure hose fitting to the spring end of the modulator valve. Inside the passage is a **pressure-relief valve.** The spring end of the modulator valve forms a seat for the pressure-relief check ball. Under normal circumstances, the check ball remains seated.

The parts of the pressure-relief valve are the following:

- Spring
- Valve piston
- Check ball
- Seat

A shim installs on the check ball seat to adjust the pressure at which the check ball unseats to open the pressure-relief valve. Normally, the spring force holds the piston against the check ball to keep it in its seat. When pressure becomes excessive in the pressure-relief passage, the check ball raises off its seat to allow fluid to flow through the relief passage and out through an orifice in the modulator valve. ● **SEE FIGURE 118–11.** The pressure when this occurs varies from 750 to 1,400 PSI (5,200 to 10,0000 kPa) depending on the calibration of the pressure-relief valve. When power steering systems are pushed to the limit, most will make a chattering or squealing noise until the pressure is reduced.

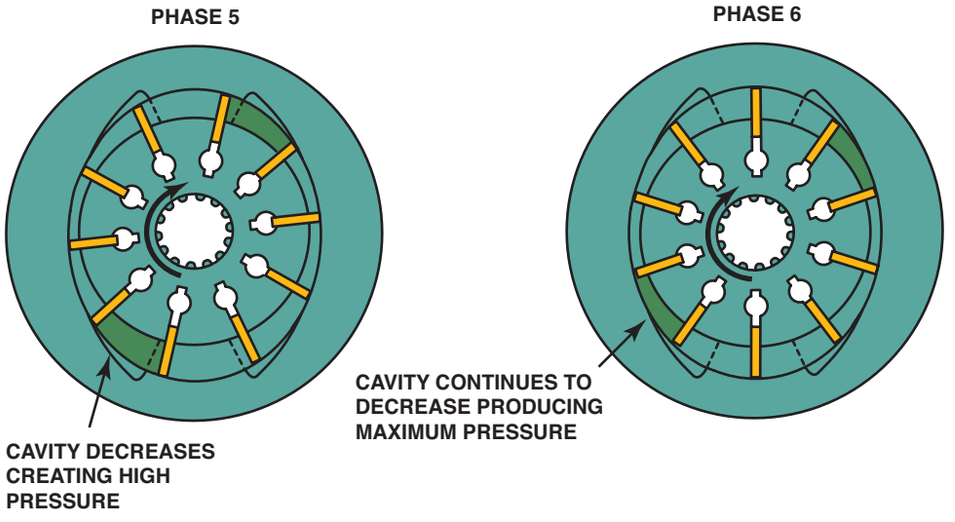

FIGURE 118–9 Vane pump operation—continued. As the rotor continues to move during phase 5, the volume of the cavity decreases, which increases the discharge pressure. At phase 6, the last phase, the contour of the ring results in the minimum cavity volume, and the discharge of fluid is completed.

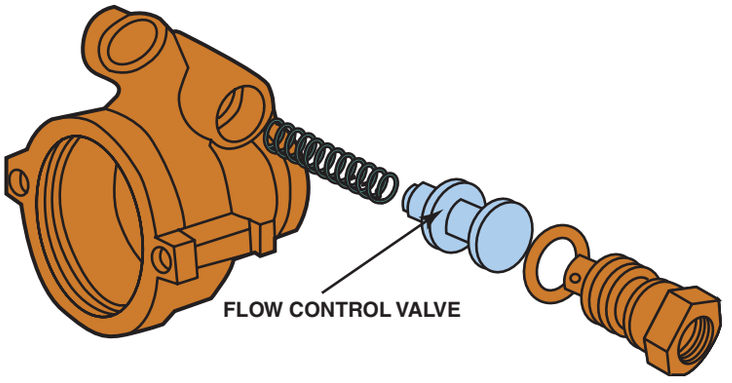

FIGURE 118–10 Flow control valve.

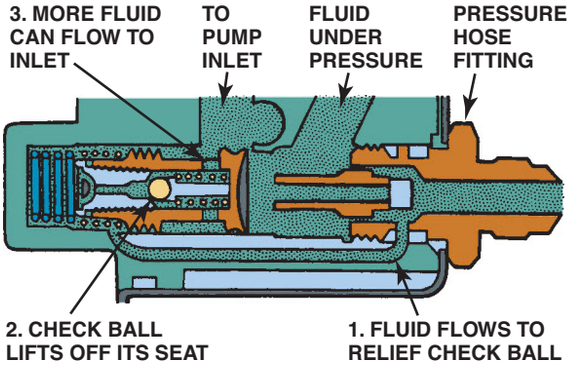

FIGURE 118–11 The pressure-relief check ball unseats, allowing fluid to flow back into the pump inlet if the pressure rises above a certain limit.

POWER STEERING HOSES

Because the power steering pump and the steering gear are not part of the same assembly, the system requires two hoses to connect the power steering pump and gear assembly. The pressure hose is connected to the flow control/relief valve. This hose supplies pressurized fluid to the steering gear. The second hose is called the return hose and it returns the fluid from the steering gear back to the pump. Some vehicles will use a cooler in the return path to the pump. The cooler is used to reduce the temperature of the fluid before it enters the pump. ● **SEE FIGURE 118–12.**

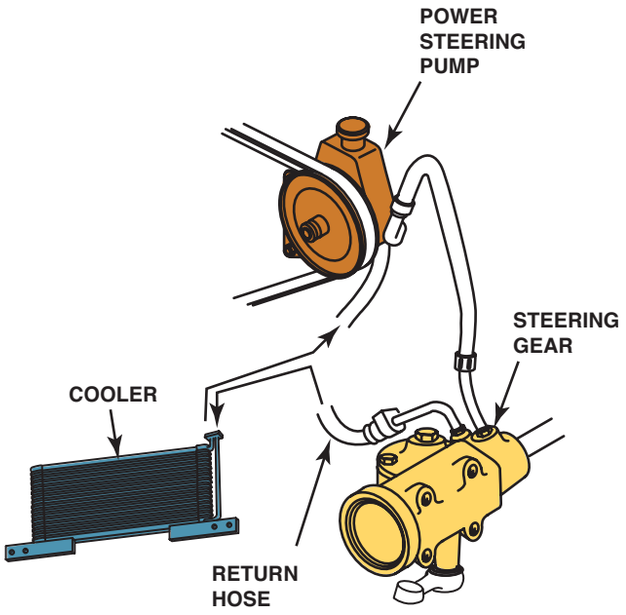

FIGURE 118–12 The power steering fluid cooler, if used, is located in the return hose. Often the "cooler" is simply a length of return metal line that is arranged in a loop and routed near the front of the vehicle. The airflow past the return line helps reduce the temperature of the fluid.

INTEGRAL POWER STEERING

In an integral power steering system, the control valve and the power piston are incorporated into the steering gear construction. The control valve regulates the application of pressurized fluid against the power piston, and the power piston helps move the output member of the steering gear when pressure is applied to one side of it.

INTEGRAL STANDARD STEERING GEAR

Most standard steering gears with power assist are the recirculating-ball type, and the ball nut functions as the power piston. Hydraulic pressure from the steering gear control valve is applied directly against the ball nut to help move it through the housing. The ball nut in this type of power steering gear is called the *power piston* because hydraulic pressure moves it as if it were a piston traveling in a cylinder. ● **SEE FIGURE 118–13.**

ROTARY CONTROL VALVE

A **rotary control valve** is a two-piece assembly that operates by rotating an inner valve within an outer valve. A steering gear with a rotary control valve is also a *torsion bar steering* gear, because a small torsion bar is used to control valve movement.

The rotary control valve consists of two cylindrical elements: the inner valve element and outer valve element. The inner valve element is secured to the steering gear input shaft and the torsion bar. In the valve, the inner element and the input shaft are one piece, and the torsion bar attaches to them. ● **SEE FIGURE 118–14.** The inner element assembly fits inside the outer valve element, and is also secured to the torsion bar by a pin. The outer valve element is also the steering worm gear. The torsion bar acts as a spring between the two elements to allow movement between them when the steering shaft turns. The spring force of the torsion bar tends to pull the elements back to their neutral positions when the steering wheel is released or returned to center. The strength of the torsion bar determines steering feel. A weak torsion bar moves easily and provides soft steering, while a strong bar resists movement and makes steering feel firm. Many high performance vehicles use a steering gear that has a thicker torsion bar to increase the firmness of the steering.

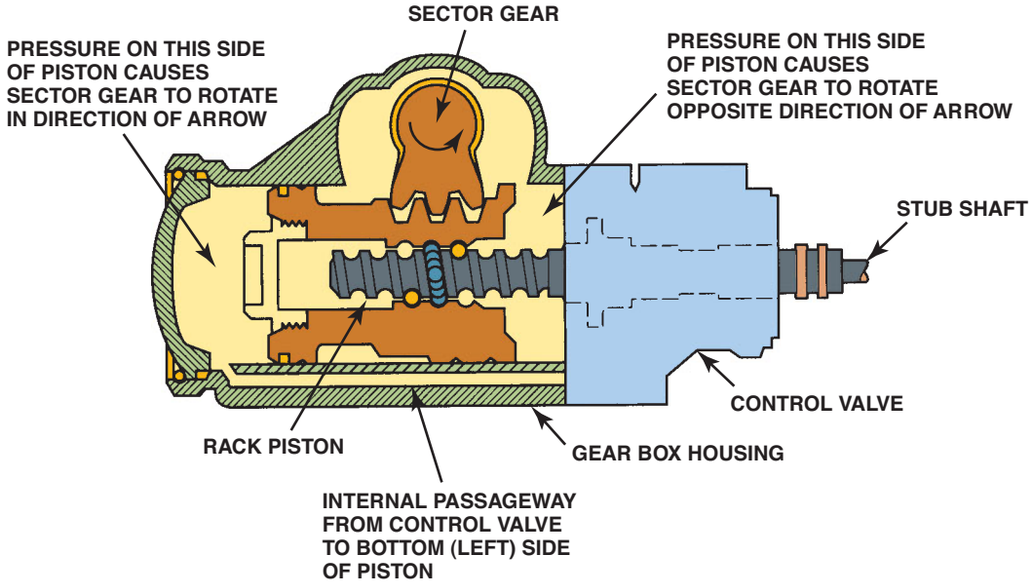

FIGURE 118–13 Forces acting on the rack piston of an integral power steering gear.

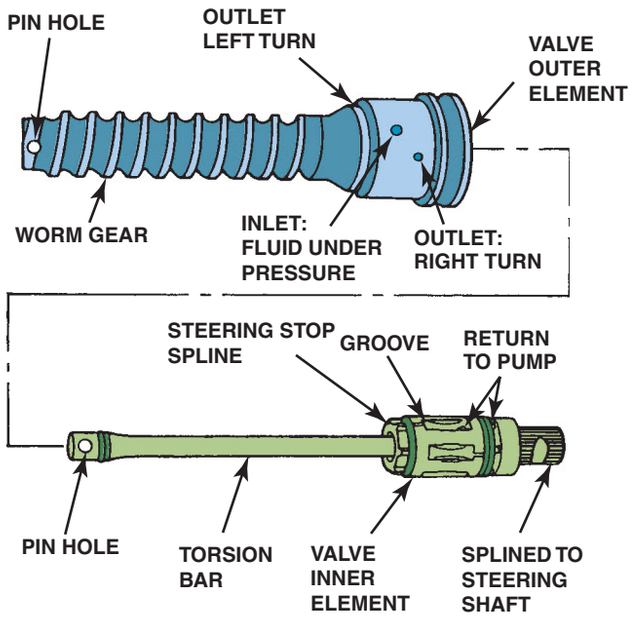

FIGURE 118–14 The rotary valve consists of inner and outer elements. The worm gear is part of the outer element and the torsion bar is part of the inner element. A pin attaches the worm gear to the bottom of the torsion bar to join the two elements together.

The facing surfaces of the inner and outer elements have grooves machined into them through which fluid can flow. Passages carry fluid from some of the inner-element grooves to the center of the element, where it travels through the return line to the pump reservoir. The outer element has three sets of fluid passages that connect the outside of the element to a groove at the inside. One set of passages carries fluid into the element from the pressure hose fitting, the second set carries fluid to and from the left-turn side of the power piston, and the third carries it to and from the right-turn side.

When the steering wheel is aimed straight ahead, the valve is in its neutral position. Fluid enters the valve and flows equally to both sides of the steering gear piston and to the return line. ● **SEE FIGURE 118–15.**

When the steering wheel and steering shaft turn to the left, the inner element twists on the torsion bar and repositions the valve ports. In this left-turn position, pressurized fluid flowing into the valve can only exit through the left-turn ports. ● **SEE FIGURE 118–16.** Meanwhile, the right-turn ports align with the return ports to bleed off residual pressure from the opposite side of the power piston. Pressurized fluid flowing through the left-turn ports is directed into the steering gear, where it applies force to the power piston and reduces the effort needed to turn the steering linkage to the left. ● **SEE FIGURE 118–17.** As the piston moves, it forces fluid out of the right-turn side, and that fluid returns through the control valve to the pump reservoir. Exactly the opposite flow occurs during a right-hand turn: The right-turn ports are opened and the left-turn ports exhaust to the return line. ● **SEE FIGURE 118–18.** Hydraulic pressure moves the piston up the housing bore during a right-hand turn. ● **SEE FIGURE 118–19.**

When the steering wheel is released, the spring force of the torsion bar returns the two elements to their natural positions. Fluid pressure equalizes throughout the steering gear and recenters the piston in the middle of the steering gear.

POWER RACK-AND-PINION STEERING The rotary control valve on a power rack-and-pinion steering gear is located between the steering gear input shaft and the pinion gear. ● **SEE FIGURE 118–20.**

STRAIGHT-AHEAD

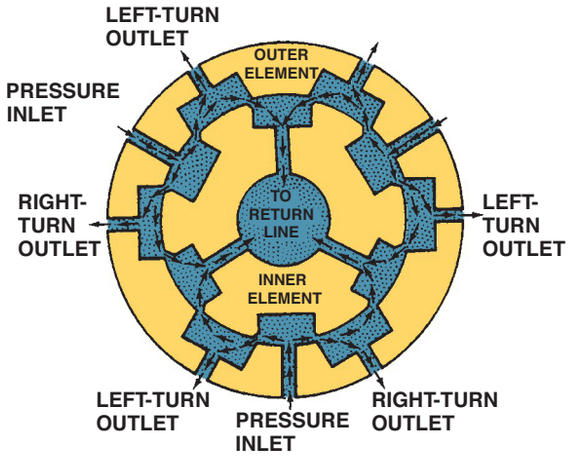

FIGURE 118–15 When the steering wheel is in the straight-ahead position, all of the ports in a rotary valve are open equally to the pressure and return circuits.

LEFT TURN

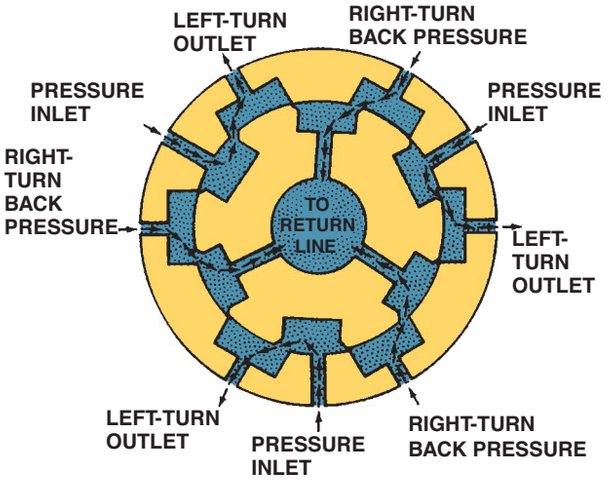

FIGURE 118–16 During a left turn, the inner element turns so that the left-turn circuits are open to pressure and the right-turn circuits are open to the return circuit.

Fluid discharged by the valve travels through external steel lines to either side of the power piston. A steel air-transfer tube allows air displacement between the boots as they compress and expand, since the power piston prevents air from passing through the rack housing. The rotary valve in a rack-and-pinion steering unit operates in the same manner as the one previously described for a standard steering gear. During a left-hand turn, the control valve directs fluid flow into the left-turn steel line, which routes it to the right-hand side of the power piston in order to move the rack to the left. As this happens, fluid on the opposite side of the power piston is forced out through the right-turn steel line and back to the control valve, where it is exhausted to the return circuit. When the steering wheel is turned to the right, fluid flow is reversed so the power piston moves to the right and fluid in the left-turn chamber is exhausted to the return circuit. ● **SEE FIGURE 118–21.**

FLOW CONTROL VALVE OPERATION When the power steering pump begins operation, the fluid from the output of the pump flows into the control valve. The fluid then flows through the orifice, where

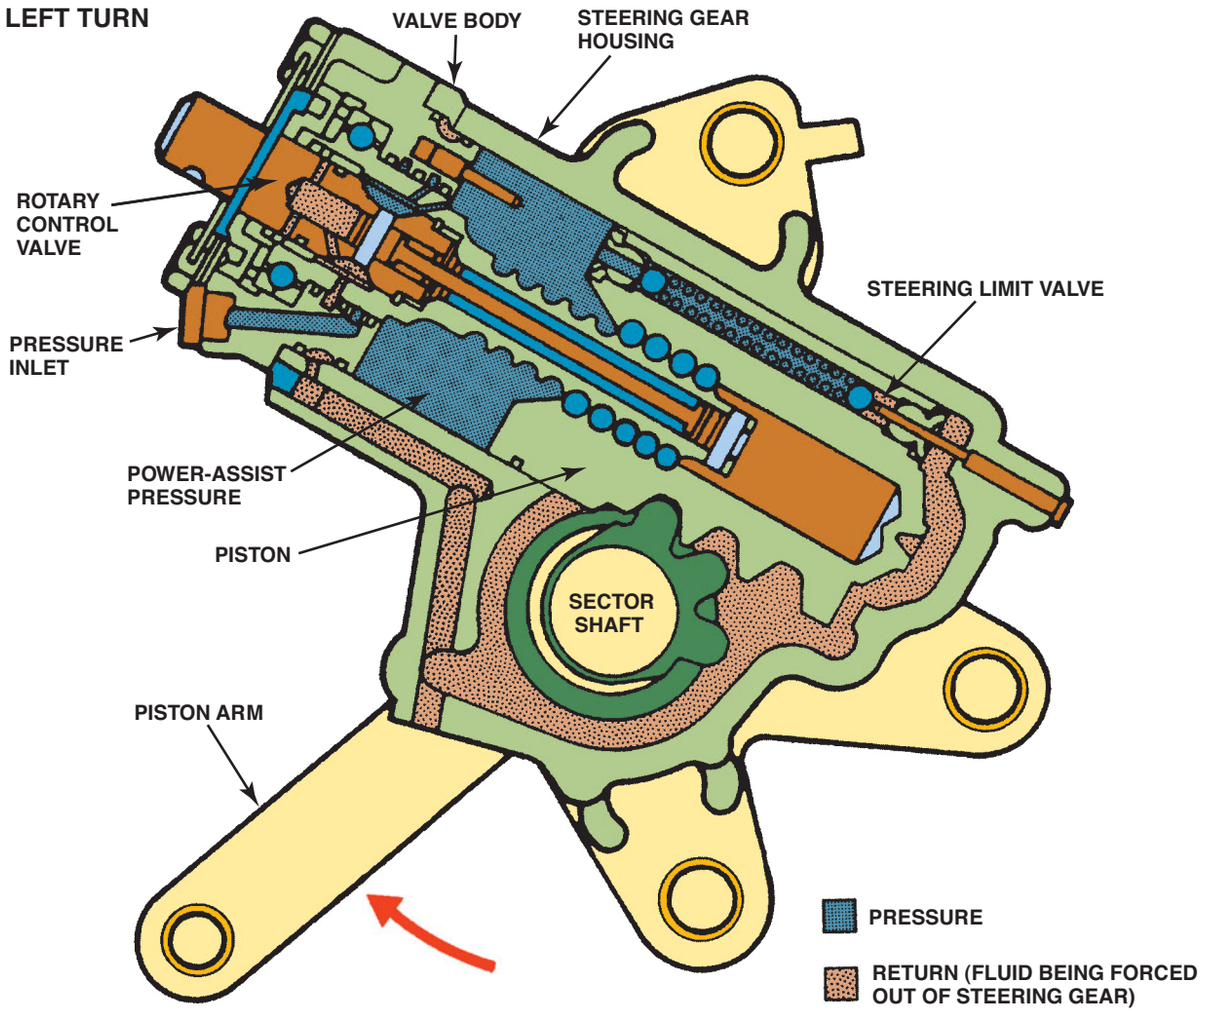

FIGURE 118–17 During a left turn, the high-pressure fluid helps push the piston along the worm gear, thereby reducing the steering effort from the driver.

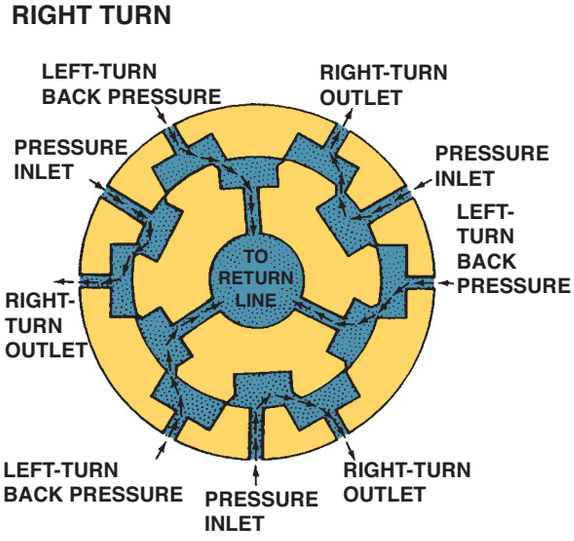

FIGURE 118–18 During a right turn, the inner element turns so that the right-turn outlets are open to pressure and the left-turn outlets are open to the return circuit.

a pressure differential is formed. The pressure differential results in a higher pressure on the pump side than on the system side. The fluid from the orifice flows into the power steering system and through a passage on the backside of the control valve. ● **SEE FIGURE 118–22.**

The fluid on the backside of the control valve is used to assist the spring force acting on the valve. At this point, the combination of the spring force and hydraulic pressure is higher than the output pressure of the pump. This causes the control valve to block the passage to the pump intake. When the output pressure is higher than the spring force, the pressure behind the valve forces the control valve to move. The movement of the valve opens the passage to the intake side of the pump. This allows some of the fluid to flow into the passage. As the pump speed continues to increase, the valve moves more to compensate for the higher pressure and flow. The pressure and flow in the power steering system must remain in the correct range or the steering system components can be damaged. Failure of the control valve to regulate the pressure in the power steering system can result in excessive pressure and temperature. As long as fluid can flow through the system, the control valve can regulate the pressure. ● **SEE FIGURE 118–23.**

However, there are times during normal operation when the flow in the system will stop. Fluid flow can stop during parking maneuvers and when the steering wheel is turned to the extreme right and left positions.

When the fluid flow through the system stops, the pressure equalizes on both sides of the orifice. This creates equal pressure on both sides of the control valve. Because the backside of the valve has a spring, the combination of the hydraulic pressure and spring force positions the control valve to prevent flow into the pump intake passage. As the pump continues to operate, the pressure in

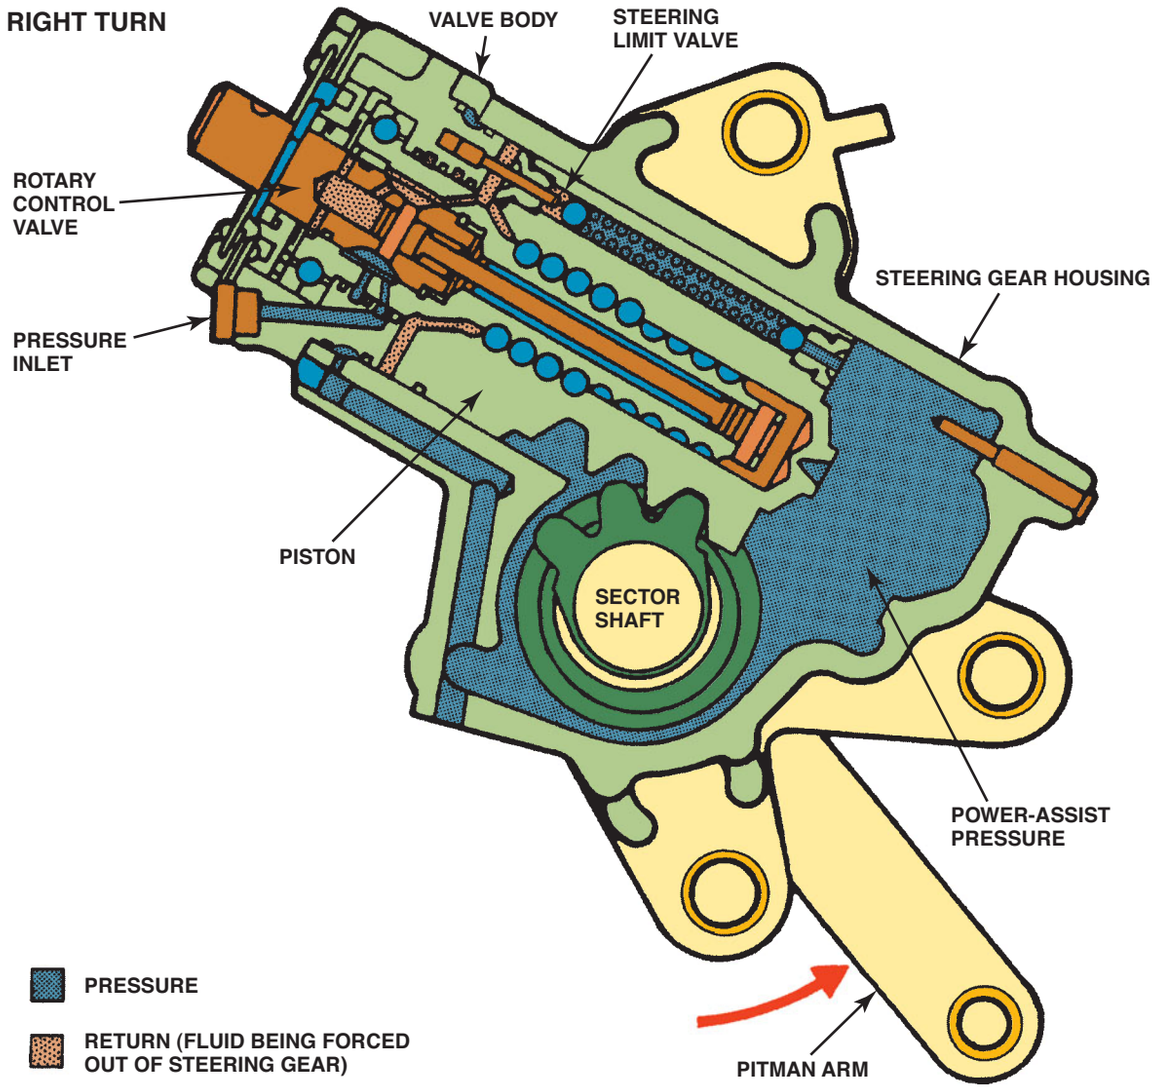

FIGURE 118–19 During a right turn, high-pressure fluid pushes the piston up the worm gear, moving the sector shaft and pitman arm to provide assist during a right turn.

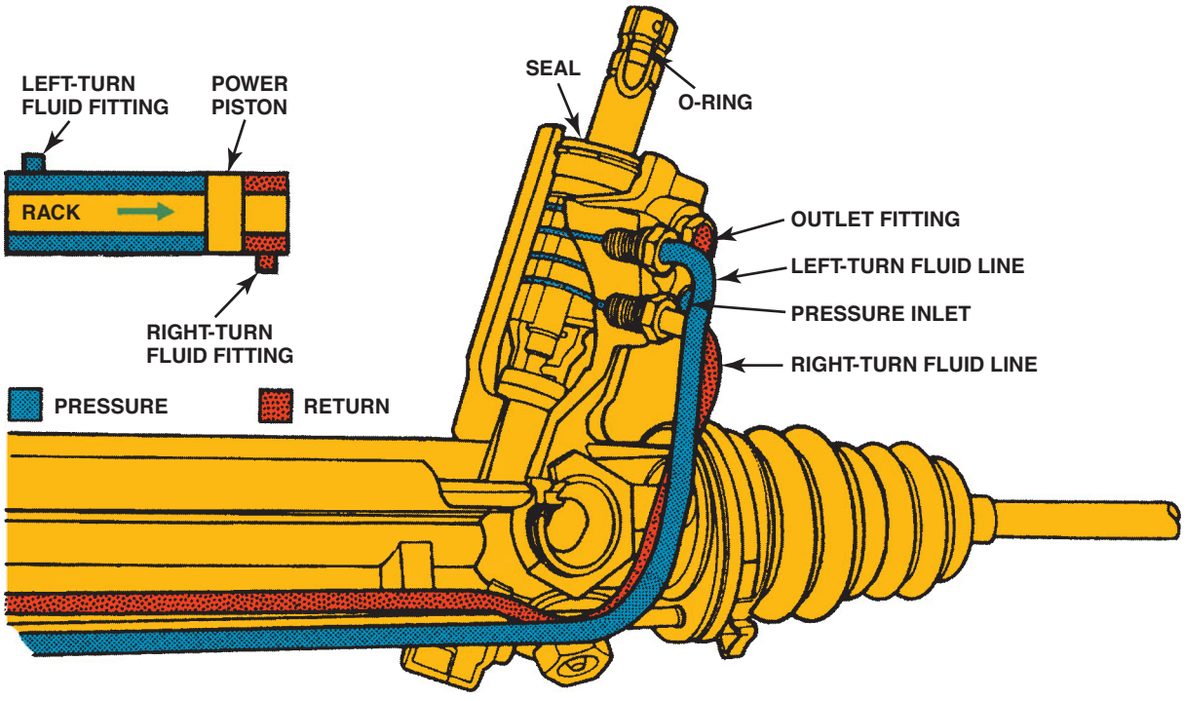

FIGURE 118–20 During a left turn, the control valve directs pressure into the left-turn fluid line and the rack moves left. (See inset.) Fluid pushed out of the right-turn fluid chamber travels back through the right-turn fluid line and control valve to the return circuit.

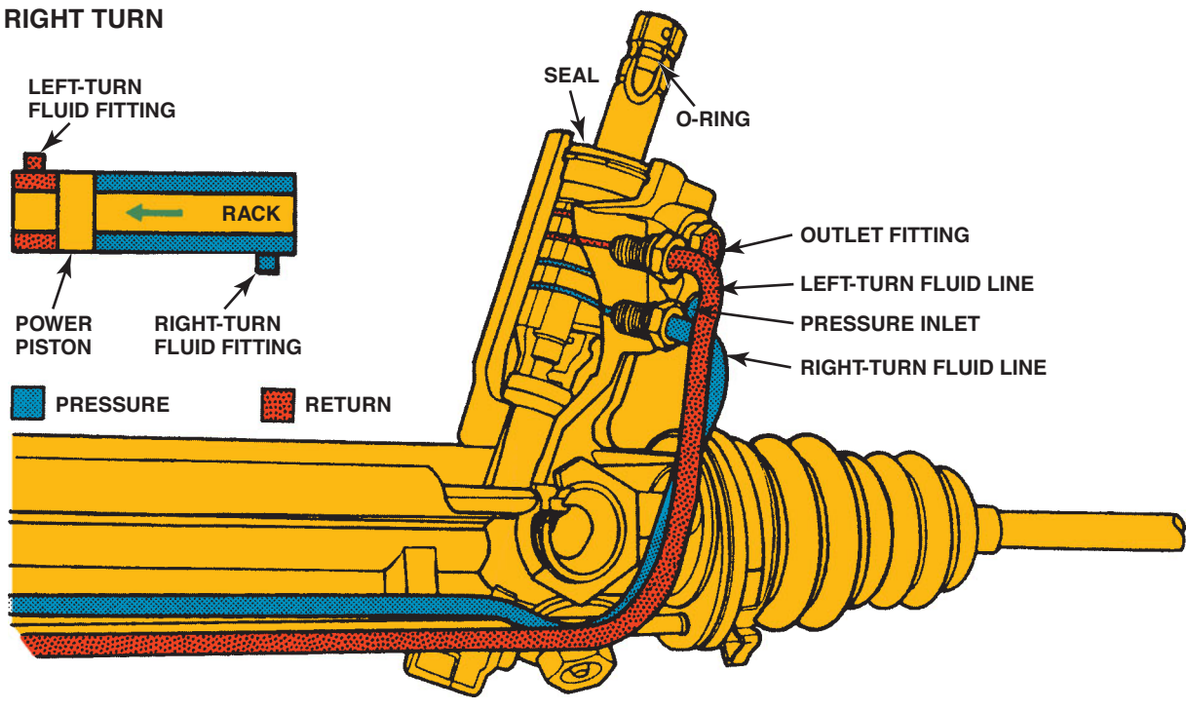

FIGURE 118–21 The control valve routes high-pressure fluid to the left-hand side of the power piston, which pushes the piston and assists in moving the rack toward the right when the steering wheel is turned right.

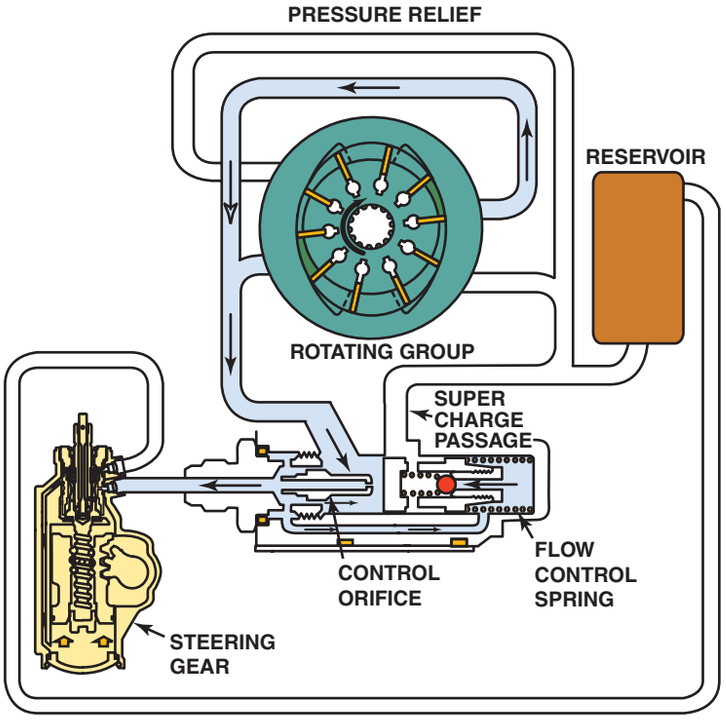

FIGURE 118–22 Low-speed flow control.

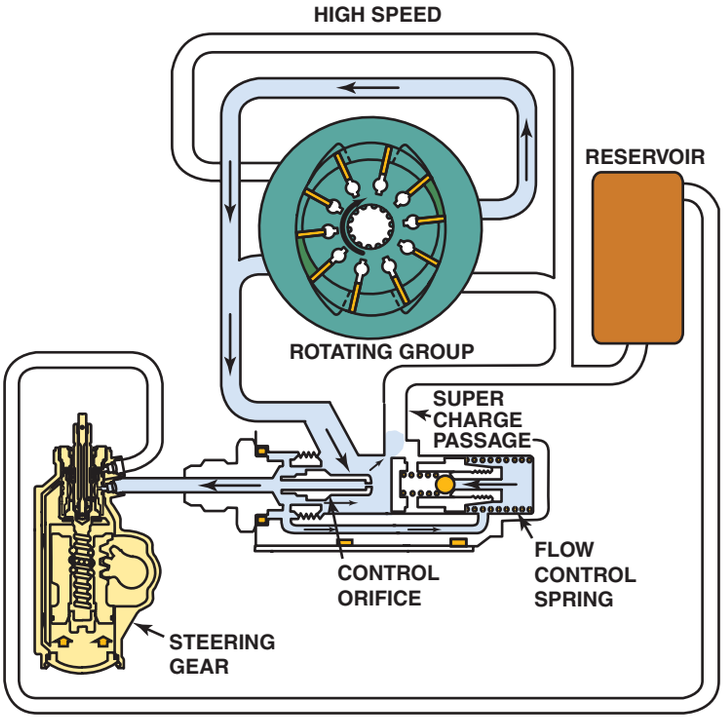

FIGURE 118–23 High-speed flow control operation.

the system builds. If the pressure is not relieved, the system can be damaged. To prevent this, the control valve has a check valve inside of it. At a specific pressure, the check valve opens to relieve the pressure on the backside of the control valve. This creates a pressure differential and allows the control valve to move. With the control valve moved, the high pressure is allowed into the pump intake passage. At this point, the check valve and control valve seat. ● **SEE FIGURE 118–24.**

VARIABLE-EFFORT STEERING

Variable-effort steering (VES) systems are designed to provide variable power-assisted steering. The amount of power assist increases at lower vehicle speeds to aid parking maneuvers and decreases at higher speeds for greater road feel.

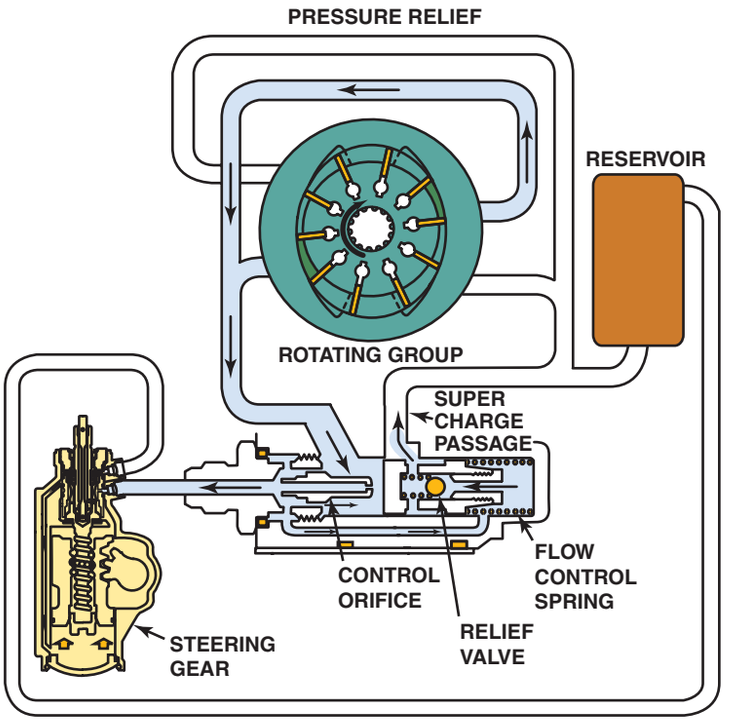

FIGURE 118–24 Pressure-relief mode. In this mode the steering gear has blocked the flow of fluid from the pump and the pressure rises, which unseats the pressure-relief valve. Now fluid flows back to the inlet through the pressure-relief orifice and passage.

As examples, General Motors uses four different variable-effort steering systems:

- **Electronic Variable Orifice (EVO)**
- **Two-Flow Electronic (TFE)**
- **Speed Sensitive Steering (SSS)**
- **Magnasteer**

The Electronic Variable Orifice (EVO) system provides a wide range of power-assisted steering based on the vehicle's operating conditions. ● **SEE FIGURE 118–25.**

The system uses vehicle speed and steering wheel speed to regulate the current to a solenoid that changes the orifice size of the flow control valve.

The size of the orifice controls the flow rate through the valve and the pressure in the hydraulic system. The desired amount is then directed to the steering gear for the power assist. The second type of power assist is the TFE system, which provides two rates of power assist:

- At low speeds, the TFE solenoid provides maximum power assist.
- At high speeds, the solenoid provides minimum power assist.

Another type of power assist is the Speed Sensitive Steering (SSS) system, which uses hydraulic pressure to resist movement in the steering gear as speed increases. This provides a firmer sense of control and stability in the steering gear at higher speeds.

ELECTRONIC VARIABLE ORIFICE (EVO) SYSTEM COMPONENTS

The main components of the EVO system are:

- Vehicle speed sensor
- Power steering control module
- Steering wheel speed sensor
- Power steering gear
- Power steering pump and solenoid actuator

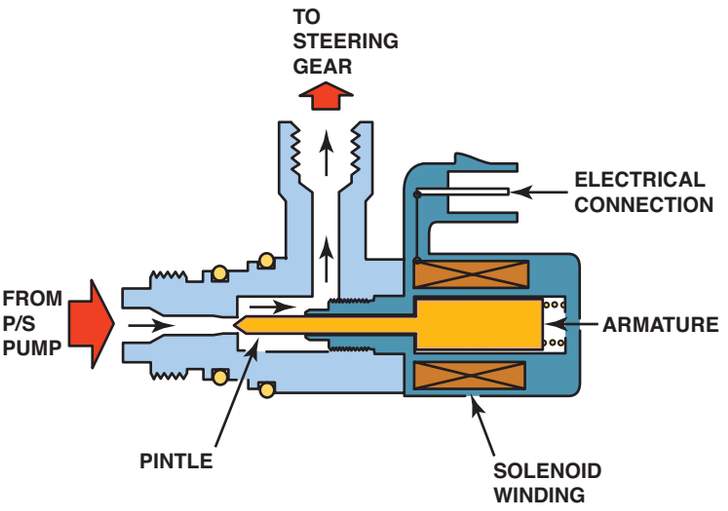

FIGURE 118–25 EVO actuator assembly.

The actuator is a solenoid-operated pintle valve. Electrical current flow through the solenoid controls the position of the pintle in relation to the orifice.

As the vehicle speed increases, the control module provides a higher current flow and the solenoid positions the pintle to change the size of the orifice.

This increased speed results in a reduced amount of hydraulic flow and provides less hydraulic pressure to the steering gear.

The control module uses the signal from the vehicle speed sensor to calculate the required amperage for the solenoid.

The amperage has a direct effect on steering effort and the flow rate to the gear. As the vehicle speed increases, the solenoid extends the pintle and reduces the size of the orifice. Hydraulic pressure is being reduced as the vehicle speed increases and less power assist is available.

The other sensor for the EVO system is the steering wheel speed sensor. This sensor is used to determine if the vehicle operator is performing an evasive steering maneuver.

In this situation, the controller increases the hydraulic pressure to assist the operator. The faster the driver turns the steering wheel, the stronger the signal generated by the sensor. The faster the steering wheel is rotated, the more the solenoid retracts the pintle and enlarges the size of the orifice. This increases hydraulic pressure to the steering gear and provides more power assist for the operator.

TWO-FLOW ELECTRONIC (TFE) SYSTEM

The main components of the TFE system are:

- Power steering pump and solenoid actuator
- Steering rack-and-pinion gear
- Powertrain Control Module (PCM)

The TFE actuator is a solenoid-operated pintle valve. The pintle valve only has two positions—maximum assist and reduced assist. When the solenoid is provided a ground from the chime module, the pintle extends out from the orifice and provides maximum assist. When the chime module opens the ground path, the pintle moves in to restrict the orifice and thus reduces steering assist.

The PCM provides the chime module with a vehicle speed signal. The logic circuits in the chime module determine when to energize the solenoid. The solenoid is energized whenever the vehicle speed is approximately 20 mph (32 km/h) or lower and the pintle is extended, causing the power steering pressure to increase.

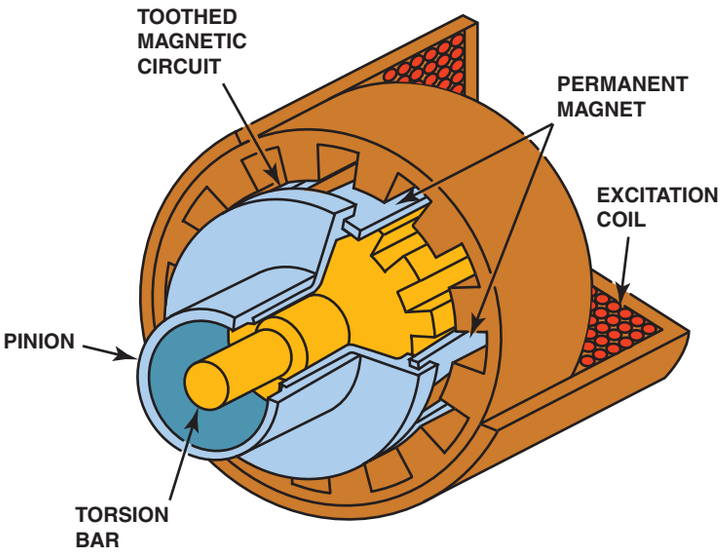

FIGURE 118–26 Integrated with the pinion shaft is a spool valve that senses the level of torque in the shaft and applies hydraulic pressure to the steering rack whenever assistance is needed. The electromagnet acts in parallel with the input shaft from the steering wheel to open or close the spool valve. The electromagnet generates variable torque, which can either increase or decrease the amount of steering torque that is needed to open the spool valve.

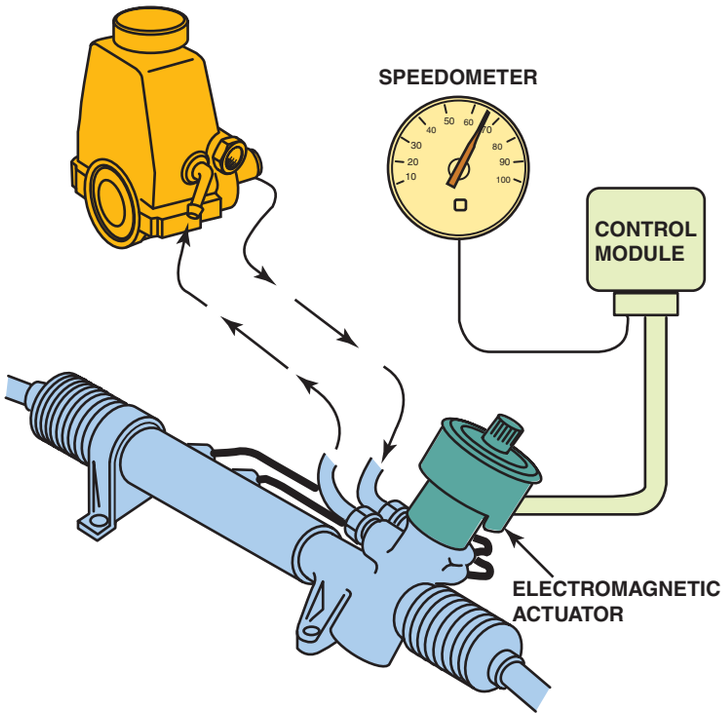

FIGURE 118–27 Magnasteer system.

This provides maximum assist and the steering effort is low. When the vehicle speed is higher than 20 mph (32 km/h), the pintle is moved in and the steering pressure is low. This provides reduced assist and higher steering effort.

SSS SYSTEM

The major components of the SSS system are:

- Power steering pump
- SSS actuator
- Steering gear
- Road sensing suspension control module

The actuator is a solenoid-operated valve that controls the flow of fluid into the chambers of the steering gear valve. As more fluid flows into the chamber, pressure is built against the four pistons that are located around the spool shaft. As the pistons are loaded and pushed against the spool shaft, steering effort is increased.

Unlike the EVO and TFE systems, the SSS system uses hydraulic pressure to resist movement in the steering gear. The amount of fluid allowed into the chambers is based on the electrical current flow through the solenoid.

The Road Sensing Suspension (RSS) control module, using the signal from the vehicle speed sensor, calculates the required amperage for the solenoid.

The amperage has a direct effect on steering effort and the hydraulic flow rate into the chambers of the spool shaft. As the vehicle's speed increases, more hydraulic pressure is built against the pistons and the steering effort is increased. The steering effort adjustment begins at a vehicle speed of 20 mph (32 km/h).

MAGNASTEER

The fourth type of VES steering system used by General Motors is the Magnasteer system. This system uses a variable bi-directional magnetic rotary actuator built into the steering rack. The bi-directional magnetic rotary actuator has no effect on the hydraulic operation of the steering rack.

The main components in the system include:

- Power steering pump
- Magnasteer actuator assembly
- Steering gear
- Electronic brake control module (EBCM)

The Magnasteer system uses a conventional rack-and-pinion steering gear and an engine-driven hydraulic pump to provide power assist. The Magnasteer actuator consists of the following:

- A permanent magnet attached to the rotary input shaft
- A pole-piece assembly attached to the pinion
- An electromagnetic coil mounted in the steering gear housing

Integrated with the pinion shaft is a spool valve that senses the level of torque in the shaft and applies hydraulic pressure to the steering rack whenever assistance is needed. The electromagnet acts in parallel with the input shaft from the steering wheel to open or close the spool valve.

The electromagnet generates variable torque, which can either increase or diminish the amount of steering torque that is needed to open the spool valve. ● **SEE FIGURES 118–26 AND 118–27.**

To vary the amount of steering assist, the EBCM uses the signal from the wheel speed sensor to calculate the required amperage and direction of current flow to the Magnasteer actuator.

The amperage and direction of current flow have a direct effect on steering effort and the flow rate to the rack piston. When the vehicle is stationary, approximately 1.6 amps of current flow through the electromagnetic coil.

As the vehicle speed increases to approximately 45 mph, the current decreases to 0 amps. The EBCM then switches the direction of current flow. Current flow through the electromagnetic coil causes either a magnetic attraction or repelling in the Magnasteer actuator.

At low vehicle speeds below 45 mph, the direction of current flow creates a magnetic field that opposes the permanent magnet.

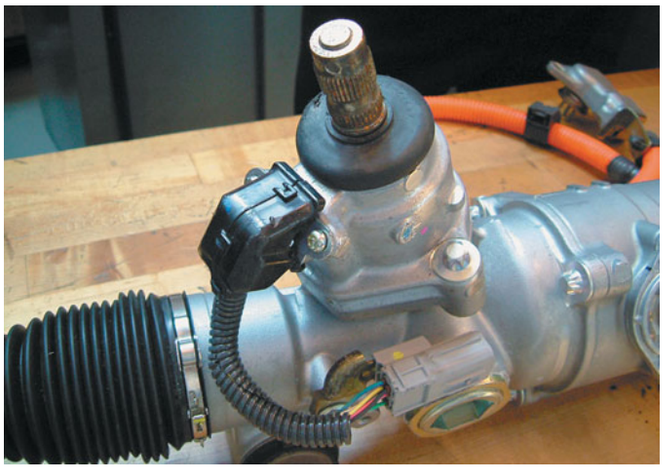

FIGURE 118–28 A Toyota Prius EPS assembly. (*Courtesy of Tony Martin*)

The repelling force of the magnetic field assists the spool valve in moving out of alignment with the valve body, and this increases the power assist.

With vehicle speeds below 45 mph, increased current provides increased steering assist. At vehicle speeds above 45 mph, the direction of current through the electromagnetic coil creates a magnetic field that attracts the permanent magnet.

- The magnet helps keep the spool valve aligned with the valve body, and this reduces the power assist and provides a greater road feel.
- As the vehicle speed increases, the amount of effort required to overcome the attracting force of the magnetic field increases.

With vehicle speeds above 45 mph, increased current flow provides decreased steering assist.

ELECTRIC POWER STEERING SYSTEM

PURPOSE AND FUNCTION Many of today's vehicles use electric power steering systems. Electric power steering takes the place of hydraulic components by using an electric motor to provide power assist effort.

PARTS AND OPERATION Most electric power steering units use a DC electric motor. Some operate from 42 volts while others operate from 12 volts. The **electric power steering (EPS)** is also called electric power-assisted steering (EPAS).

The Toyota system on a Prius uses a DC motor, reduction gear, and torque sensor all mounted to the steering column. ● **SEE FIGURE 118–28.**

The electric power steering (EPS) is controlled by the EPS electronic control unit (ECU), which calculates the amount of needed assist based on the input from the steering torque sensor. The steering torque sensor is a noncontact sensor that detects the movement and torque applied to the torsion bar. The torsion bar twists when the drive exerts torque to the steering wheel, and the more torque

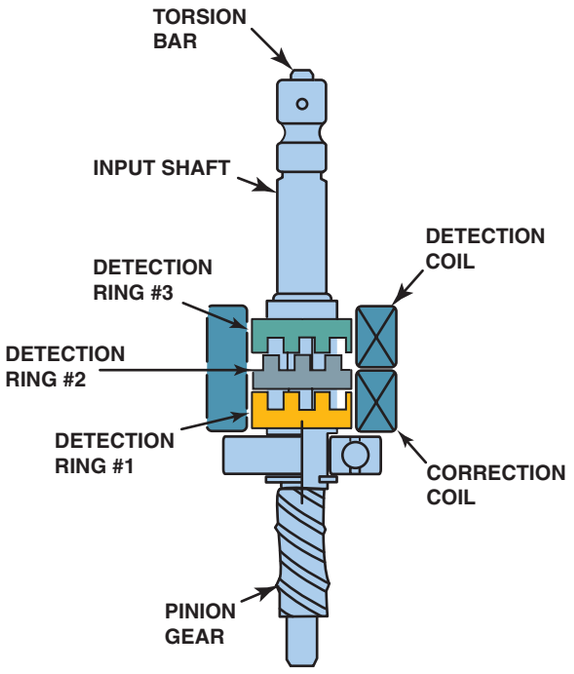

FIGURE 118–29 The torque sensor converts the torque the driver is applying to the steering wheel into a voltage signal.

applied the farther the bar will twist. This generates a higher-voltage signal to the EPS ECU. ● **SEE FIGURE 118–29.**

The steering shaft torque sensor and the steering wheel position sensor are not serviced separately from each other or from the steering column assembly. The steering column assembly does not include the power steering motor and module assembly. The detection ring 1 and detection ring 2 are mounted on the input shaft and detection ring 3 is mounted on the output shaft. The input shaft and the output shaft are connected by a torsion bar. When the steering wheel is turned, the difference in relative motion between detection rings 2 and 3 is sensed by the detection coil and it sends two signals to the EPS ECU. These two signals are called Torque Sensor Signal 1 and Torque Signal 2. The EPS ECU uses these signals to control the amount of assist, and also uses the signals for diagnosis.

NOTE: If the steering wheel, steering column, or steering gear is removed or replaced, the zero point of the torque sensors must be reset.

The Toyota Highlander and Lexus RX 400h use a different electric power steering unit due to the larger size of the vehicles. This unit uses a brushless DC motor on the steering rack. ● **SEE FIGURES 118–30 AND 118–31.**

The Honda electric power steering uses an electric motor to provide steering assist and torque sensor is used to measure road resistance and the direction that the driver is turning the steering wheel. The torque sensor input and the vehicle speed are used by the EPS controller to supply the EPS motor with the specified current to help assist the steering effort. ● **SEE FIGURE 118–32.**

The motor turns the pinion shaft using a worm gear. The worm gear is engaged with the worm wheel so that the motor turns the pinion shaft directly when providing steering assist. The steering rack is unique because the tie rods are mounted to the center of the rack rather than at the ends of the rack as in a conventional Honda power steering arrangement. ● **SEE FIGURE 118–33.**

If a major fault were to occur, the control module would first try to maintain power-assisted steering even if some sensors had failed. If the problem is serious, then the vehicle can be driven and

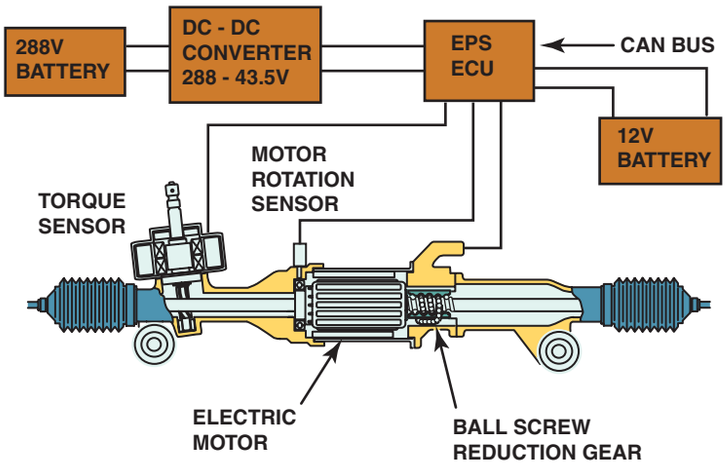

FIGURE 118–30 The electric power steering in Toyota/Lexus SUVs uses a brushless DC motor around the rack of the unit and operates on 42 volts.

FIGURE 118–33 Honda electric power steering unit cutaway.

FIGURE 118–31 Photo of the electric power steering gear on a Lexus RX 400h taken from underneath the vehicle.

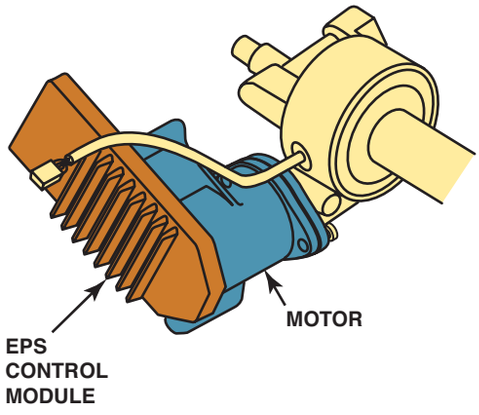

FIGURE 118–34 The Power Steering Control Module (PSCM) is attached to the motor of the electric power steering assembly.

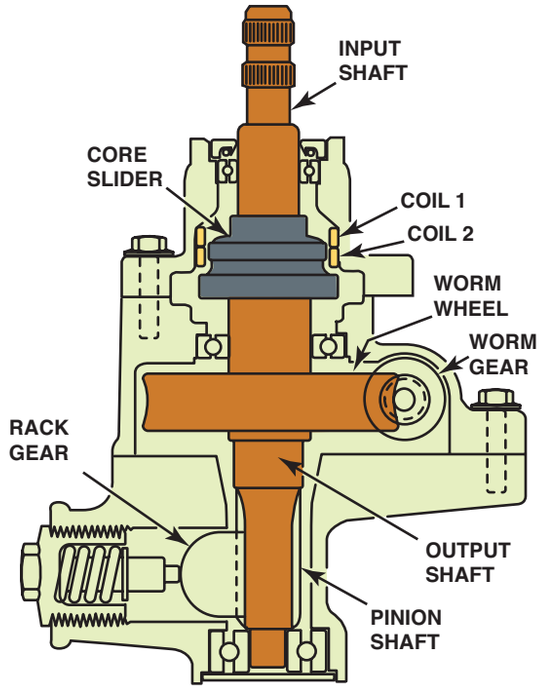

FIGURE 118–32 A cross-sectional view of a Honda electric power steering (EPS) gear.

steered manually. The EPS control unit will turn on the EPS dash warning light if a fault has been detected. A fault in the system will not cause the malfunction indicator light to come on because that light is reserved for emission-related faults only. Fault codes can be retrieved by using a scan tool. Check service information for the exact procedures to follow when diagnosing electric power steering faults.

EPS INPUTS AND OUTPUTS

The EPS system includes the following components and inputs/outputs:

- Powertrain Control Module (PCM)
- Body control module (BCM)
- Power steering control module (PSCM)
- Battery voltage
- Steering shaft torque sensor
- Steering wheel position sensor
- Power steering motor
- Driver information center (DIC)
- Serial data circuit to perform the system functions

The **power steering control module (PSCM)** and the power steering motor are serviced as an assembly and are serviced separately from the steering column assembly. ● **SEE FIGURE 118–34.**

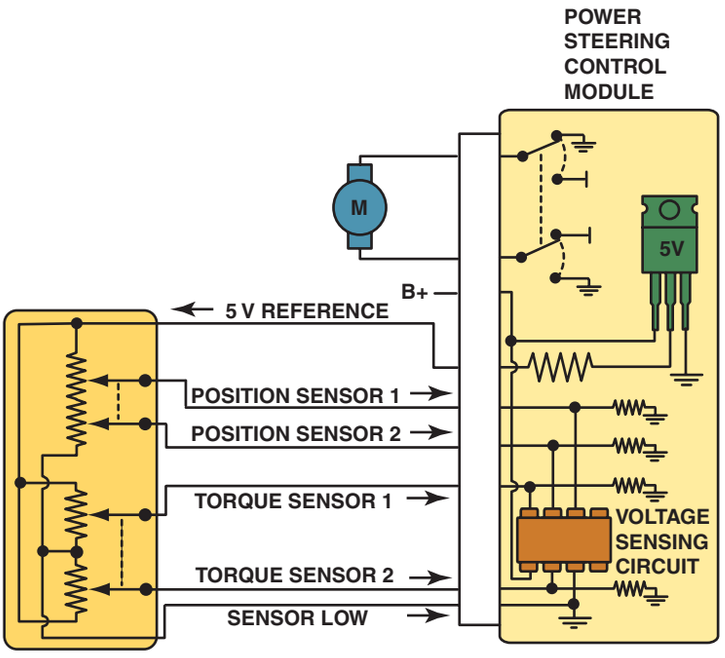

FIGURE 118–35 Schematic showing the electric power steering and the torque/position sensor.

The steering shaft torque sensor and the steering wheel position sensor are not serviced separately from each other or from the steering column assembly. The steering column assembly does not include the power steering motor and module assembly.

STEERING SHAFT TORQUE SENSOR The PSCM uses the steering shaft torque sensor as a main input for determining steering direction and the amount of assist needed. The steering column has an input shaft, from the steering wheel to the torque sensor, and an output shaft, from the torque sensor to the steering shaft coupler. The input and output shafts are separated by a section of torsion bar, where the torque sensor is located. The sensor is a 5-volt dual-analog inverse signal device with a signal voltage range of 0.25 to 4.75 volts. The sensors are used to detect the direction the steering wheel is being rotated.

- When torque is applied to the steering column shaft during a right turn, the sensor signal 1 voltage increases, while the signal 2 voltage decreases.
- When torque is applied to the steering column shaft during a left turn, the sensor signal 1 voltage decreases, while the signal 2 voltage increases.

The PSCM recognizes this change in signal voltage as steering direction and steering column shaft torque.

STEERING WHEEL POSITION SENSOR The PSCM uses the **steering position sensor (SPS)** to determine the steering system on-center position. Because the power steering motor provides a slight amount of return-to-center assist, the PSCM will command the power steering motor to the steering system center position and not beyond. The sensor is a 5-volt dual-analog signal device with a signal voltage range of 0 to 5 volts. The sensor's signal 1 and signal 2 voltage values will increase and decrease within 2.5 to 2.8 volts of each other as the steering wheel is turned. ● **SEE FIGURE 118–35.**

POWER STEERING MOTOR The power steering motor is a 12-volt brushless DC reversible motor with a 65-amp rating. The motor assists steering through a worm gear and reduction gear located in the steering column housing.

POWER STEERING CONTROL MODULE (PSCM) The PSCM uses a combination of steering shaft torque sensor input, vehicle speed, calculated system temperature, and steering tuning to determine the amount of steering assist. When the steering wheel is turned, the PSCM uses signal voltage from the steering shaft torque sensor to detect the amount of torque and steering direction being applied to the steering column shaft and then commands the proper amount of current to the power steering motor. The PSCM receives a vehicle speed message from the PCM by way of the serial data circuit. At low speeds more assist is provided for easy turning during parking maneuvers, and at higher speeds, less assist is provided for improved road feel and directional stability.

NOTE: The PSCM and the power steering motor are not designed to handle 65 amps continuously. If the power steering system is exposed to excessive amounts of static steering conditions, the PSCM will go into a protection mode to avoid thermal damage to the power steering components. In this mode the PSCM will limit the amount of current commanded to the power steering motor, which reduces system temperature and steering assist levels. The PSCM has the ability to detect malfunctions within the power steering system. Any malfunction detected will cause the driver information center to display the *power steering* warning message and/or the *service vehicle soon* indicator.

The PSCM must also be set up with the correct steering tunings, which are different in relation to the vehicle's powertrain configuration, model type, tire and wheel size.

SELF-PARKING SYSTEM

Several vehicle manufacturers offer a **self-parking** feature that uses the electric power steering to steer the vehicle. The driver has control of the brakes. Most systems use the following sensors:

- Wheel speed sensor (WSS)
- Steering-angle sensor
- Ultrasonic sensors, which are used to plot a course into a parking space

Some systems, such as those manufactured by Valeo for Volkswagen, allow the driver to control the accelerator as well as the brakes, making it possible to add power to park uphill. The Toyota/Lexus system stops working if the accelerator is depressed during a self-parking event. The Toyota/Lexus system is camera based and uses the navigation system to display the parking spot with touchscreen controls. The system displays a green video box to indicate that the spot is large enough and a red box to indicate that the spot is too small. The driver positions a yellow flag on the video screen to mark the front corner of the parking spot and then the vehicle backs into the space at idle speed. The driver has to complete the parking event by straightening the vehicle and pulling forward in the spot.

DIAGNOSIS AND TESTING Self-parking systems use many sensors to achieve the parking event, and a fault in any one sensor will disable self-parking. Before trying to diagnose a self-parking fault, be sure that the driver is operating the system as designed. For example, the self-parking event is cancelled if the accelerator pedal is depressed on some units. Always follow the factory-recommended diagnostic and testing procedures.

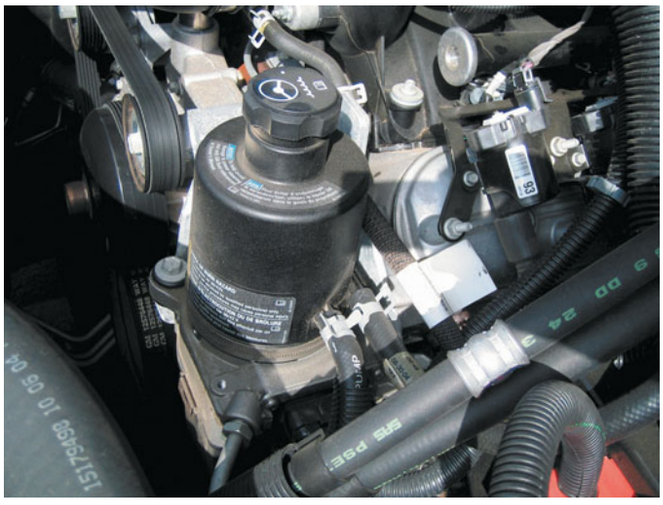

FIGURE 118–36 An electrohydraulic power steering assembly on a Chevrolet hybrid pickup truck.

ELECTROHYDRAULIC POWER STEERING

PURPOSE AND FUNCTION Electrohydraulic power steering is used on the Chevrolet Silverado hybrid truck. This system uses an electric motor to drive a hydraulic pump.

The **electrohydraulic power steering (EHPS)** module controls the power steering motor, which has the function of providing hydraulic power to the brake booster and the steering gear.

A secondary function includes the ability to improve fuel economy by operating on a demand basis and the ability to provide speed-dependent variable-effort steering.

The EHPS module controls the EHPS powerpack, which is an integrated assembly consisting of the following components:

- Electric motor
- Hydraulic pump
- Fluid reservoir
- Reservoir cap
- Fluid level sensor
- Electronic controller
- Electrical connectors

SEE FIGURE 118–36.

EHPS MODULE The electrohydraulic power steering (EHPS) module is operated from the 36-volt (nominal) power supply. The EHPS module uses class 2 for serial communications. A 125-amp, 36-volt fuse is used to protect the EHPS module. If this fuse were to blow open, the EHPS system would not operate and communication codes would be set by the modules that communicate with the EHPS module. The Powertrain Control Module (PCM) is the gateway that translates controller area network (CAN) messages into class 2 messages when required for diagnostic purposes. The EHPS module receives the following messages from the CAN bus:

- Vehicle speed
- Service disconnect status
- PRNDL (shift lever) position
- Torque converter clutch (TCC)/Cruise Dump signal (gives zero-adjust brake switch position)

The EHPS module outputs the following messages to the CAN bus:

- Brake pedal rate, position, in-range rationality, and out-of-range diagnosis
- EHPS system status
- Diagnostic messages to driver information center (DIC) via hybrid control module (HCM)
- Diagnostic information requested by service technicians via Tech 2 link (class 2 via PCM)
- Steering wheel sensor diagnostic message (in-range, out-of-range failure)

The EHPS module is not attached to class 2 data and receives several signals through wiring. The signals received and used by the EHPS module include:

- The digital steering wheel speed signals from the steering wheel sensor mounted on the steering column. The steering wheel speed sensor output contains three digital signals that indicate the steering wheel position. The signals are accurate to within 1 degree. The index output references a steering wheel position of 0 degrees plus or minus 10 degrees (steering wheel centered) and is repeated every 360 degrees of steering wheel rotation.
- An analog brake pedal position signal from the brake-pedal-mounted **brake pedal position (BPP)** sensor. The BPP sensor outputs an analog signal, referenced to 5 volts, that increases or decreases with brake pedal depression. The electrical range of the BPP sensor motion is −55 degrees to +25 degrees. The mechanical range of the BPP sensor is −70 degrees to +40 degrees.
- The EHPS module also receives ignition key position signals. These signals are the ignition signal and the accessory signal. The EHPS module receives an input from the ignition 0 circuit indicating when the key is in the ACCY position. This input is used to provide an independent wake-up signal in the event of loss of the ignition input, and to activate the EHPS module when the key remains in the ACCY position.

EHPS system performance may be reduced with power steering fluid temperature change.

POWER STEERING DIAGNOSIS AND TROUBLESHOOTING

Power steering systems are generally very reliable, yet many problems, such as hard steering, are caused by not correcting simple service items such as the following:

1. **A loose, worn, or defective power steering pump drive belt.** This can cause jerky steering and belt noise, especially when turning. It is generally recommended that all belts, including the serpentine (poly V) belt, be replaced every four years.

   If the vehicle does not use a belt tensioner, then a belt tension gauge is needed to achieve the specified belt tension. Install the belt and operate the engine with all of the accessories turned on to "run-in" the belt for at least five minutes. Adjust the tension of the accessory drive belt to factory

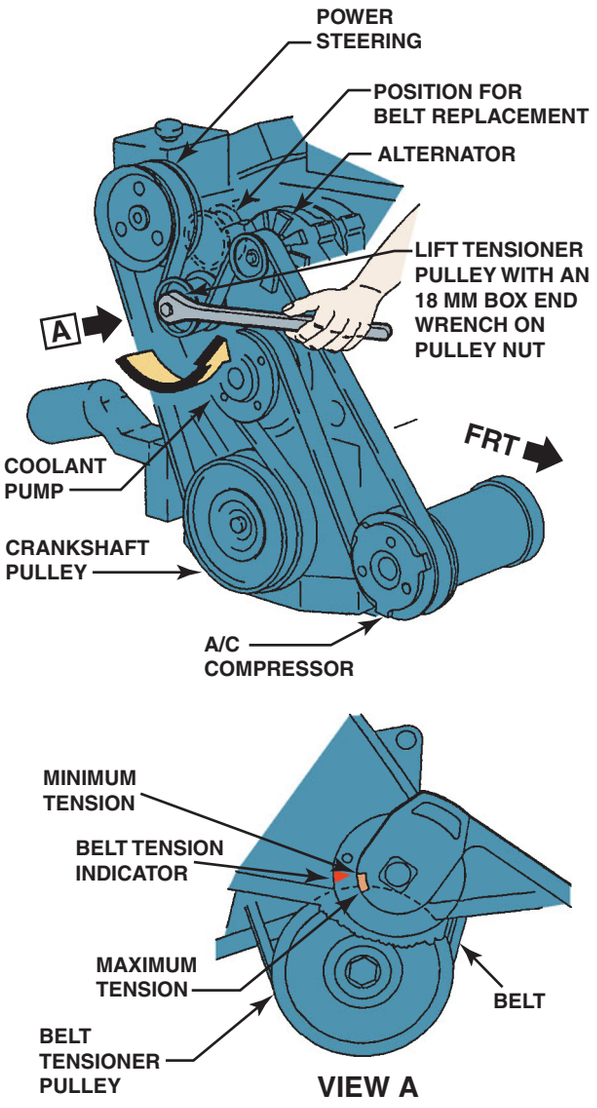

FIGURE 118–37 A typical service manual illustration showing the method to use to properly tension the accessory drive belt.

specifications or use the following table for an example of the proper tension based on the size of the belt.

Serpentine Belts

Number of Ribs Used	Tension Range (lbs.)
3	45–60
4	60–80
5	75–100
6	90–125
7	105–145

Replace any serpentine belt if more than three cracks appear in any one rib within a 3-inch span.

NOTE: Do not guess at the proper belt tension. Always use a belt tension gauge or observe the marks on the tensioner. ● **SEE FIGURE 118–37.**

2. **A bent or misaligned drive pulley** is usually caused by an accident or improper reassembly of the power steering pump after an engine repair procedure. This can cause a severe grinding noise whenever the engine is running and may sound like an engine problem.

TECH TIP

The Visual Test

Whenever diagnosing any power steering complaint, check the level *and* condition of the power steering fluid. Often this is best accomplished by putting your finger down into the power steering fluid reservoir and pulling it out to observe the texture and color of the fluid. ● **SEE FIGURE 118–38.**

A common problem with some power rack-and-pinion units is the wearing of grooves in the housing by the Teflon sealing rings of the spool (control) valve. When this wear occurs, aluminum particles become suspended in the power steering fluid, giving it a grayish color and thickening the fluid.

Normally clear power steering fluid that is found to be grayish in color and steering that is difficult when cold are clear indications as to what has occurred and why the steering is not functioning correctly.

3. **Low or contaminated power steering fluid** is usually caused by a slight leak at the high-pressure hose or defective inner rack seals on a power rack-and-pinion power steering system. This can cause a loud whine and a lack of normal power steering assist. See the Tech Tip, "The Visual Test."
4. **Broken or loose power steering pump mounting brackets.** In extreme cases, the pump mounting bolts can be broken. These problems can cause jerky steering. It is important to inspect the pump mounting brackets and hardware carefully when diagnosing a steering-related problem. The brackets tend to crack at the adjustment points and pivot areas. Tighten all the hardware to ensure the belt will remain tight and not slip, which would cause noise or a power-assist problem.
5. **Underinflated tires.**
6. **Engine idle speed below specifications.**
7. **A defective power steering pressure switch.** If this switch fails, the computer will not increase engine idle speed while turning.
8. **Internal steering gear mechanical binding.** As part of a complete steering system inspection and diagnosis, a steering wheel turning effort test should be performed. The power steering force, as measured by a spring scale during turning, should be less than 5 lb (2.3 kg).

NOTE: Some vehicles use power steering reservoir caps with *left-hand threads.* Always clean the top of the cap and observe all directions and cautions. Many power steering pump reservoirs and caps have been destroyed by technicians attempting to remove a cap in the wrong direction using large pliers.

POWER STEERING FLUID

The correct power steering fluid is *critical* to the operation and service life of the power steering system! The exact power steering fluid to use varies as to vehicle manufacturer. There are even differences within the same company because of various steering component suppliers.

FIGURE 118–38 A check of the power steering fluid should include inspecting not only the level but the condition and color of the fluid, which could indicate a possible problem with other components in the steering system.

NOTE: Remember, multiple-purpose power steering fluid does not mean *all*-purpose power steering fluid. Always consult the power steering reservoir cap, service manual, or owner's manual for the exact fluid to be used in the vehicle being serviced.

The main reason for using the specified power steering fluid is the compatibility of the fluid with the materials used in seals and hoses of the system. Using the wrong fluid (substituting ATF, for example) can lead to seal or hose deterioration and/or failure and fluid leaks.

NOTE: Always use the power steering fluid recommended by the manufacturer. The correct fluid to use is usually imprinted on or near the power steering reservoir fill cap. ● **SEE FIGURE 118–39.**

1. Check the power steering fluid level. Bleed the air from the system by turning the steering wheel lock-to-lock with the engine off and the front wheel off the ground.
2. Check the condition and tension of the drive belt. If in doubt, replace the belt.
3. Inspect the condition of all hoses, checking for any soft hose or places where the hose could touch another component.
4. Check the tightness of all mounting bolts of the pump and gear.
5. Check for leaks at pump, reservoir, hoses, steering gear and/or rack and pinion assembly.

POWER STEERING FLUID FLUSHING PROCEDURE

Whenever there is any power steering service performed, such as replacement of a defective pump or steering gear or rack-and-pinion unit, the entire system should be flushed. If all of the old fluid is not flushed from the system, small pieces of a failed bearing or rotor could be circulated through the system. These metal particles can block paths in the control valve and cause failure of the new power steering pump or gear assembly.

NOTE: Besides flushing the old power steering fluid from the system and replacing it with new fluid, many technical experts recommend installing a filter in the low-pressure return line as an added precaution against serious damage from debris in the system. Power steering filters are commonly available through vehicle dealer parts departments, as well as aftermarket sources from local auto supply stores.

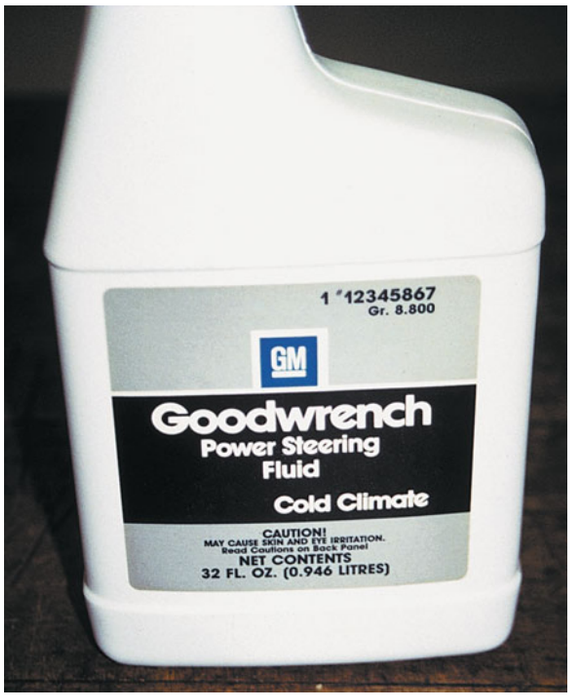

FIGURE 118–39 Some power steering fluid is unique to the climate, such as this **cold climate fluid** recommended for use in General Motors vehicles when temperatures are low.

Always follow the vehicle manufacturer's recommended flushing procedure. Two people are needed to flush the system. Use the following steps:

STEP 1 Raise the front wheels off the ground.

STEP 2 Remove the low-pressure return hose from the pump and plug the line fitting on the pump.

STEP 3 Place the low-pressure return hose into an empty container.

STEP 4 Fill the pump reservoir with fresh fluid and start the engine.

STEP 5 As the old and dirty power steering fluid is being pumped into the container, keep the reservoir full of clean fluid while the assistant turns the steering wheel full lock one way to full lock the other way.

CAUTION: Never allow the pump reservoir to run dry of power steering fluid. Severe internal pump damage can result.

STEP 6 When the fluid runs clean, stop the engine and reattach the low-pressure return hose to the pump reservoir.

STEP 7 Restart the engine and fill the reservoir to the full mark. Turn the steering wheel back and forth, avoiding the stops one or two times to bleed any trapped air in the system.

BLEEDING AIR OUT OF THE SYSTEM

If the power steering fluid is tan, there may be air bubbles trapped in the fluid. Stop the engine and allow the air to burp out to the surface for several minutes. Lift the vehicle off the ground, then rotate the steering wheel. This method prevents the breakup of large air bubbles into thousands of smaller bubbles that are more difficult to bleed out of the system.

NOTE: To help rid the power steering system of unwanted trapped air, it is recommend that the engine be cranked and that the wheels be turned from stop to stop *with the tires*

off the ground. **Check service information for the specified procedure to follow to the disable ignition or fuel injection system to keep the engine from starting. Do not crank the engine for longer than 15 seconds to prevent starter damage due to overheating. Allow the starter to cool at least 30 seconds before cranking again.**

Sometimes trapped air just cannot be bled out of the system using ordinary methods. This trapped air makes the pump extremely noisy and this noise sometimes convinces the technician that the pump itself is defective. If the power steering system has been opened for repairs and the system has been drained, trapped air may be the cause.

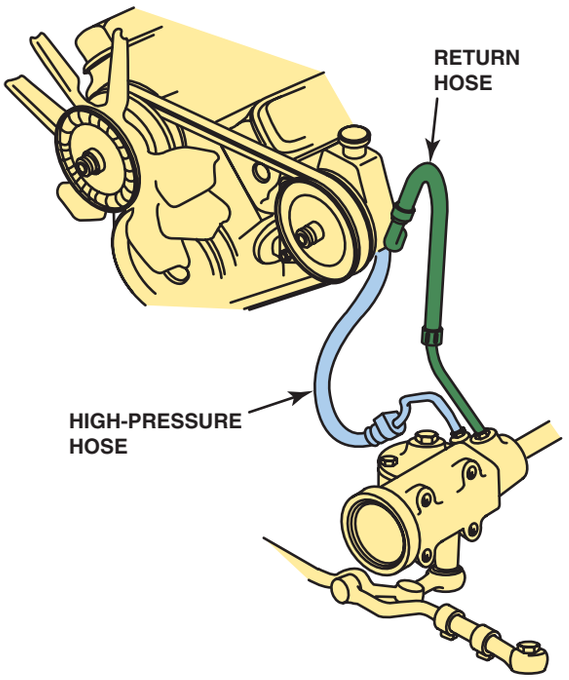

FIGURE 118–40 Inspect both high-pressure and return power steering hoses. Make sure the hoses are routed correctly and not touching sections of the body to prevent power steering noise from being transferred to the passenger compartment.

HOSE INSPECTION Both high-pressure and low-pressure return hoses should be inspected as part of any thorough vehicle inspection. While the low-pressure return hose generally feels softer than the high-pressure return hose, neither should feel *spongy.* A soft, spongy hose should always be replaced. ● **SEE FIGURE 118–40.**

When replacing any power steering hose, make certain that it is routed the same as the original and does not interfere with any accessory drive belt, pulley, or other movable component such as the intermediate steering shaft.

PRESSURE TESTING Use of a power steering pressure tester involves the following steps:

1. Disconnect the pressure hose at the pump.
2. Connect the hoses of the tester to the pump and the disconnected pressure line. ● **SEE FIGURE 118–41**.
3. Open the valve on the tester.
4. Start the engine. Allow the power steering system to reach operating temperatures.
5. The pressure gauge should register 80 to 125 PSI (550 to 860 kPa). If the pressure is greater than 150 PSI (1,400 kPa), check for restrictions in the system, including the operation of the poppet valve located in the inlet of the steering gear.
6. Fully close the valve three times. (Do not leave the valve closed for more than five seconds!) All three readings should be within 50 PSI (345 kPa) of each other and the peak pressure should be higher than 1,0000 PSI (6,900 kPa).
7. If the pressure readings are high enough *and* within 50 PSI (345 kPa) of each other, the pump is OK.
8. If the pressure readings are high enough, yet not within 50 PSI (345 kPa) of each other, the flow control valve is sticking.

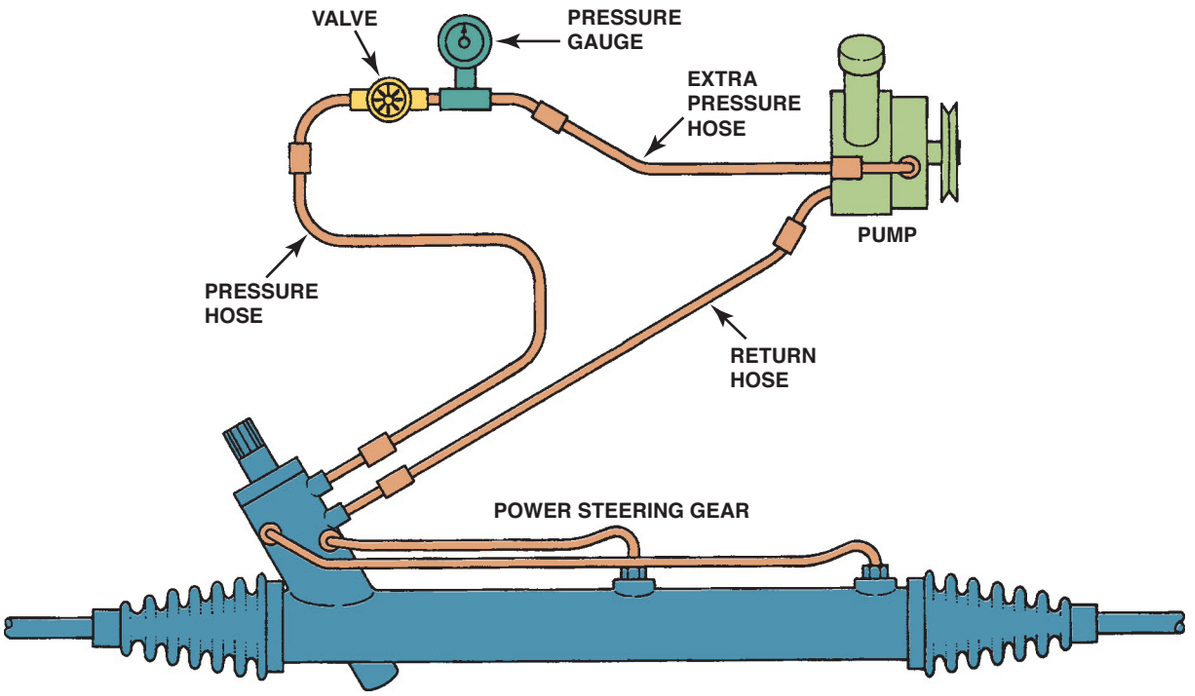

FIGURE 118–41 A drawing showing how to connect a power steering pressure gauge to the system.

FIGURE 118–42 A power steering analyzer that measures both pressure and volume. The shut-off valve is used to test the maximum pressure of the pump.

9. If the pressure readings are less than 1,0000 PSI (6,900 kPa), replace the flow control valve and recheck. If the pressures are still low, replace the rotor and vanes in the power steering pump.
10. If the pump is OK, turn the steering wheel to both stops. If the pressure at both stops is not the same as the maximum pressure, the steering gear (or rack and pinion) is leaking internally and should be repaired or replaced.

Many vehicle manufacturers recommend using a power steering analyzer that measures both pressure and volume, as shown in ● **FIGURE 118–42.**

Knowing the volume flow in the system provides information to the technician in addition to that of the pressure gauge. Many manufacturers' diagnostic procedures specify volume measurements and test results that can help pinpoint flow control or steering gear problems. Always follow the vehicle manufacturer's recommended testing procedures. Pressure and volume measurements specified by the manufacturer usually fall within the range noted in the following chart.

Typical Power Steering Pressures and Volume Specifications

Steering Action	Pressure, PSI (kPa)	Volume* (gal/min) (l/min)
Straight ahead, no steering	Less than 150 PSI (1,0000 kPa)	2.0 to 3.3 gpm (10 to 15 lpm)
Slow cornering	300–450 PSI (2,000–3,000 kPa)	Within 1 gpm (4 lpm) of straight ahead
Full turn at stops	750–1,450 PSI** (5,200–10,000 kPa)	Less than 1 gpm (4 lpm)

*Volume is determined by orifice size in the outlet of the pump and is matched to the steering gear.

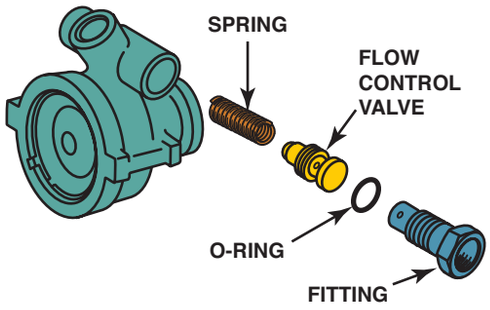
**Upper-limit pressure is determined by the calibration of the pressure-relief valve.

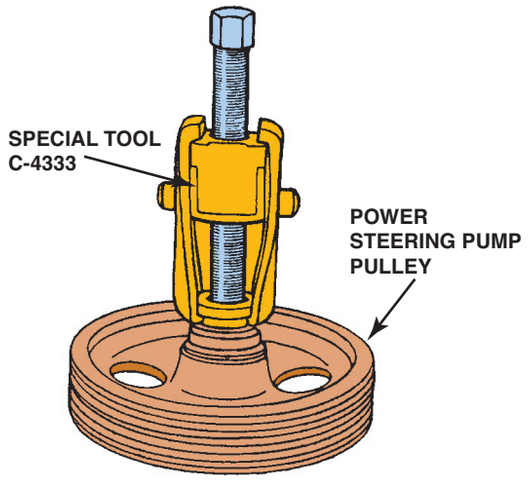
PUMP SERVICE

Some power steering pump service can usually be performed without removing the pump, including the following:

1. Replacing the high-pressure and return hoses.
2. Removing and cleaning the flow control valve assembly. ● **SEE FIGURE 118–43.**

Most power steering pump service requires the removal of the pump from the engine mounting and/or removal of the drive pulley.





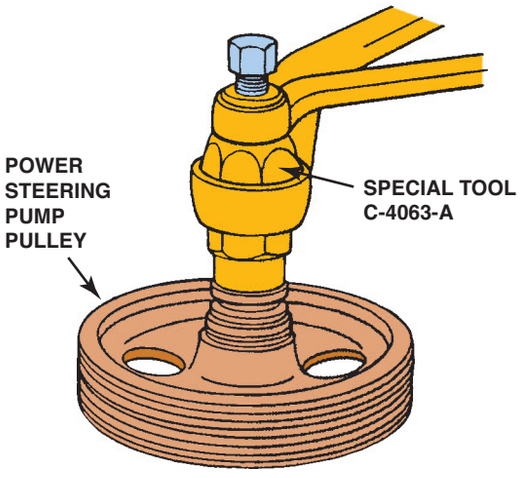


FIGURE 118–43 Typical power steering pump showing the order of assembly. The high-pressure (outlet) hose attaches to the fitting (#16). The flow control valve can be removed from the pump by removing the fitting.

REMOVE DRIVE PULLEY (TYPICAL)

INSTALL DRIVE PULLEY (TYPICAL)

FIGURE 118–44 Typical tools required to remove and install a drive pulley on a power steering pump. Often these tools can be purchased at a relatively low cost from automotive parts stores and will work on many different makes of vehicles.

NOTE: Most replacement pumps are not equipped with a pulley. The old pulley must be removed and installed on the new pump. The old pulley should be carefully inspected for dents, cracks, or warpage. If the pulley is damaged, it must be replaced.

The pulley must be removed and installed with a pulley removal and installation tool. ● **SEE FIGURE 118–44.**

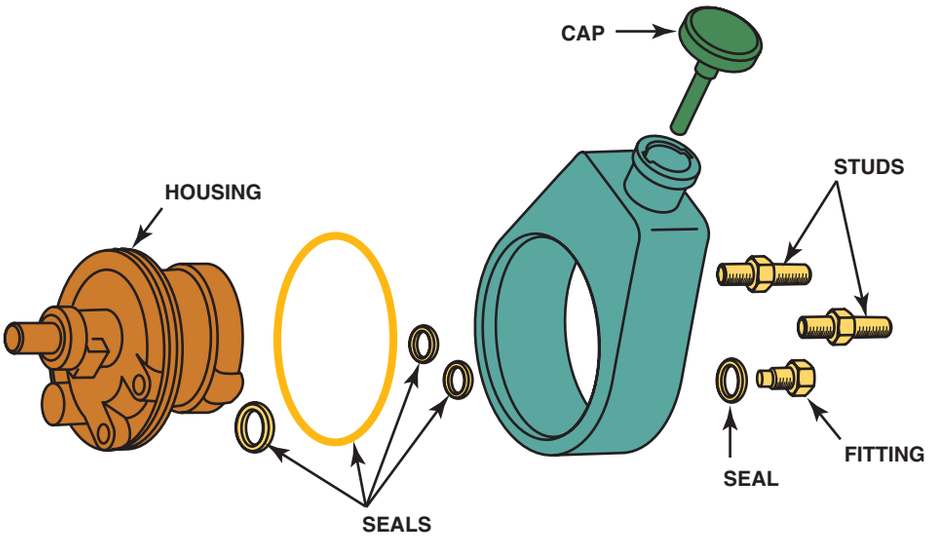

FIGURE 118–45 A typical submerged-type power steering pump. The pump is housed inside the fluid reservoir. (*Courtesy of Chrysler Corporation*)

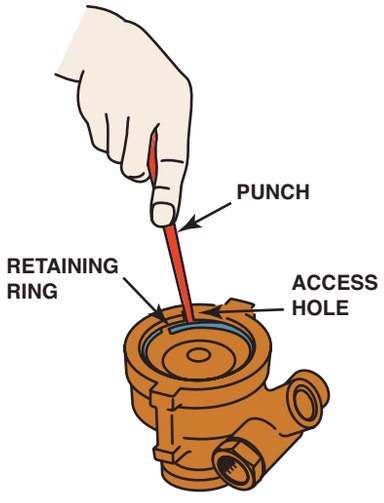

FIGURE 118–46 A punch is used to dislodge the retaining ring.

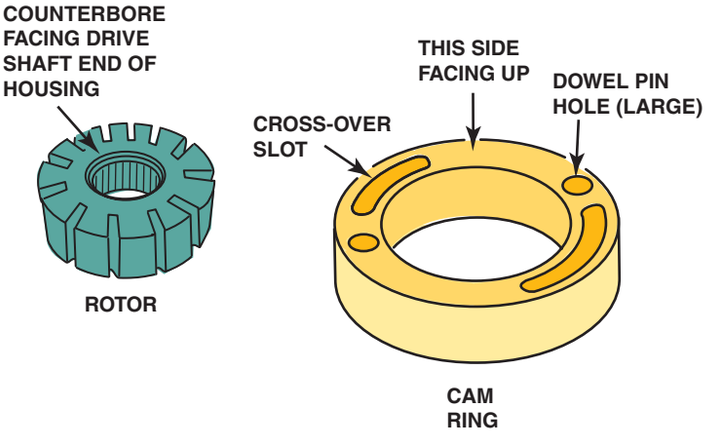

FIGURE 118–48 The pump ring *must* be installed correctly. If it is installed upside down, the internal passages will not line up and the pump will have no output.

CAUTION: Do not hammer the pump shaft or pulley in an attempt to install the pulley. The shock blows will damage the internal components of the pump.

Most vehicle manufacturers recommend replacing rather then overhauling or repairing power steering pumps. If the pump is to be disassembled, follow the vehicle manufactures instructions as found in service information. ● **SEE FIGURES 118–45 THROUGH 118–49** for the disassembly and reassembly of a typical power steering pump.

Clean all parts in power steering fluid. Replace any worn or damaged parts and all seals.

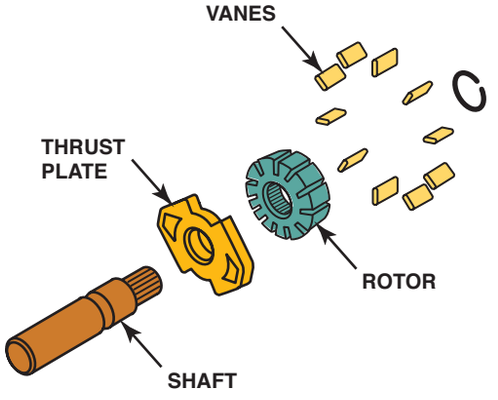

FIGURE 118–47 The driveshaft attaches to the drive pulley at one end and is splined to the pump rotor at the other end. The vanes are placed in the slots of the rotor.

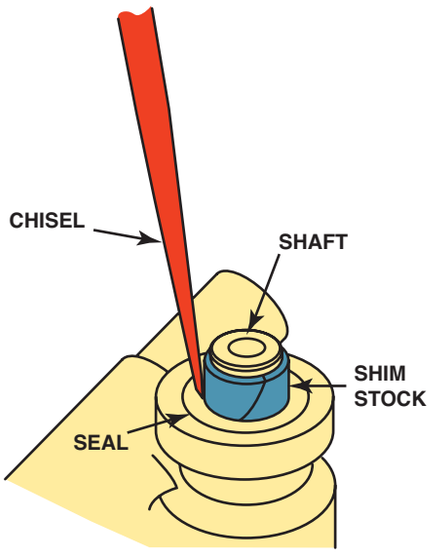

FIGURE 118–49 The shaft seal must be chiseled out. A thin metal shim stock should be used to protect the shaft from damage. Some technicians drill a small hole in the seal, then thread in a self-tapping sheet metal screw. Then pliers are used to pull out the old seal.

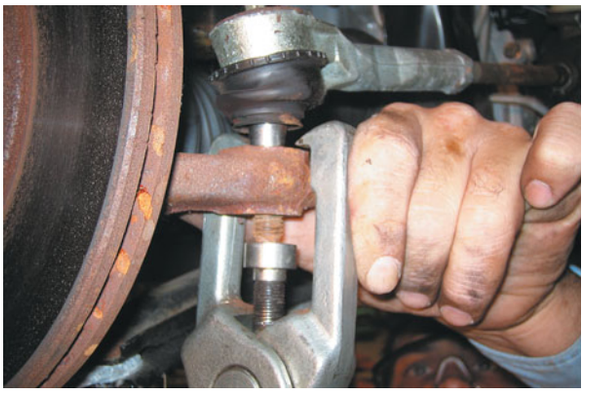
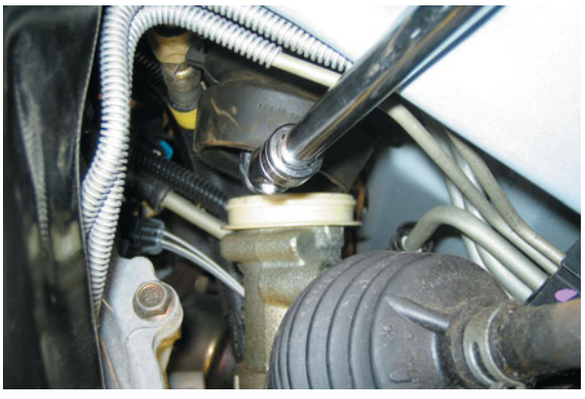
TECH TIP

Pocket the Ignition Key to Be Safe

When replacing any steering gear such as a rack-and-pinion steering unit, be sure that no one accidentally turns the steering wheel! If the steering wheel is turned without being connected to the steering gear, the airbag wire coil (clock spring) can become off center. This can cause the wiring to break when the steering wheel is rotated after the steering gear has been replaced. To help prevent this from occurring, simply remove the ignition key from the ignition (make sure the steering wheel is locked) and put it in your pocket while servicing the steering gear.



1 The tools required include a tie rod end puller and basic hand tools.

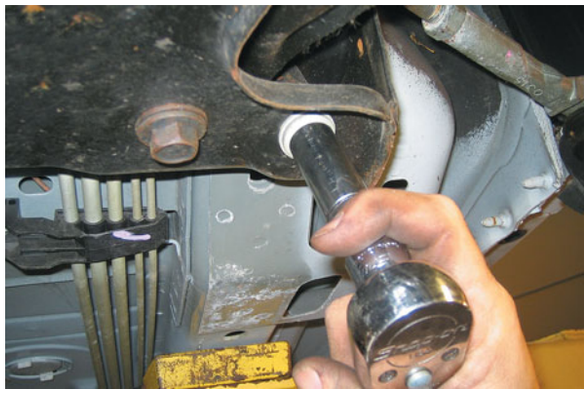


2 To help keep the steering wheel from rotating when the steering rack assembly is removed a steering wheel lock is being used.

3 After safely hoisting the vehicle and removing the front wheels, the outer tie rod end retaining nuts are removed.

4 Using a tie rod taper breaker to separate the outer tie rods from the steering knuckle without harming the rubber grease boots.

5 After moving the protective cover aside, the bolt used to retain the intermediate shaft to the steering gear stub shaft is removed.



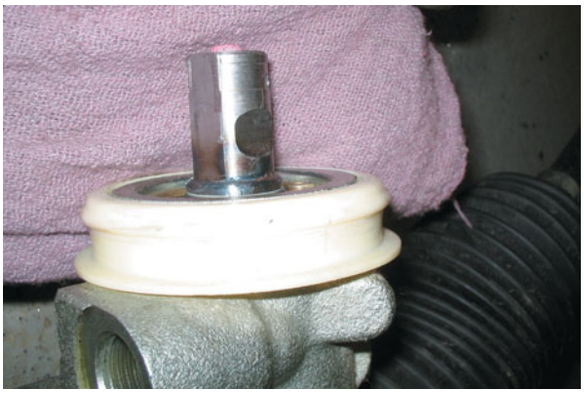
6 The hydraulic lines attached to the steering rack to the power steering rack assembly are removed using a line wrench.

CONTINUED ▶

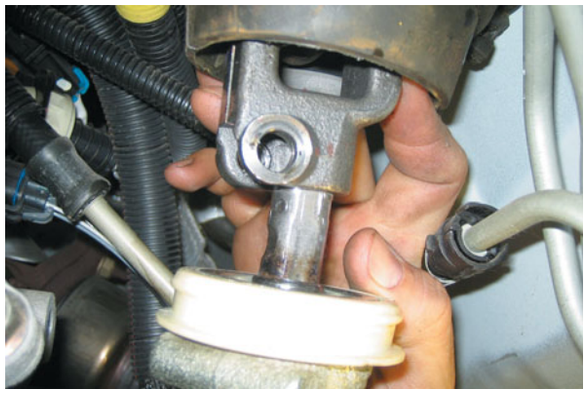
7 After supporting the engine cradle using a tall safety stand, an air impact wrench with a long extension is used to remove the engine cradle bolts.

8 Removing the lower engine cradle bolts. This will allow the cradle to be lowered to gain access to the steering rack assembly.

9 The screw jack on the tall safety stands is rotated allowing the engine cradle to be lowered.

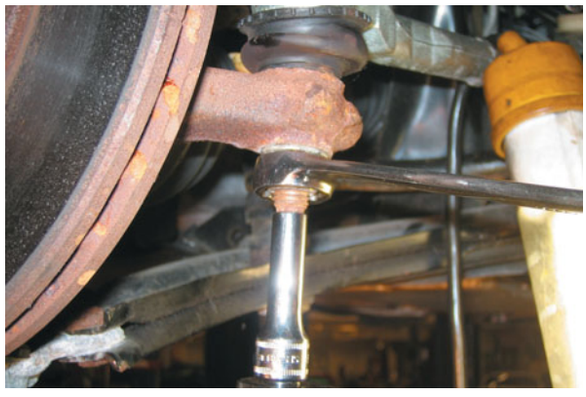


10 Removing the steering rack attachment bolts.



11 The steering rack assembly can be lifted out of the support brackets.

12 On this General Motors vehicle, the steering rack assembly is removed from the driver's side.



13 Before reinstalling the steering gear assembly, note the notch on the stub shaft. This notch has to be aligned with the intermediate shaft retaining bolt when it is placed back into the vehicle.

14 Installation is the reverse of removal. Be sure that the rack is centered and check that the through-bolt is properly aligned with the notch in the steering rack stub shaft.

15 While using a tall safety stand to support the engine cradle, the retaining bolts are installed.

16 A socket is being used to keep the tapered tie rod end from rotating while the retaining nut is tightened with a wrench.

17 After the hydraulic lines and retaining bolts have been installed, the power steering pump reservoir is filled using the specified fluid.

18 To bleed the trapped air out of the system, the steering wheel is rotated lock to lock with engine off and the wheels off the ground. Check for leaks then perform a test drive to verify a proper repair.

REVIEW QUESTIONS

1. List five possible causes for hard steering.
2. Explain the procedure for flushing a power steering system.
3. Describe how to pressure test a power steering system.
4. Briefly describe adjustment and service procedures for a power rack-and-pinion steering unit.

CHAPTER QUIZ

1. Two technicians are discussing the proper procedure for bleeding air from a power steering system. Technician A says that the front wheels of the vehicle should be lifted off the ground before bleeding. Technician B says that the steering wheel should be turned left and right with the engine off during the procedure. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. A power steering pressure test is being performed, and the pressure is higher than specifications with the engine running and the steering wheel stationary in the straight-ahead position. Technician A says that a restricted high-pressure line could be the cause. Technician B says that internal leakage inside the steering gear or rack-and-pinion unit could be the cause. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. When pressure testing an hydraulic assisted power steering system, the highest pressures were greater than 50 PSI of each other. This indicates a problem with the _____.
   a. Pump rotor
   b. Pump vanes
   c. Flow control valve
   d. Defective hose
4. Integral power steering gears use _____ for lubrication of the unit.
   a. SAE 80W-90 gear lube
   b. Chassis grease (NLGI #2)
   c. Power steering fluid in the system
   d. Molybdenum disulfide
5. What can cause hard steering on a vehicle equipped with hydraulic power assisted steering system?
   a. Low tire pressure
   b. Slipping P.S. pump drive belt
   c. Low or contaminated power steering fluid
   d. Any of the above
6. High-pressure hoses have to be used on the high-pressure side of the power steering system because pressures can reach as high as _____.
   a. 200 PSI
   b. 750 PSI
   c. 1,500 PSI
   d. 2,500 PSI
7. Some vehicles are equipped to signal the computer whenever the power steering pressures increase so that the idle speed can be increased to prevent stalling during turns at low speeds. What component signals the computer?
   a. Pressure-relief valve
   b. Power steering pressure switch
   c. Rotary valve
   d. Flow control valve
8. What type of motor is used in most electric power steering (EPS) systems?
   a. AC brush type
   b. DC brushless
   c. Stepper
   d. DC capacitor start
9. Electronically controlled variable-assist power steering systems vary the amount of boost by _____.
   a. Varying the pump output orifice size
   b. Speeding up or slowing down the power steering pump
   c. Changing the flow of fluid through the steering gear
   d. Bypassing some of the fluid back into the reservoir
10. Two technicians are discussing electric power steering (EPS) systems. Technician A says that some systems operate on 12 volts. Technician B says that some systems operate on 42 volts such as some hybrid electric vehicles. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 119

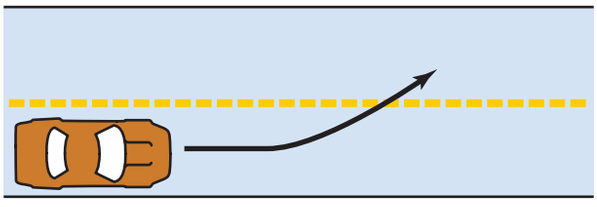
WHEEL ALIGNMENT PRINCIPLES

OBJECTIVES: **After studying Chapter 119, the reader will be able to:** • Prepare for ASE Suspension and Steering (A4) certification test content area "D" (Wheel Alignment Diagnosis, Adjustment, and Repair). • Discuss which vehicle handling problems can and cannot be corrected by an alignment. • Define camber, toe, caster, SAI, included angle, scrub radius, turning radius, setback, and thrust line. • Explain how camber, caster, and toe affect the handling and tire wear of the vehicle.

KEY TERMS: BJI 1421 • Camber 1414 • Camber roll 1417 • Caster 1416 • Dog tracking 1425 • Drift 1413 • Four-wheel alignment 1426 • Included angle 1421 • KPI 1421 • Lead 1413 • MSI 1421 • Pull 1413 • Returnability 1417 • Road crown 1413 • SAI 1421 • Scrub radius 1422 • Setback 1424 • Shimmy 1414 • Steering dampener 1418 • Steering offset 1422 • Thrust line 1425 • Toe 1418 • TOOT 1424 • Tramp 1414 • Wander 1413

DEFINITION OF A WHEEL ALIGNMENT

A wheel alignment is the adjustment of the suspension and steering component angles to ensure proper vehicle handling with minimum tire wear. When a vehicle is new, the alignment angles are set at the factory. After many miles and/or months of driving, the alignment angles can change slightly. The change in alignment angles may result from one or more of the following conditions:



1. Wear of the steering and the suspension components
2. Bent or damaged steering and suspension parts
3. Sagging springs, which can change the ride height of the vehicle and therefore the alignment angles

By adjusting the suspension and steering components, proper alignment angles can be restored. An alignment includes checking and adjusting, if necessary, both front and rear wheels.

ALIGNMENT-RELATED PROBLEMS

Most alignment diagnosis is symptom-based diagnosis. This means that the problem with the alignment is determined from symptoms such as excessive tire wear or a pull to one side of the road. The definitions of alignment symptom terms used in this book are discussed next.

PULL A **pull** is generally defined as a definite tug on the steering wheel toward the left or the right while driving straight on a level road. ● **SEE FIGURE 119–1.** Bent, damaged, or worn suspension and/or steering components can cause this problem, as well as a tire problem.

PULL

FIGURE 119–1 A pull is usually defined as a tug on the steering wheel toward one side or the other.

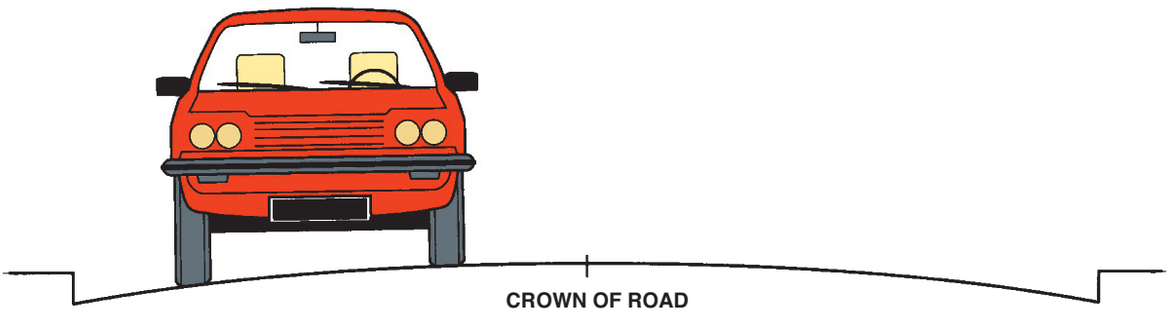
LEAD OR DRIFT A **lead** or **drift** is a mild pull that does not cause a force on the steering wheel that the driver must counteract. A lead or drift is observed by momentarily removing your hands from the steering wheel while driving on a straight, level road. When the vehicle moves toward one side or the other, this is called a lead or a drift.

CAUTION: When test-driving a vehicle for a lead or a drift, make sure that the road is free of traffic and that your hands remain close to the steering wheel. Your hands should be held away from the steering wheel for just a second or two—just long enough to check for a lead or drift condition.

ROAD CROWN EFFECTS Most roads are constructed with a slight angle to permit water to drain from the road surface. On a two-lane road, the center of the road is often higher than the berms, resulting in a **road crown.** ● **SEE FIGURE 119–2.**

On a four-lane expressway (freeway), the crown is often *between the two sets* of lanes. Because of this slight angle to the road, some vehicles may lead or drift away from the road crown. In other words, it may be perfectly normal for a vehicle to lead toward the right while being driven in the slow lane and toward the left while being driven in the fast (or inside) lane of a typical divided highway.

WANDER A **wander** is a condition where constant steering wheel corrections are necessary to maintain a straight-ahead direction on a straight, level road. ● **SEE FIGURE 119–3.**



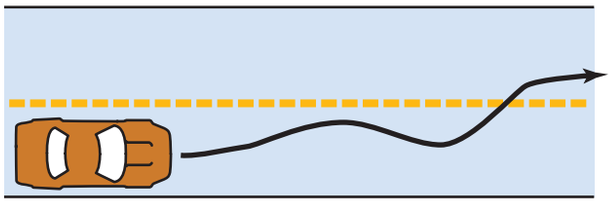


FIGURE 119–2 The crown of the road refers to the angle or slope of the roadway needed to drain water off the pavement. (*Courtesy of Hunter Engineering Company*)

WANDER

FIGURE 119–3 Wander is an unstable condition requiring constant driver corrections.

Worn suspension and/or steering components are the most likely cause of this condition. Incorrect or unequal alignment angles such as caster and toe, as well as defective tire(s), can also cause this condition.

STIFF STEERING OR SLOW RETURN TO CENTER

Hard-to-steer problems are commonly caused by leaks, either low tire pressure (due to the leak of air) and/or lack of proper power steering (due to the leak of power steering fluid). Other causes include excessive positive caster on the front wheels or binding steering linkage.

TRAMP OR SHIMMY VIBRATION

Tramp is a vertical-type (up-and-down) vibration usually caused by out-of-balance or defective tires or wheels. **Shimmy** is a back-and-forth vibration that can be caused by an out-of-balance tire or defective wheel or by an alignment problem.

NOTE: Wheel alignment will not correct a tramp-type vibration.

ALIGNMENT ANGLES

CAMBER

Camber *is the inward or outward tilt of the wheels from true vertical as viewed from the front or rear of the vehicle.*

1. If the top of the tire is tilted out, then camber is positive (+), as shown in ● **FIGURE 119–4.**
2. If the top of the tire is tilted in, then camber is negative (−), as shown in ● **FIGURE 119–5**.
3. Camber is zero (0 degrees) if the tilt of the wheel is true vertical, as shown in ● **FIGURE 119–6**.
4. Camber is measured in degrees or fractions of degrees.
5. *Camber can cause tire wear if not correct.*
   a. *Excessive positive camber* causes scuffing and wear on the outside edge of the tire, as shown in ● **FIGURE 119–7**.
   b. *Excessive negative camber* causes scuffing and wear on the inside edge of the tire, as shown in ● **FIGURE 119–8**.

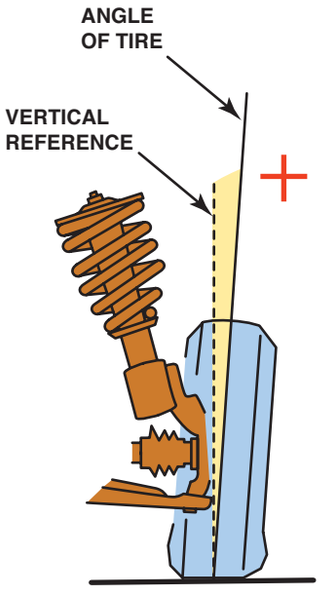

FIGURE 119–4 Positive camber. The solid vertical line represents true vertical, and the dotted line represents the angle of the tire.

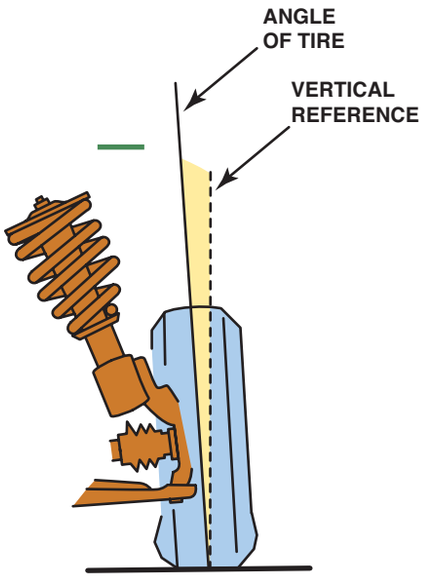

FIGURE 119–5 Negative camber. The solid vertical line represents true vertical, and the dotted line represents the angle of the tire.

6. Camber can cause pull if it is unequal side-to-side. The vehicle will pull toward the side with the most positive camber. A difference of more than 1/2 degree from one side to the other will cause the vehicle to pull. ● **SEE FIGURES 119–9 THROUGH 119–11.**

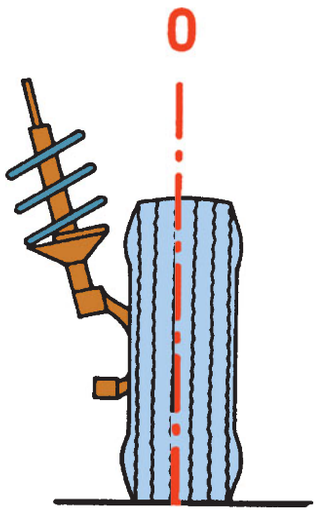

FIGURE 119–6 Zero camber. Note that the angle of the tire is true vertical.

7. Incorrect camber can cause excessive wear on wheel bearings, as shown in ● **FIGURES 119–12 AND 119–13**. Many vehicle manufacturers specify positive camber so that the vehicle's weight is applied to the larger inner wheel bearing and spindle. As the vehicle is loaded or when the springs sag, camber usually decreases. If camber is kept positive, then the running camber is kept near zero degrees for best tire life.

   NOTE: Many front-wheel-drive vehicles that use sealed wheel bearings often specify negative camber.

8. Camber is *not* adjustable on many vehicles.
9. If camber is adjustable, the change is made by moving the upper or the lower control arm or strut assembly by means of one of the following methods:
   a. Shims
   b. Eccentric cams
   c. Slots

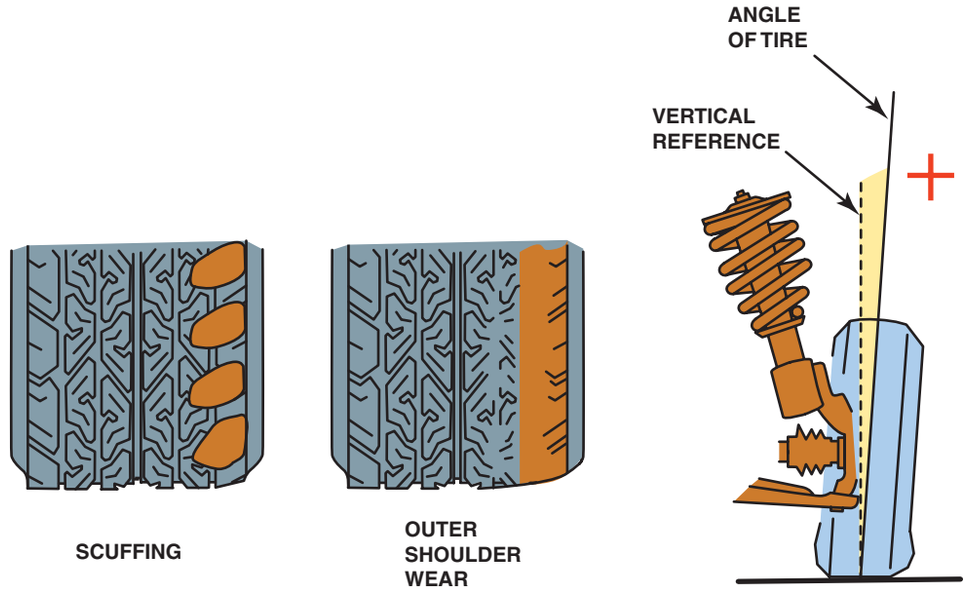

FIGURE 119–7 Excessive positive camber and how the front tires would wear due to the excessive camber.

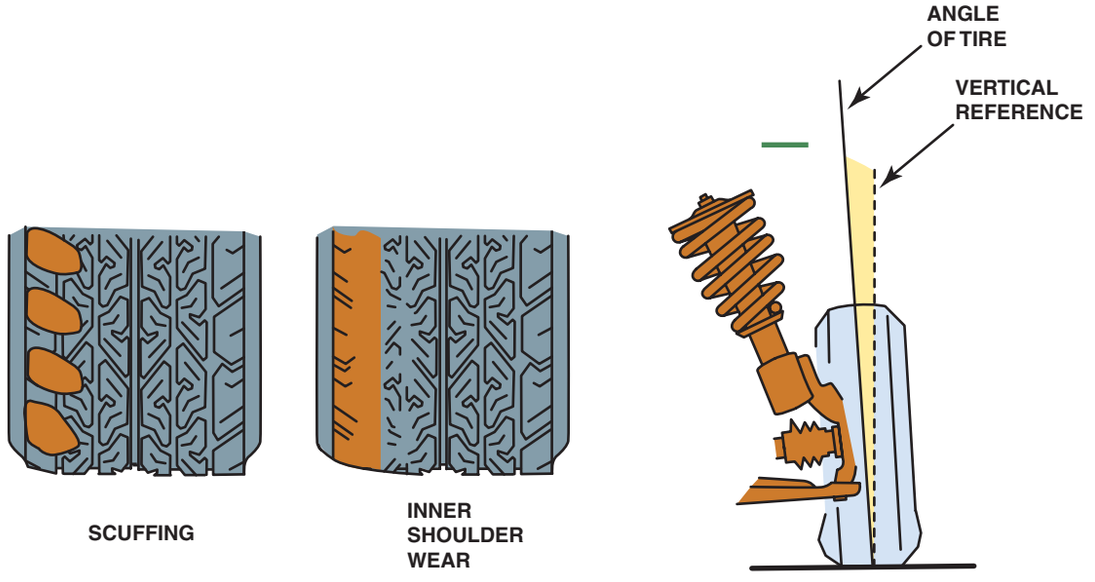

FIGURE 119–8 Excessive negative camber and how the front tires would wear due to the excessive camber.

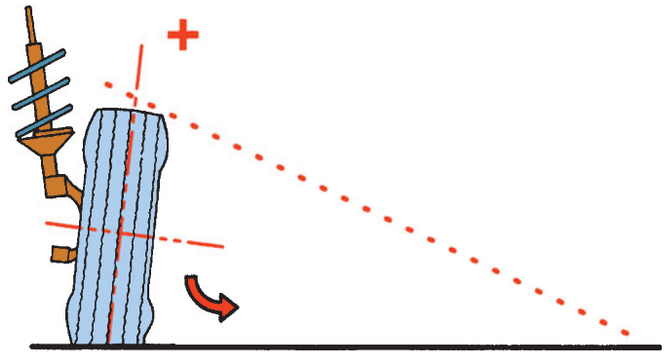

FIGURE 119–9 Positive camber tilts the tire and forms a cone shape that causes the wheel to roll away or pull outward toward the point of the cone.

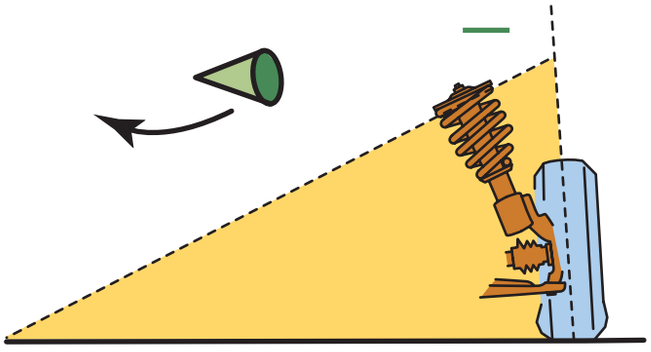

FIGURE 119–10 Negative camber creates a pulling force toward the center of the vehicle.

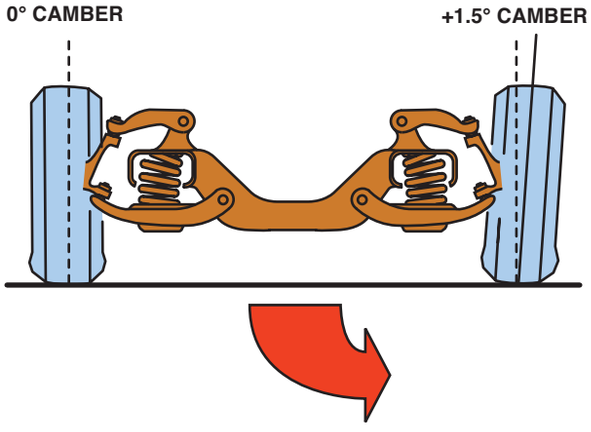

FIGURE 119–11 If camber angles are different from one side to the other, the vehicle will pull toward the side with the most camber.

10. Camber should be equal on both sides; however, if camber cannot be adjusted exactly equal, make certain that there is more camber on the front of the left side to help compensate for the road crown (1/2 degree maximum difference).

CASTER

Caster *is the forward or rearward tilt of the steering axis in reference to a vertical line as viewed from the side of the vehicle.* The steering axis is defined as the line drawn through the upper and lower steering pivot points. On an SLA suspension system, the upper pivot is the upper ball joint and the lower pivot is the lower ball joint. On a MacPherson strut system, the upper pivot is the center of the upper bearing mount and the lower pivot point is the lower ball joint. Zero caster means that the steering axis is straight up and down, also called 0 degrees or perfectly vertical, as shown in ● **FIGURE 119–14.**

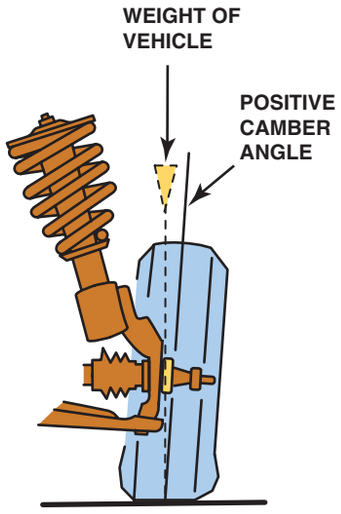

FIGURE 119–12 Positive camber applies the vehicle weight toward the larger inner wheel bearing. This is desirable because the larger inner bearing is designed to carry more vehicle weight than the smaller outer bearing.

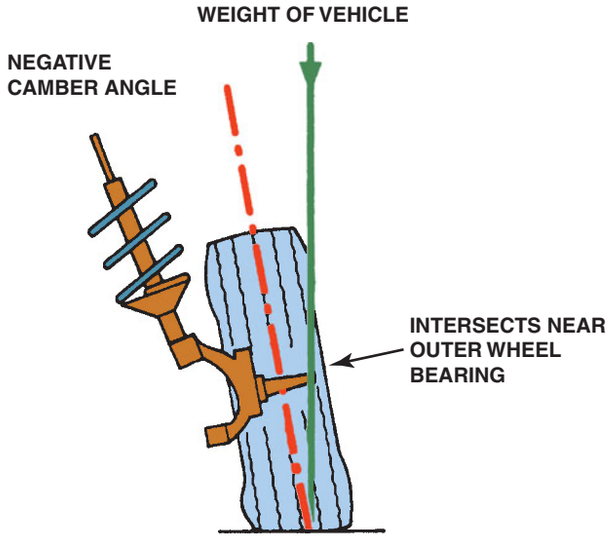

FIGURE 119–13 Negative camber applies the vehicle weight to the smaller outer wheel bearing. Excessive negative camber, therefore, may contribute to outer wheel bearing failure.

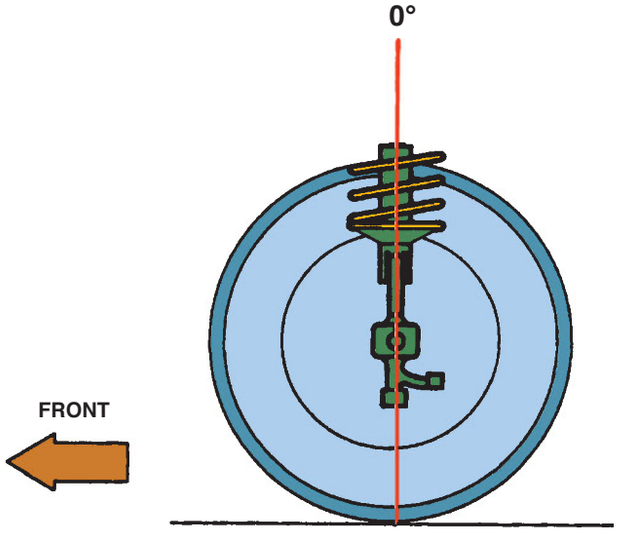

FIGURE 119–14 Zero caster.

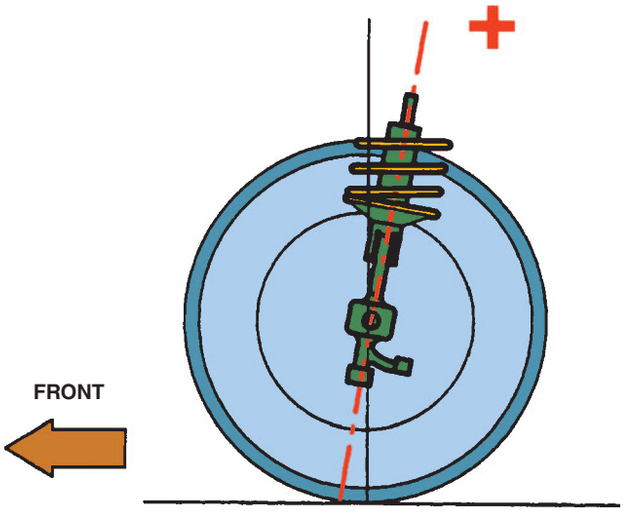

FIGURE 119–15 Positive (+) caster.

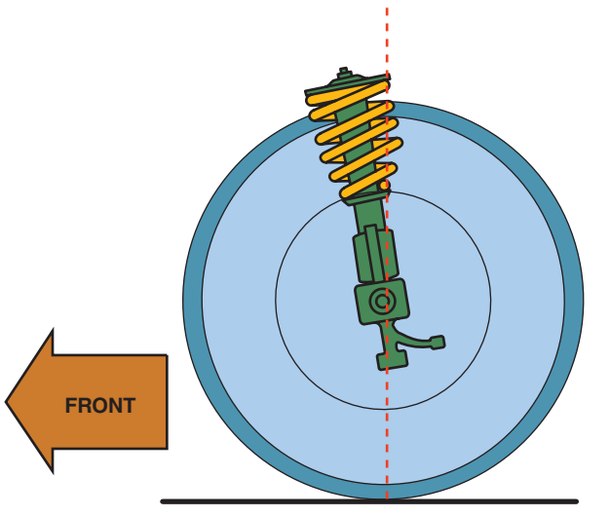

FIGURE 119–16 Negative (−) caster is seldom specified on today's vehicles because it tends to make the vehicle unstable at highway speeds. Negative caster was specified on some older vehicles not equipped with power steering to help reduce the steering effort.

TECH TIP

Think of a Bicycle

How caster affects steering stability and steering wheel returning to the straight ahead position after a turn is made easy by remembering how a bicycle acts. Caster allows a rider to travel straight ahead with their hands off the handle bars because the weight is behind the axle.

1. Positive (+) caster is present when the upper suspension pivot point is behind the lower pivot point (ball joint) as viewed from the side. ● **SEE FIGURE 119–15**.
2. Negative (−) caster is present when the upper suspension pivot point is ahead of the lower pivot point (ball joint) as viewed from the side. ● **SEE FIGURE 119–16**.
3. Caster is measured in degrees or fractions of degrees.
4. Caster is not a tire-wearing angle, but positive caster does cause changes in camber during a turn. ● **SEE FIGURE 119–17**. This condition is called **camber roll** (see the Tech Tip titled "Caster Angle Tire Wear").

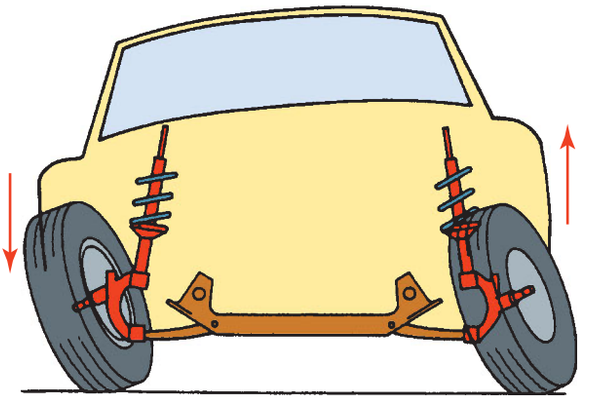

FIGURE 119–17 As the spindle rotates, it lifts the weight of the vehicle due to the angle of the steering axis. (*Courtesy of Hunter Engineering Company*)

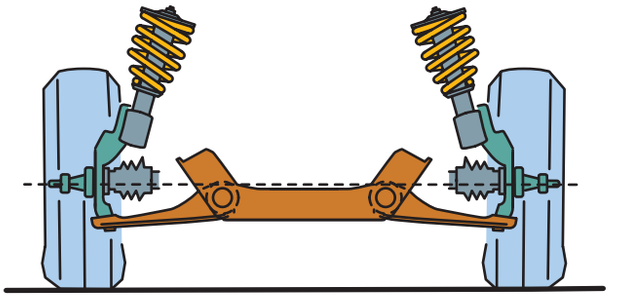

FIGURE 119–18 Vehicle weight tends to lower the spindle, which returns the steering to the straight-ahead position.

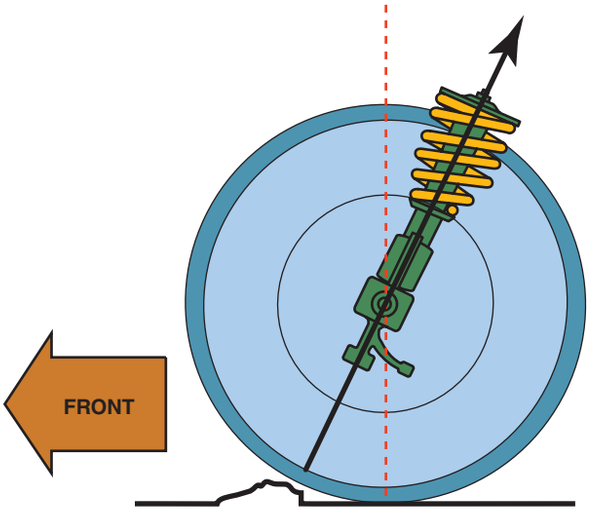

FIGURE 119–19 High positive caster provides a road shock path to the vehicle.

5. Caster is a stability angle.
   a. If caster is positive, the vehicle steering will be very stable (will tend to go straight with little steering wheel correction needed). This degree of caster helps with steering wheel **returnability** after a turn. ● **SEE FIGURE 119–18**.
   b. If the caster is positive, steering effort will increase with increasing positive caster. Greater road shocks will be felt by the driver when driving over rough road surfaces. ● **SEE FIGURE 119–19**. Vehicles with as many as 11 degrees positive caster, such as many Mercedes vehicles, usually use a steering dampener to control possible shimmy at high speeds and to dampen the snap-back of the spindle after a turn. ● **SEE FIGURE 119–20**.

c. If caster is negative, or excessively unequal, the vehicle will not be as stable and will tend to wander (constant steering wheel movement will be required to maintain straight-ahead direction). If a vehicle is heavily loaded in the rear, caster increases. ● **SEE FIGURE 119–21**.

6. Caster can cause pull if unequal; the vehicle will pull toward the side with the least positive caster. However, the pulling force of unequal caster is only about one-fourth the pulling force of camber. It would require a difference of caster of one full degree to equal the pulling force of only 1/4-degree difference of camber.

7. Caster is *not* adjustable on many vehicles.

8. If caster is adjustable, it is changed by moving either the lower or the upper pivot point forward or backward by means of the following:
- **a.** Shims
- **b.** Eccentric cams
- **c.** Slots
- **d.** Strut rods

9. Caster should be equal on both sides; however, if caster cannot be adjusted to be exactly equal, make certain that there is more caster on the right side (maximum 1/2-degree difference) to help compensate for the crown of the road.

TECH TIP

Caster Angle Tire Wear

The caster angle is generally considered to be a *non*-tire-wearing angle. However, excessive or unequal caster can *indirectly* cause tire wear. When the front wheels are turned on a vehicle with a lot of positive caster, they become angled. This is called *camber roll.* (Caster angle is a measurement of the difference in camber angle from when the wheel is turned inward compared to when the wheel is turned outward.) Most vehicle manufacturers have positive caster designed into the suspension system. This positive caster increases the directional stability.

However, if the vehicle is used exclusively in city driving, positive caster can cause tire wear to the outside shoulders of both front tires. ● **SEE FIGURE 119–22.**

NOTE: Caster is only measured on the front turning wheels of the vehicle. While some caster is built into the rear suspension of many vehicles, rear caster is not measured as part of a four-wheel alignment.

TOE **Toe** *is the difference in distance between the front and rear of the tires.* Toe is the most important of the alignment angles. As viewed from the top of the vehicle (a bird's eye view), zero toe means that both wheels on the same axle are parallel, as shown in ● **FIGURE 119–23.**

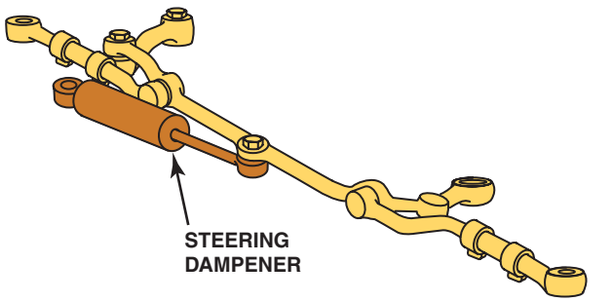

FIGURE 119–20 A **steering dampener** is used on many pickup trucks, sport utility vehicles (SUVs), and many luxury vehicles designed with a high-positive-caster setting. The dampener helps prevent steering wheel kickback when the front tires hit a bump or hole in the road and also helps reduce steering wheel shimmy that may result from the high-caster setting.

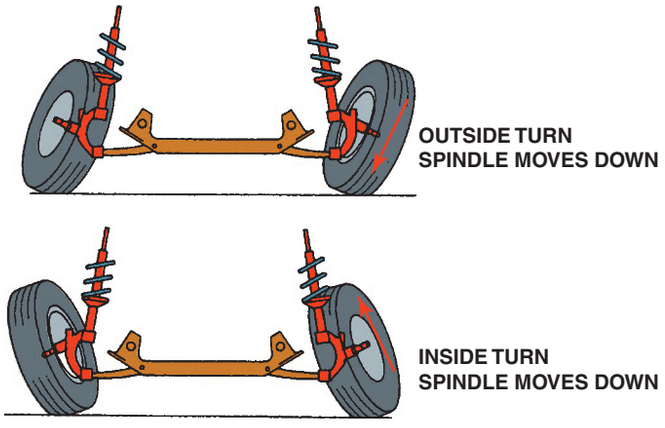

FIGURE 119–22 Note how the front tire becomes tilted as the vehicle turns a corner with positive caster. The higher the caster angle, the more the front tires tilt, causing camber-type tire wear.

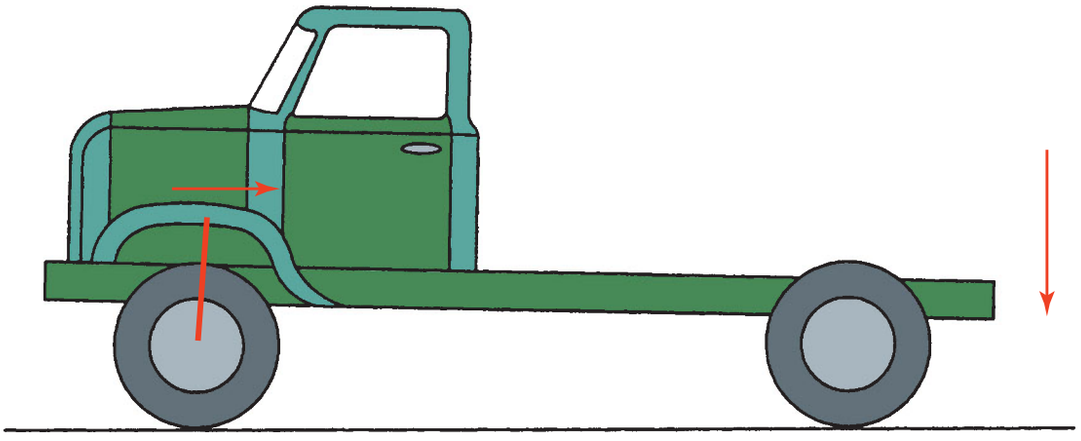

FIGURE 119–21 As the load increases in the rear of a vehicle, the top steering axis pivot point moves rearward, increasing positive (+) caster.

Toe is also described as a comparison of horizontal lines drawn through both wheels on the same axle, as shown in ● **FIGURE 119–24.**

If the front of the tires is closer than the rear of the same tires, then the toe is called *toe-in* or positive (+) toe. ● **SEE FIGURE 119–25.**

If the front of the tires is farther apart than the rear of the same tires, then the wheels are *toed-out,* or have negative (−) toe. ● **SEE FIGURE 119–26.**

The purpose of the correct toe setting is to provide maximum stability with a minimum of tire wear when the vehicle is being driven.

1. Toe is measured in fractions of degrees or in fractions of an inch (usually 1/16s), millimeters (mm), or decimals of an inch (such as 0.06 in.).
2. *Incorrect toe is the major cause of excessive tire wear!* ● **SEE FIGURE 119–27**.

   NOTE: If the toe is improper by just 1/8 in. (3 mm), the resulting tire wear is equivalent to dragging a tire sideways 28 feet (8.5 m) for every mile traveled (1.6 km).

   If not correct, toe causes camber-type wear on one side of the tire. ● **SEE FIGURES 119–28 AND 119–29**. Feather-edge wear is also common, especially if the vehicle is equipped with nonradial tires. ● **SEE FIGURE 119–30**.
3. *Incorrect front toe does not cause a pull condition.* Incorrect toe on the front wheels is split equally as the vehicle is driven because the forces acting on the tires are exerted through the tie rod and steering linkage to both wheels.
4. *Incorrect (or unequal) rear toe can cause tire wear.* ● **SEE FIGURES 119–31 THROUGH 119–33**. If the toe of the rear wheels is not equal, the steering wheel will not be straight and will pull toward the side with the most toe-in.
5. All vehicles can be adjusted for front toe.
6. Front toe adjustment must be made correctly by adjusting the tie rod sleeves. ● **SEE FIGURE 119–34** on page 1421.

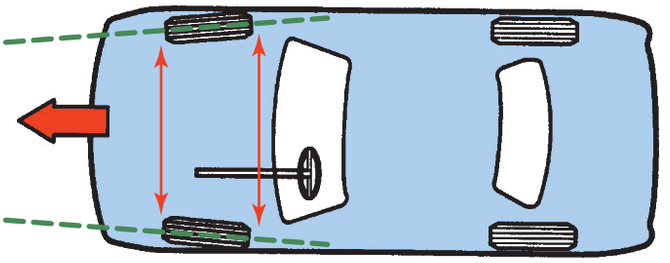

FIGURE 119–25 Toe-in, also called positive (+) toe.

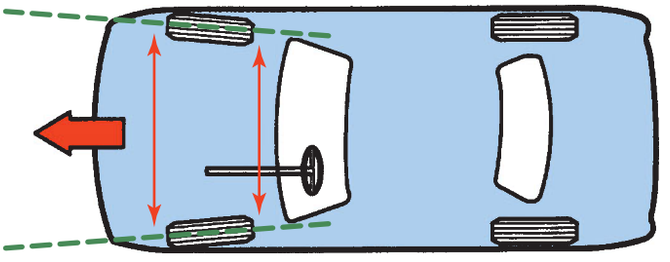

FIGURE 119–26 Toe-out, also called negative (−) toe. (*Courtesy of Hunter Engineering Company*)

FIGURE 119–27 This tire is just one month old! It was new and installed on the front of a vehicle that had about 1/4 inch (6 mm) of toe-out. By the time the customer returned to the tire store for an alignment, the tire was completely bald on the inside. Note the almost new tread on the outside.

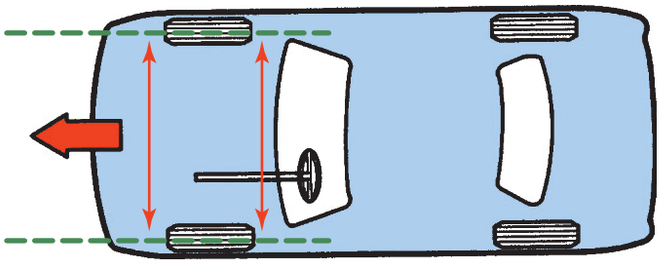

FIGURE 119–23 Zero toe. Note how both tires are parallel to each other as viewed from above the vehicle.

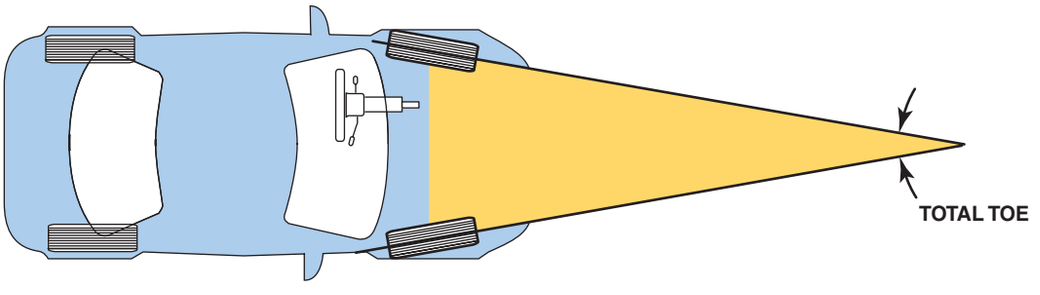

FIGURE 119–24 Total toe is often expressed as an angle. Because both front wheels are tied together through the tie rods and center link, the toe angle is always equally split between the two front wheels when the vehicle moves forward.

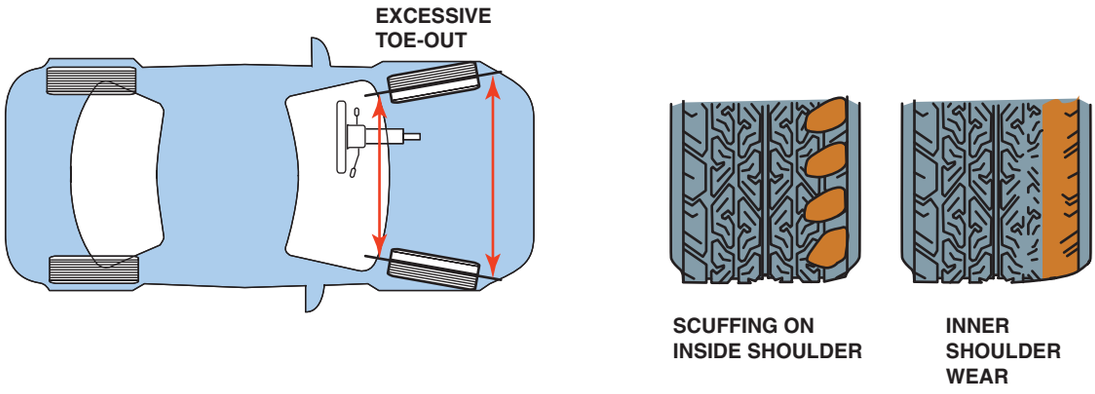

FIGURE 119–28 Excessive toe-out and the type of wear that can occur to the side of both front tires.

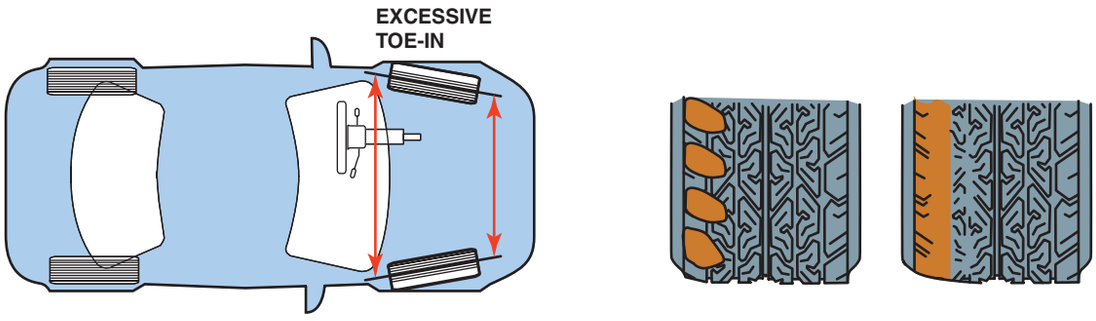

FIGURE 119–29 Excessive toe-in and the type of wear that can occur to the outside of both front tires.

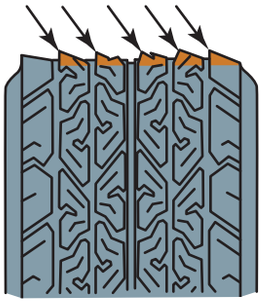

FIGURE 119–30 Feather-edge wear pattern caused by excessive toe-in or toe-out.

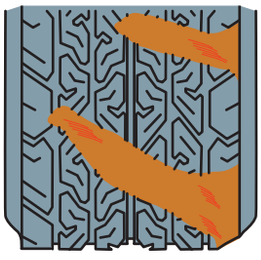

FIGURE 119–32 Incorrect toe can cause the tire to run sideways as it rolls, resulting in a diagonal wipe.

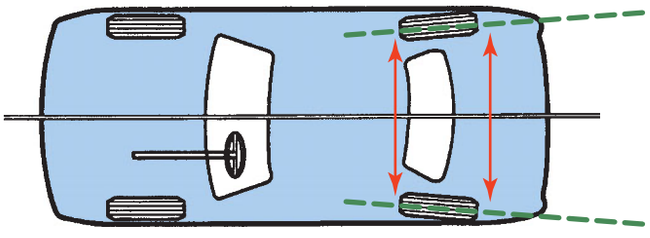

FIGURE 119–31 Rear toe-in (+). The rear toe (unlike the front toe) can be different for each wheel while the vehicle is moving forward because the rear wheels are not tied together as they are in the front. (*Courtesy of Hunter Engineering Company*)

7. Many vehicle manufacturers specify a slight amount of toe-in to compensate for the natural tendency of the front wheels to spread apart (become toed-out) due to centrifugal force of the rolling wheels acting on the steering linkage.

   NOTE: Some manufacturers of front-wheel-drive vehicles specify a toe-out setting to compensate for the toe-in forces created by the engine drive forces on the front wheels.

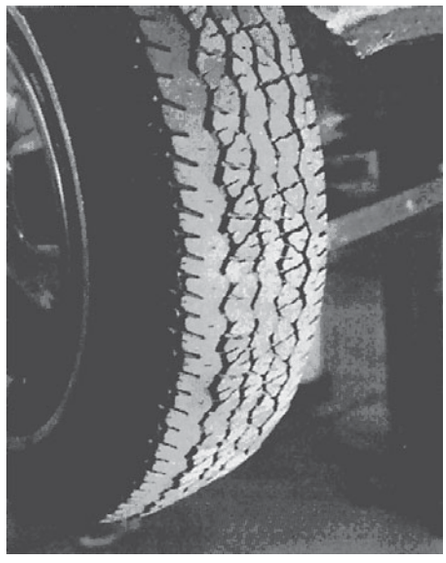

FIGURE 119–33 Diagonal wear such as shown here is usually caused by incorrect toe on the rear of a front-wheel-drive vehicle.

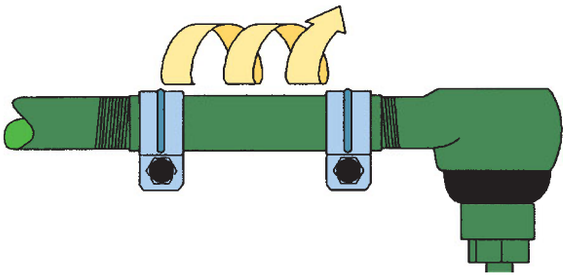

FIGURE 119–34 Toe on the front of most vehicles is adjusted by turning the tie rod sleeve as shown. (*Courtesy of John Bean Company*)

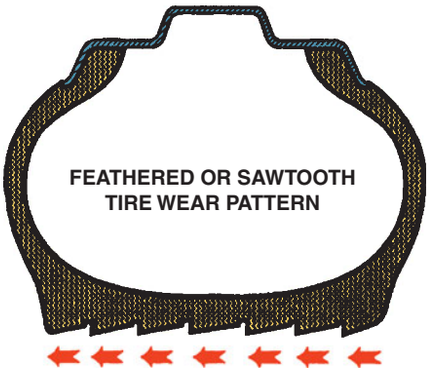

FIGURE 119–35 While the feathered or sawtooth tire tread wear pattern may not be noticeable to the eye, this wear can usually be felt by rubbing your hand across the tread of the tire. (*Courtesy of John Bean Company*)

FREQUENTLY ASKED QUESTION

Why Doesn't Unequal Front Toe on the Front Wheels Cause the Vehicle to Pull?

Each wheel could have individual toe, but as the vehicle is being driven, the forces on the tires tend to split the toe, causing the steering wheel to cock at an angle as the front wheels both track the same. If the toe is different on the rear of the vehicle, the rear will be "steered" similar to a rudder on a boat because the rear wheels are not tied together as are the front wheels.

TECH TIP

Smooth In, Toed-In; Smooth Out, Toed-Out

Whenever the toe setting is not zero, a rubbing action occurs that causes a feather-edge-type wear. ● **SEE FIGURE 119–35.** A quick, easy method to determine if incorrect toe could be causing problems is simply to rub your hand across the tread of the tire. If it feels smoother moving your hand toward the center of the vehicle than when you move your hand toward the outside, then the cause is excessive toe-in. The opposite effect is caused by toe-out. This may be felt on all types of tires, including radial-ply tires where the wear may not be seen as feather edged. Just remember this simple saying: "Smooth in, toed-in; smooth out, toed-out."

8. Normal wear to the tie rod ends and other steering linkage parts usually causes toe-out.

Excessive front toe-out will cause wandering (lack of directional stability), especially during braking. Incorrectly set toe will cause an uncentered steering wheel. If toe is unequal in the *rear,* the vehicle will pull toward the side with the most toe-in.

STEERING AXIS INCLINATION (SAI)

The steering axis is the angle formed between true vertical and an imaginary line drawn between the upper and lower pivot points of the spindle. ● **SEE FIGURE 119–36. Steering axis inclination (SAI)** is the inward tilt of the steering axis. SAI is also known as **kingpin inclination (KPI)** and is the imaginary line drawn through the kingpin as viewed from the front. SAI is also called **ball joint inclination (BJI),** if SLA-type suspension is used, or **MacPherson strut inclination (MSI).**

The purpose of SAI is to provide an upper suspension pivot location that causes the spindle to travel in an arc when turning, which tends to raise the vehicle, as shown in ● **FIGURE 119–37.**

Vehicle weight tends to keep the front wheels in a straight-ahead position when driving, thereby increasing vehicle stability, directional control, and steering wheel returnability. The greater the SAI, the more stable the vehicle. It also helps center the steering wheel after making a turn and reduces the need for excessive positive caster. The SAI/KPI angle of all vehicles ranges between 2 and 16 degrees. Front-wheel-drive vehicles usually have greater than 9 degrees SAI (typically 12 to 16 degrees) for directional stability, whereas rear-wheel-drive vehicles usually have less than 8 degrees of SAI. The steering axis inclination angle and the camber angle together are called the *included angle.*

INCLUDED ANGLE

The **included angle** is the SAI added to the camber reading of the front wheels only. *The included angle is determined by the design of the steering knuckle, or strut construction.* ● **SEE FIGURES 119–38 AND 119–39.**

Included angle is an important angle to measure for diagnosis of vehicle handling or tire wear problems. For example, if the cradle is out of location due to previous service work or an accident, knowing SAI, camber, and the included angle can help in determining what needs to be done to correct the problem. ● **SEE FIGURE 119–40.**

Figure 119–40 shows the included angle is equal on both sides but the camber and SAI are not equal. For best handling both the included angle and SAI should be within 1/2 degree of the other side of the vehicle.

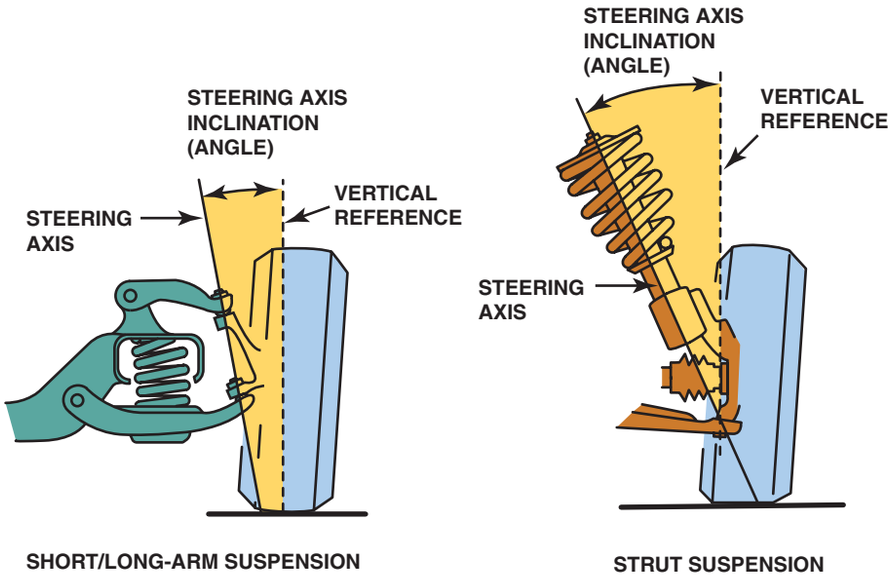

FIGURE 119–36 The left illustration shows that the steering axis inclination angle is determined by drawing a line through the center of the upper and lower ball joints. This represents the pivot points of the front wheels when the steering wheel is rotated during cornering. The right illustration shows that the steering axis inclination angle is determined by drawing a line through the axis of the upper strut bearing mount assembly and the lower ball joint.

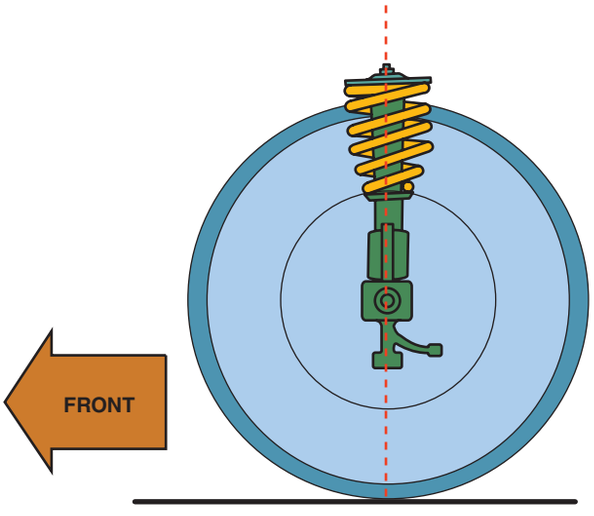

FIGURE 119–37 The SAI causes the spindle to travel in an arc when the wheels are turned. The weight of the vehicle is therefore used to help straighten the front tires after a turn and to help give directional stability.

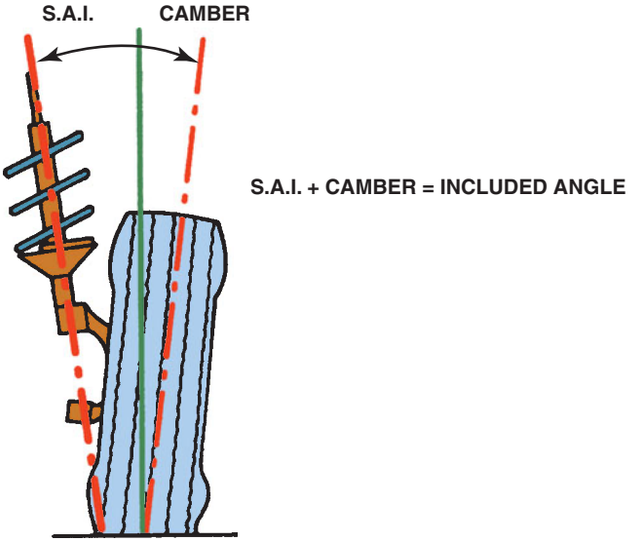

FIGURE 119–38 Included angle on a MacPherson-strut-type suspension.

SCRUB RADIUS

Scrub radius refers to the *distance* between the line through the steering axis and the centerline of the wheel at the contact point with the road surface. ● **SEE FIGURE 119–41.**

Scrub radius is *not* adjustable and cannot be measured. Scrub radius can be zero, positive, or negative. Zero scrub radius means that the line through the steering axis intersects the centerline of the tire at the road surface. Positive scrub radius means that the line intersects the centerline of the tire below the road surface. Negative scrub radius means that the line intersects the centerline of the tire above the road surface. Scrub radius is also called **steering offset** by some vehicle manufacturers. If a wheel is permitted to roll rather than pivot, then steering will be more difficult because a tire can pivot more easily than it can roll while turning the front wheels.

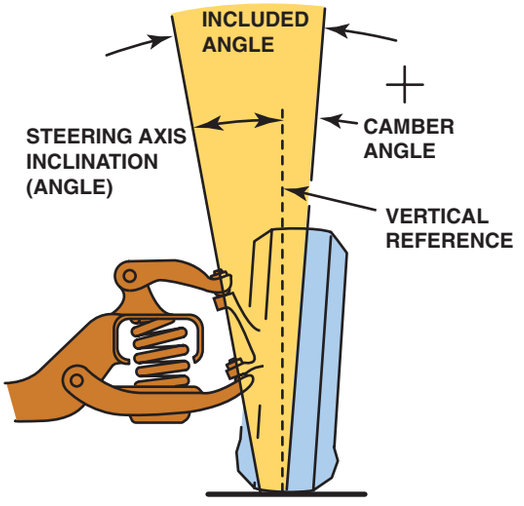

FIGURE 119–39 Included angle on an SLA-type suspension. The included angle is the SAI angle and the camber angle added together.

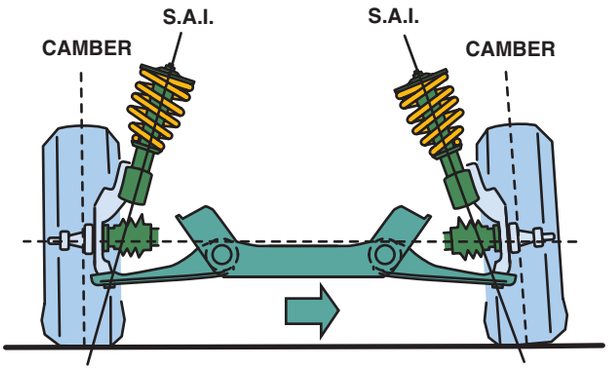

FIGURE 119–40 Cradle placement. If the cradle is not replaced in the exact position after removal for a transmission or clutch replacement, the SAI, camber, and included angle will not be equal side-to-side.

If the point of intersection is inside the centerline of the tire and below the road surface, this creates a toe-out force on the front wheels. Negative scrub radius is required on front-wheel-drive vehicles to provide good steering stability during braking. ● **SEE FIGURES 119–42 AND 119–43.**

Scrub radius is designed into each vehicle to provide acceptable handling and steering control under most conditions. Scrub radius also causes resistance to rolling of the front wheels to exert force on the steering linkage. This tends to dampen the effect of minor movements of the front wheels. Negative scrub radius causes the tire to toe-in during acceleration, braking, or traveling over bumps.

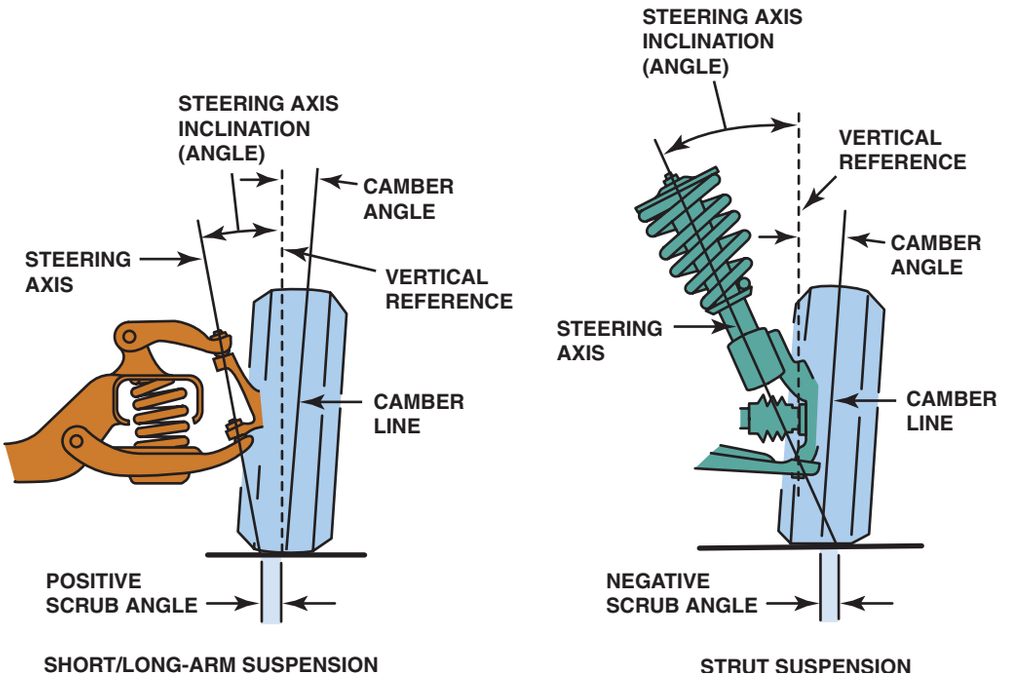

FIGURE 119–41 A positive scrub radius (angle) is usually built into most SLA front suspensions, and a negative scrub radius is usually built into most MacPherson-strut-type front suspensions.

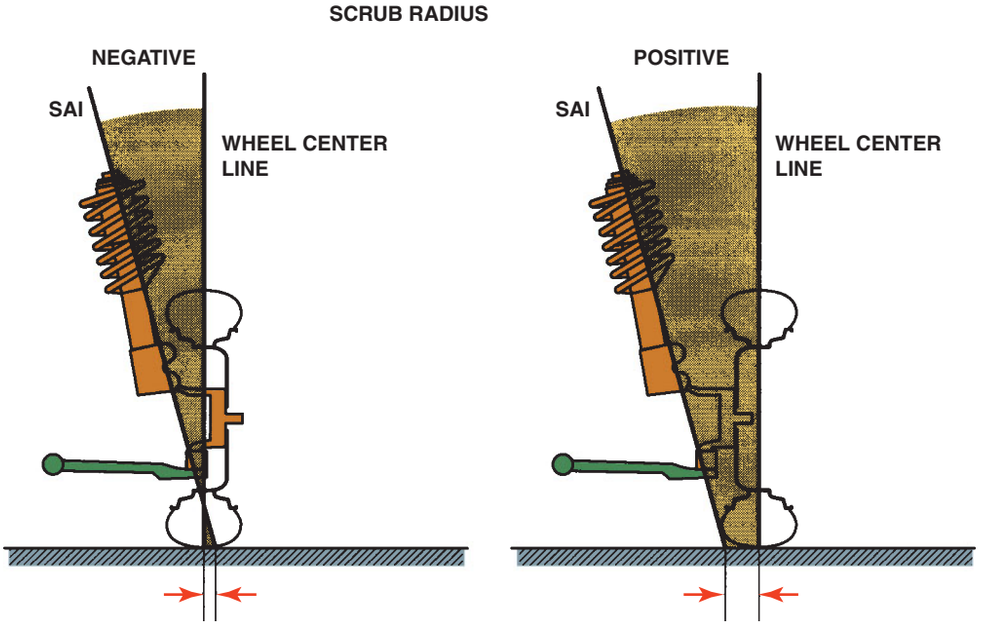

FIGURE 119–42 With negative scrub radius, the imaginary line through the steering axis inclination (SAI) intersects the road outside of the centerline of the tire. With positive scrub radius, the SAI line intersects the road inside the centerline of the tires.

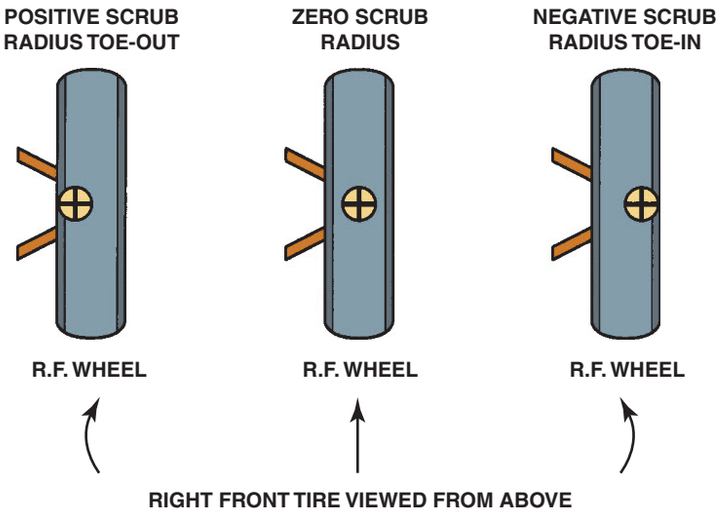

FIGURE 119–43 With a positive scrub radius, the pivot point, marked with a + mark, is inside the centerline of the tire and will cause the wheel to turn toward the outside, especially during braking. Zero scrub radius does not create any force on the tires and is not usually used on vehicles because it does not create an opposing force on the tires, which in turn makes the vehicle more susceptible to minor bumps and dips in the road. Negative scrub radius, as is used with most front-wheel-drive vehicles, generates an inward force on the tires.

NOTE: It is this tendency to toe-in caused by the negative scrub radius and engine torque that requires many front-wheel-drive vehicles to specify a toe-out setting for the front-drive wheels.

Zero scrub radius is acceptable; positive scrub radius is less desirable because it causes the wheel to toe-out during acceleration, braking, or traveling over bumps and causes instability. Positive scrub radius is commonly used on rear-wheel-drive vehicles and requires a toe-in setting to help compensate for the tendency to toe-out.

A bent spindle can cause a change in the scrub radius and could cause hard steering, wander, or pull.

Also, changing tire or wheel sizes can affect the centerline location of the wheel or the height of the tire assembly and will change the scrub radius, which can negatively affect the steering control. When larger-diameter tires and positive-offset wheels are installed, the scrub radius becomes positive and the wheels tend to toe-out, causing wander, poor handling, and tire wear.

TURNING RADIUS (TOE-OUT ON TURNS)

Whenever a vehicle turns a corner, the inside wheel has to turn at a sharper angle than the outside wheel because the inside wheel has a shorter distance to travel. ● **SEE FIGURE 119–44.**

Turning radius is also called **toe-out on turns,** abbreviated TOT or **TOOT,** and is determined by the angle of the steering knuckle arms. **Turning radius is a nonadjustable angle.** The turning radius can and should be measured as part of an alignment to check if the steering arms are bent or damaged. Symptoms of out-of-specification turning angle include the following:

1. Tire squeal noise during normal cornering, even at low speeds
2. Scuffed tire wear

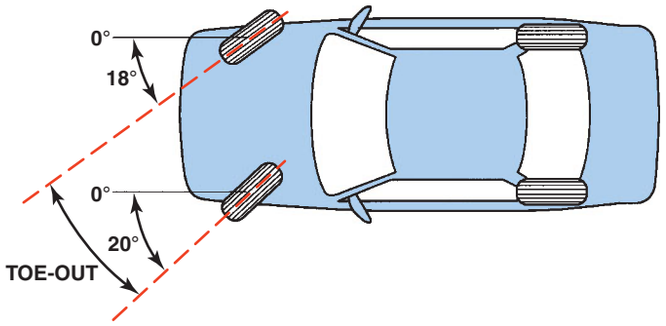

FIGURE 119–44 To provide handling, the inside wheel has to turn at a greater turning radius than the outside wheel.

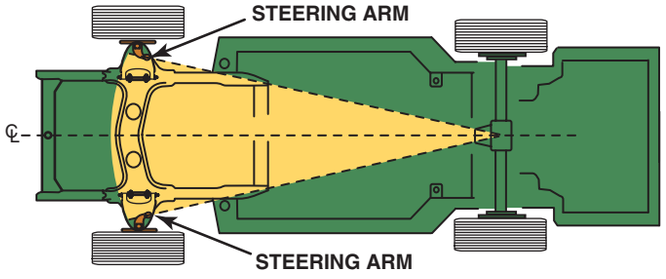

FIGURE 119–45 The proper toe-out on turns is achieved by angling the steering arms.

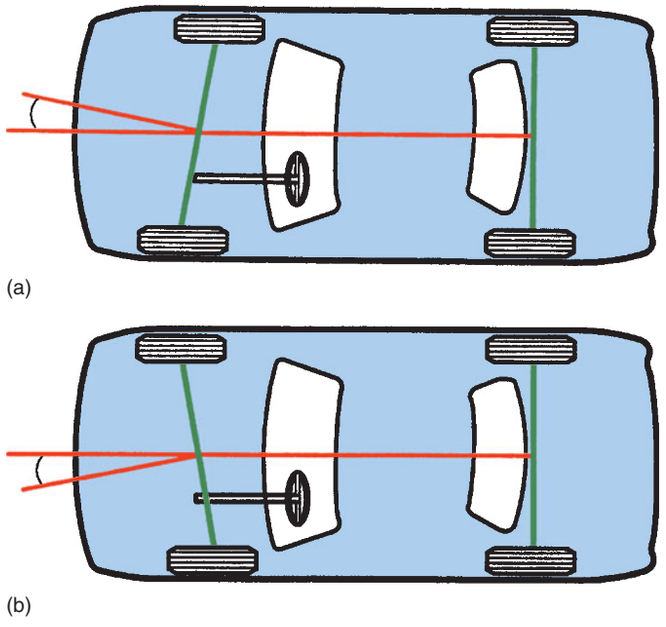

FIGURE 119–46 (a) Positive setback. (b) Negative setback.

The proper angle of the steering arms is where imaginary lines drawn from the steering arms should intersect exactly at the center of the rear axle. ● **SEE FIGURE 119–45.** This angle is called the Ackerman Effect (named for its promoter, an English publisher, Rudolph Ackerman, circa 1898).

SETBACK

Setback is the angle formed by a line drawn perpendicular (at 90 degrees) to the front axles. ● **SEE FIGURE 119–46.**

Setback is a nonadjustable measurement, even though it may be corrected. Positive setback means the right front wheel is set

back farther than the left; negative setback means the left front wheel is set back farther than the right.

Setback can be measured with a four-wheel alignment machine or can be determined by measuring the wheel base on both sides of the vehicle.

NOTE: The wheel base of any vehicle is the distance between the center of the front wheel and the center of the rear wheel on the same side. The wheel base should be within 1/8 in. (3 mm) side-to-side.

The causes of setback include the following:

1. Cradle placement not correct on a front-wheel-drive vehicle. This can be caused by incorrectly installing the cradle after a transmission, clutch, or engine replacement or service. ● **SEE FIGURE 119–47**.

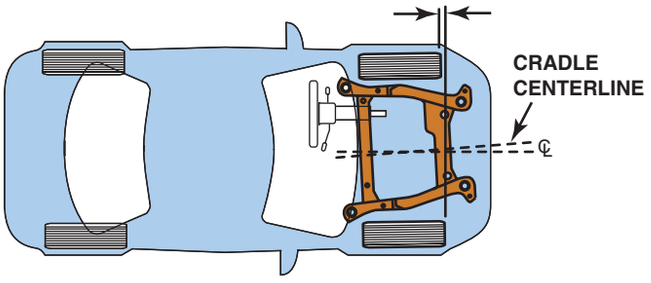

FIGURE 119–47 Cradle placement affects setback.

2. An accident that affected the frame or cradle of the vehicle and was unnoticed or not repaired.

Most vehicle manufacturers do not specify a minimum setback specification. However, a reading of 0.50 degrees or 0.5 in. (13 mm) or less of setback is generally considered to be acceptable.

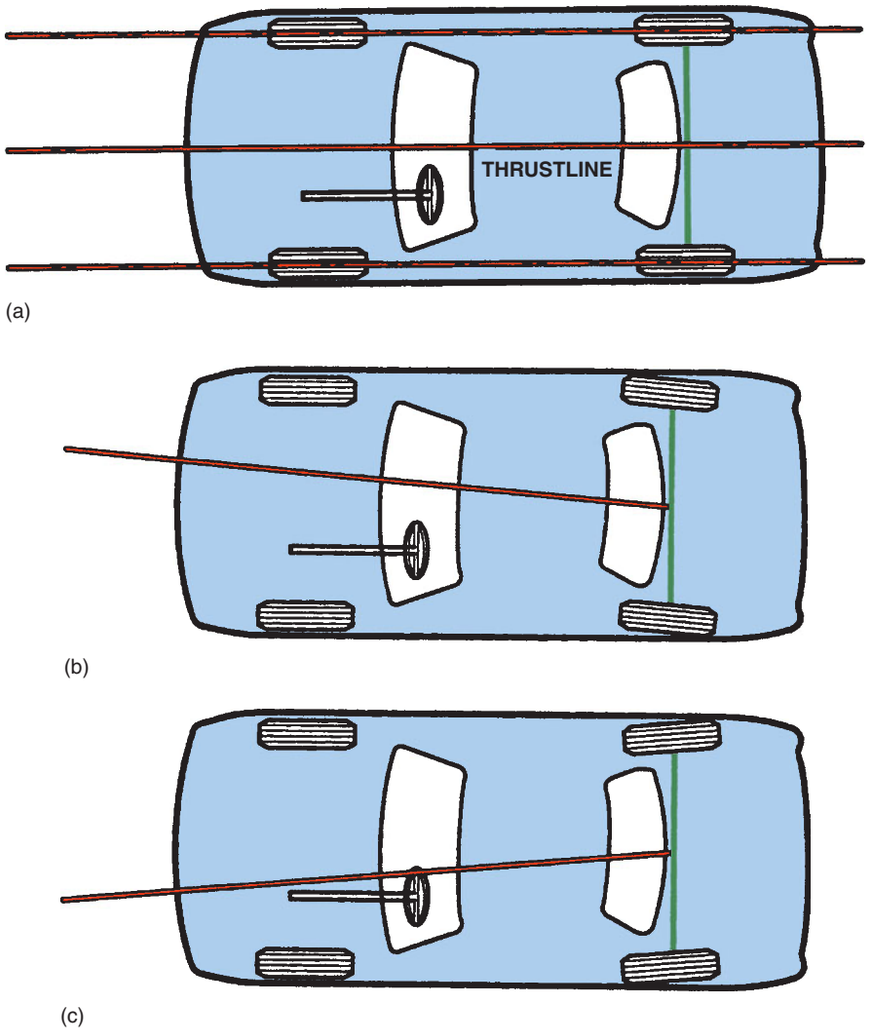
THRUST ANGLE

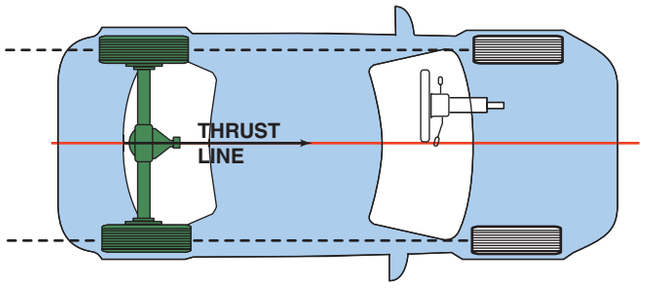
Thrust angle is the angle of the rear wheels as determined by the total rear toe. If both rear wheels have zero toe, then the thrust angle is the same as the geometric centerline of the vehicle. The total of the rear toe setting determines the **thrust line,** or the direction the rear wheels are pointed. ● **SEE FIGURE 119–48.**

On vehicles with an independent rear suspension, if both wheels do not have equal toe, the vehicle will pull in the direction of the side with the most toe-in.

TRACKING

The rear wheels should track directly behind the front wheels. If the vehicle has been involved in an accident, it is possible that the frame or rear axle mounting could cause **dog tracking.** ● **SEE FIGURE 119–49.**





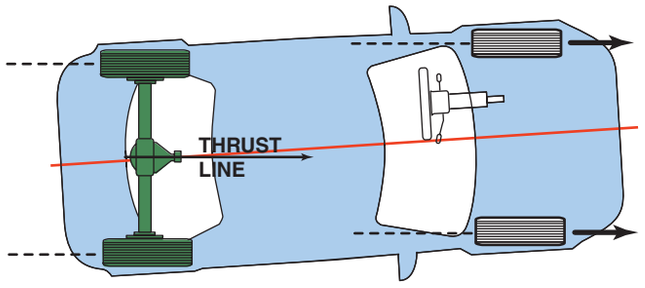


FIGURE 119–48 (a) Zero thrust angle. (b) Thrust line to the right. (c) Thrust line to the left.

(a)

(b)

FIGURE 119–49 (a) Proper tracking. (b) Front wheels steering toward thrust line.

To check the frame for possible damage, two diagonal measurements of the frame and/or body are required. The diagonal measurements from known points at the front and the rear should be within 1/8 in. (3 mm) of each other.

FOUR-WHEEL ALIGNMENT

Four-wheel alignment refers to the checking and/or adjustment of all four wheels. Four-wheel alignment is important for proper handling and tire wear. Some rear-wheel-drive vehicles equipped with independent rear suspension can be adjusted for camber and toe. Rear-wheel caster cannot be measured or adjusted because to measure caster, the wheels must be turned from straight ahead. Since rear wheels are securely attached, a caster *sweep* (turning the wheels to take a caster reading) is not possible. While rear camber can cause tire wear problems, by far the greatest tire wear occurs due to toe settings. *Unequal* toe in the rear can cause the vehicle to pull or lead. The rear camber and toe are always adjusted first before adjusting the front caster, camber, and toe. This procedure ensures that the thrust line and centerline of the vehicle are the same.

REVIEW QUESTIONS

1. Explain the three basic alignment angles of camber, caster, and toe.
2. Describe what happens to tire wear and vehicle handling if toe, camber, and caster are out of specification or *not* equal side-to-side.
3. Explain how knowing SAI, TOOT, and included angle can help in the correct diagnosis of an alignment problem.
4. Explain what thrust angle means.

CHAPTER QUIZ

1. When performing an alignment, which angle is the most important for tire wear?
   a. Toe **c.** Caster
   b. Camber **d.** SAI (KPI)
2. Positive camber means _____.
   a. The top of the tire is tilted outward.
   b. The top of the tire is tilted inward.
   c. Either a or b
   d. Both a and b
3. Which alignment angle is adjustable on all vehicles?
   a. Camber **c.** Toe
   b. Caster **d.** SAI (KPI)
4. Positive (+) toe is _____.
   a. Toe-in **b.** Toe-out
5. If the top of the steering axis is tilted 2 degrees toward the rear of the vehicle, this is _____.
   a. Positive camber **c.** Negative caster
   b. Negative camber **d.** Positive caster
6. A steering dampener may be needed to reduce shimmy on vehicles that have high positive _____.
   a. Camber **c.** Toe
   b. Caster **d.** Included angle
7. If the turning radius (toe-out on turns, or TOOT) is out of specification, what part or component is defective?
   a. The strut is bent.
   b. The steering arm is bent.
   c. The spindle is bent.
   d. The control arm is bent.
8. Which angle determines the thrust angle?
   a. Front toe
   b. Rear toe
   c. Rear camber
   d. Front caster, SAI, and included angle
9. Included angle is _____.
   a. SAI + caster
   b. Camber + caster
   c. Camber + SAI
   d. Toe + camber
10. Two technicians are discussing scrub radius. Technician A says that scrub radius cannot be measured. Technician B says that scrub radius cannot be adjusted. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 120

ALIGNMENT DIAGNOSIS AND SERVICE

OBJECTIVES: After studying Chapter 120, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "D" (Wheel Alignment Diagnosis, Adjustment, and Repair). • List the many checks that should be performed before aligning a vehicle. • Describe the proper alignment setup procedure. • Explain how to correct for memory steer, torque steer, pull, drift (lead), and wander. • Describe the use of unit conversion and diagnostic charts. • Discuss tolerance alignment and how to check for accident damage.

KEY TERMS: Degrees 1431 • Eccentric cam 1442 • Five-wheel alignment 1430 • Four-wheel alignment 1436 • Fractional 1431 • Geometric centerline 1434 • Memory steer 1429 • Minutes 1431 • Prealignment checks 1428 • Ride height 1428 • Shim chart 1442 • Spoke angle 1443 • Thrust line 1436 • Tolerance adjustment 1447 • Torque steer 1429 • Total toe 1433

NEED FOR PROPER ALIGNMENT

Proper wheel alignment of all four wheels is important for the safe handling of any vehicle. When all four wheels are traveling the same path and/or being kept nearly vertical, tire life and fuel economy are maximized and vehicle handling is sure and predictable. A complete wheel alignment is a complex process that includes many detailed steps and the skill of a highly trained technician.

PREALIGNMENT CORRECTION TECHNIQUES

There are four basic steps in the correction of any problem:

1. **Verify.** What, when, where, and to what extent does the problem occur? This step usually involves a test drive to verify the problem.
2. **Isolate.** Eliminate known good parts and systems. Always start with the simple things first. For example, checking and correcting tire pressure and rotation of the tires should be one of the first things performed whenever trying to isolate the cause of an alignment-related problem.
3. **Repair the problem.** This step involves replacing any worn or damaged components and making sure that the alignment is within factory specifications. ● **SEE FIGURE 120–1**.
4. **Recheck.** *Always* test-drive the vehicle after making a repair. Never allow the customer to be the first to drive the vehicle after any service work.

A thorough inspection of the steering, suspension, and tires should be performed *before* the alignment of the vehicle is begun.

TECH TIP

Align and Replace at the Same Time

Magnetic bubble-type camber/caster gauges can be mounted directly on the hub or on an adapter attached to the wheel or spindle nut on front-wheel-drive vehicles. ● **SEE FIGURE 120–2.** Besides being used as an alignment setting tool, a magnetic alignment head is a great tool to use whenever replacing suspension components.

Any time a suspension component is replaced, the wheel alignment should be checked and corrected as necessary. An easy way to avoid having to make many adjustments is to use a magnetic alignment head on the front wheels to check camber with the vehicle hoisted in the air *before* replacing front components, such as new MacPherson struts. Then, before tightening all of the fasteners, check the front camber readings again to make sure they match the original setting. This is best done when the vehicle is still off the ground. For example, a typical front-wheel-drive vehicle with a MacPherson strut suspension may have a camber reading of +1/4 degree on the ground and +2 degrees while on the hoist with the wheels off the ground. After replacing the struts, simply return the camber reading to +2 degrees and it should return to the same +1/4 degree when lowered to the ground.

Though checking and adjusting camber before and after suspension service work does not guarantee a proper alignment, it does permit the vehicle to be moved around with the alignment fairly accurate until a final alignment can be performed.

FIGURE 120–1 The owner of this Honda thought that all it needed was an alignment. Obviously, something more serious than an alignment caused this left rear wheel to angle inward at the top.

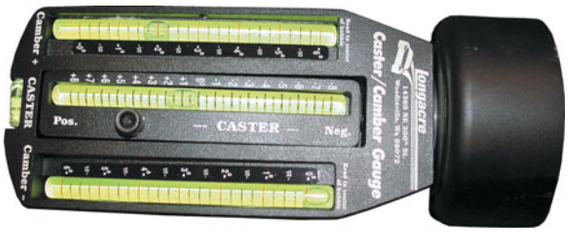

FIGURE 120–2 Magnetic bubble-type camber/caster gauge. To help it keep its strong magnetism, it is best to keep it stored stuck to a metal plate or metal tool box.

PREALIGNMENT CHECKS

Before checking or adjusting the front-end alignment, the following items should be checked and corrected, if necessary, as part of the **prealignment checks:**

1. Check all the tires for proper inflation pressures. Tires should be approximately the same size and tread depth, and the recommended size for the vehicle. ● **SEE FIGURE 120–3.**

   NOTE: Some alignment technicians think that the vehicle must have new tires installed before an accurate alignment can be performed. Excessively worn tires, especially if only one tire is worn, can cause the vehicle to lean slightly. It is this unequal ride height that is the important fact to consider. If, for example, all four tires are equally worn, then the vehicle *can* be properly aligned. (Obviously, excessively worn tires should be replaced, and it would be best to align the vehicle with the replacement tires installed to be assured of an accurate alignment.)

2. Check the wheel bearings for proper adjustment.
3. Check for loose ball joints or torn ball joint boots.
4. Check the tie rod ends for damage or looseness.
5. Check the center link or rack bushings for play.
6. Check the pitman arm for any movement.
7. Check for runout of the wheels and the tires.
8. Check for vehicle ride height (should be level front to back as well as side-to-side). Make sure that the factory load-leveling system is functioning correctly, if the vehicle is so equipped. Check height according to the manufacturer's specifications. ● **SEE FIGURES 120–4 AND 120–5.**

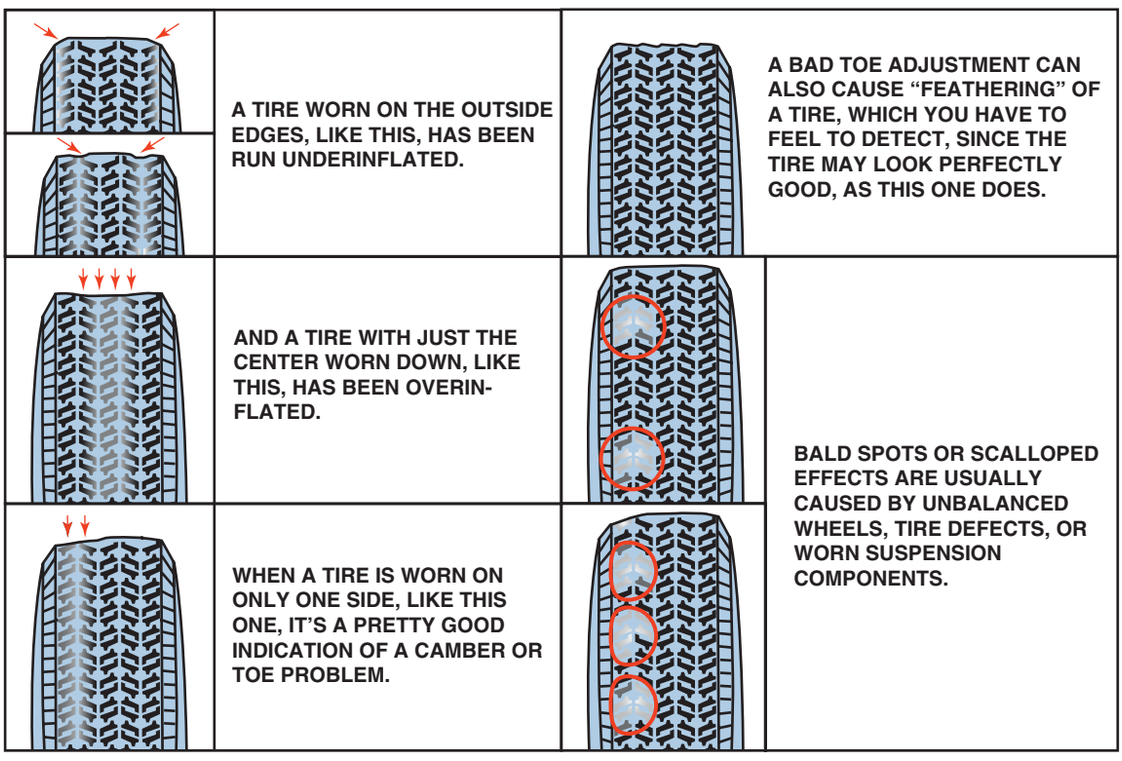

FIGURE 120–3 Typical tire wear chart as found in a service manual. Abnormal tire wear usually indicates a fault in a steering or suspension component that should be corrected or replaced before an alignment is performed.

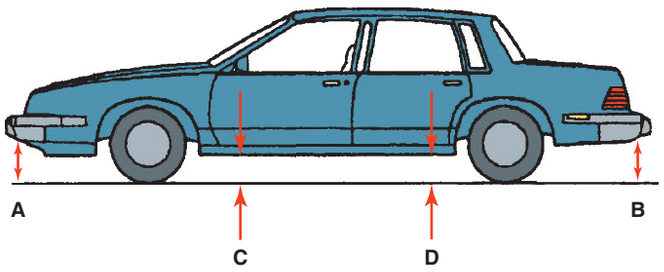

FIGURE 120–4 Measuring points for ride (trim) height vary by manufacturer. (*Courtesy of Hunter Engineering Company*)

FIGURE 120–5 Measuring to be sure the left and right sides of the vehicle are of equal height. If this measurement is not equal side-to-side by as little as 1/8 in. (3 mm), it can affect the handling of the vehicle.

9. Check for steering gear looseness at the frame.
10. Check for improperly operating shock absorbers.
11. Check for worn control arm bushings.
12. Check for loose or missing stabilizer bar attachments.
13. Check the trunk for excess loads.
14. Check for dragging brakes.

NOTE: Checking for dragging brakes is usually performed when installing alignment heads to the wheels prior to taking an alignment reading. A brake dragging can cause the vehicle to pull or lead toward the side with the dragging brake.

LEAD/PULL

DIAGNOSIS Many alignment requests come from customers attempting to have a lead or pull condition corrected. Before aligning the vehicle, verify the customer complaint first, then perform a careful inspection.

1. Inspect all tires for proper inflation. Both tires on the same axle (front and rear) should be the same size and brand. A lead/pull problem could be due to a defect or condition in one or more of the tires, as shown in ● **FIGURE 120–6**. Before attempting to correct the lead/pull condition by changing alignment angles, try rotating the tires front to back or side to side.
2. Road test the vehicle on a straight, level road away from traffic, if possible. Bring the vehicle to about 40 mph (65 km/h), shift into neutral, and feel for a pull in the steering, either to the left or to the right. A lead or drift is less severe than a pull, and may occur only if you momentarily remove your hands from the steering wheel while driving.
3. If the lead/pull problem is sometimes toward the left and other times toward the right, check for a **memory steer** condition. If the lead/pull problem occurs during acceleration and deceleration, check for a **torque steer** condition.

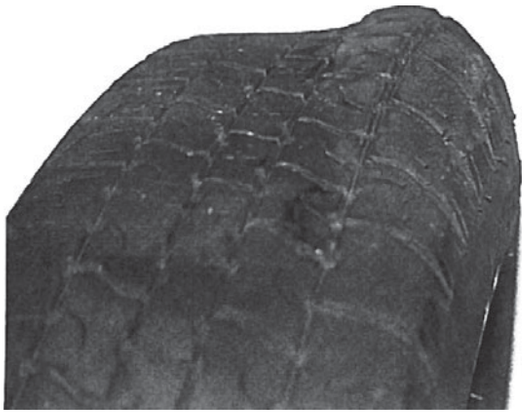

FIGURE 120–6 The bulge in this tire was not noticed until it was removed from the vehicle as part of a routine brake inspection. After replacing this tire, the vehicle stopped pulling and vibrating.

MEMORY STEER

DIAGNOSIS *Memory steer* is a term used to describe the lead or pull of a vehicle caused by faults in the steering or suspension system. Often a defective upper strut bearing or steering gear can cause a pulling condition in one direction after making a turn in the same direction. It is as if the vehicle had a memory and pulled in the same direction. To test for memory steer, follow these simple steps during a test drive:

1. With the vehicle stopped at an intersection or in a parking area, turn the steering wheel completely to the left stop and then straighten the wheel without going past the straight-ahead position.
2. Lightly accelerate the vehicle and note any tendency of the vehicle to lead or pull toward the left.
3. Repeat the procedure, turning the steering wheel to the right.

If the vehicle first pulls to the left, then pulls to the right, the vehicle has a memory steer condition.

CORRECTION A binding suspension or steering component is the most likely cause of memory steer. Disconnect each wheel from its tie rod end and check for free rotation of movement of each wheel. Each front wheel should rotate easily without binding or roughness. Repair or replace components as necessary to eliminate the binding condition.

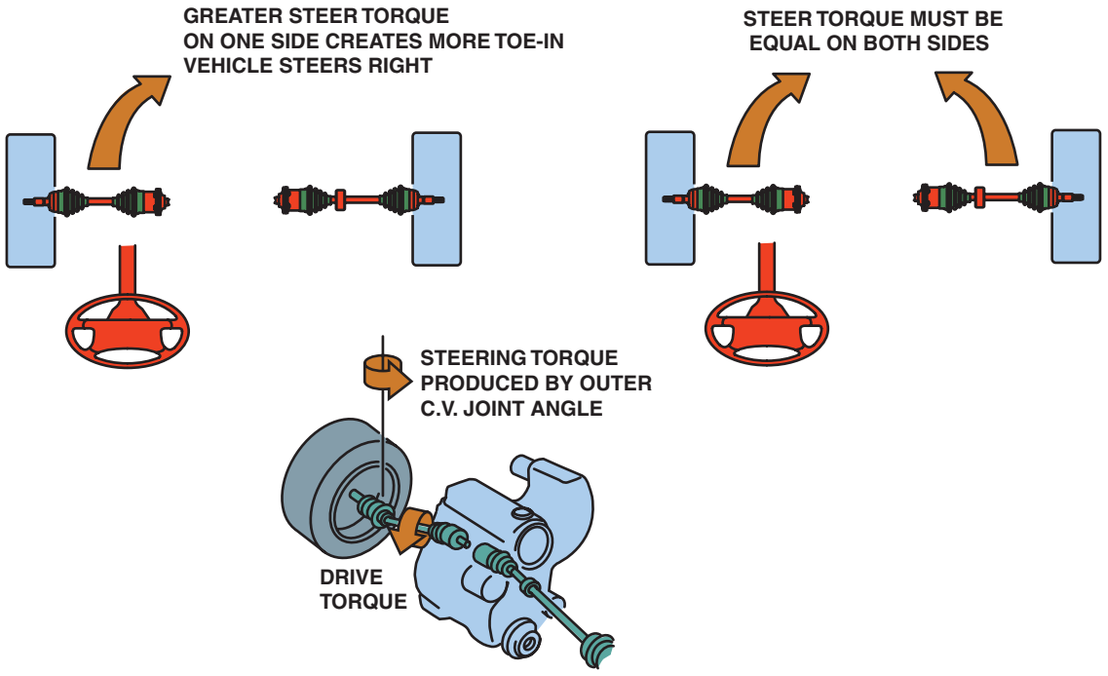

FIGURE 120–7 Equal outer CV joint angles produce equal steer torque (toe-in). If one side receives more engine torque, that side creates more toe-in and the result is a pull toward one side, especially during acceleration.

REAL WORLD FIX

The Five-Wheel Alignment

The steering wheel should always be straight when driving on a straight, level road. If the steering wheel is not straight, the customer will often think that the wheel alignment is not correct. One such customer complained that the vehicle pulled to the right while driving on a straight road. The service manager test drove the vehicle and everything was perfect, except that the steering wheel was not perfectly straight, even though the toe setting was correct. Whenever driving on a straight road, the customer would "straighten the steering wheel" and, of course, the vehicle went to one side. After adjusting toe with the steering wheel straight, the customer and the service manager were both satisfied. The technician learned that regardless of how accurate the alignment, the steering wheel *must* be straight; it is the "fifth wheel" that the customer notices most. Therefore, a **five-wheel alignment** rule includes a check of the steering wheel.

NOTE: Many vehicle manufactures now include the maximum allowable steering wheel angle variation from straight. This specification is commonly ±3 degrees (plus or minus 3 degrees) or less.

NOTE: One of the most common causes of memory steer is the installation of steering or suspension components while the front wheels are turned. Most steering and suspension parts contain rubber, which has a memory if moved from its installed position. If the memory steer condition is only in one direction, then this is the most likely cause. The rubber component exerts a force on the suspension or steering that causes the vehicle to pull toward the side that the wheels were turned toward when the part was installed.

TORQUE STEER

DIAGNOSIS Torque steer occurs in front-wheel-drive vehicles when engine torque causes a front wheel to change its angle from straight ahead. ● **SEE FIGURE 120–7.** This resulting pulling effect is most noticeable during rapid acceleration, especially whenever upshifting of the transmission creates a sudden change in torque being applied to the front wheels. When turning and accelerating at the same time, torque steer has a tendency to straighten the vehicle, so more steering effort may be required to make the turn. Then, if the accelerator is released, a reversing force is applied to the front wheels. Now the driver must take corrective steering motions to counteract the change in steering effect of engine torque.

Torque steer sequence of events	
Torque to wheel	creates a toe-in condition
More torque	creates more toe-in
Unequal torque	creates unequal toe-in
Unequal driveshaft angles	creates unequal torque to the wheels

Most manufacturers try to reduce torque steer in the design of their vehicles by keeping drive axle angles low and equal side-to-side. If the engine and transaxle are level and the drive axle shafts are kept level, then the torque from the engine will be divided equally between the front wheels.

CORRECTION The service technician cannot change the design of a vehicle, but the technician can, and should, check and correct problems that often cause torque steer. **Check to be sure that the condition is not normal.** It is normal for front-wheel-drive vehicles to exert a tug on the steering wheel and steer toward one side (usually to the right) during acceleration. This is especially noticeable when the transmission shifts from first to second gear under heavy acceleration. To determine how severe the problem is, place a strip

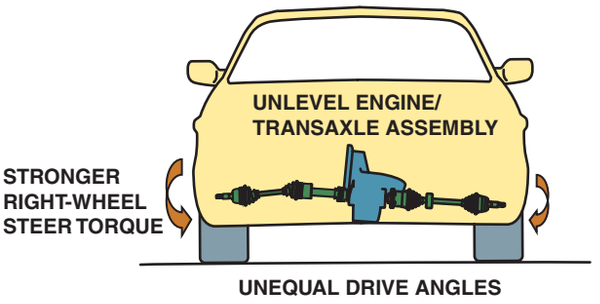

FIGURE 120–8 Broken or defective engine or transaxle mounts can cause the powertrain to sag, causing unequal drive axle shaft CV joint angles.

of masking tape at the top of the steering wheel. Drive the vehicle and observe the amount of movement required to steer the vehicle straight during heavy acceleration. Repeat the test with a vehicle of similar make and model. If the torque steer is excessive, determine and correct the cause by carefully following the prealignment inspection steps and checking for a level powertrain.

A defective engine mount can cause the entire drivetrain to sag on one end. If the engine and transaxle of any front-wheel-drive vehicle is not level, the drive axle shaft angles will not be equal, as shown in ● **FIGURE 120–8.**

Hold a straightedge along the engine's supporting frame and measure up to points along the transaxle pan rail or the drive axle shaft. Side-to-side distances should be equal. Standard alignment shims can be used to shim the mounts and level the drivetrain.

If torque steer is still excessive, check all alignment angles, including SAI and included angle. Unequal alignment angles can cause a pull or a lead condition. SAI and included angle should be within 1/2 (0.5) degree side-to-side for best results. A vehicle will tend to pull toward the side with the least SAI.

ALIGNMENT SPECIFICATIONS

Before attempting any alignment, consider the following:

1. Determine the make, model, and year of the vehicle.
2. Determine if the vehicle is equipped with power steering or manual steering. (Some older models use lower caster specifications for manual steering to reduce steering effort.)
3. Check the trunk and with the customer to determine the normal load being carried. Sometimes customers take out heavy things they normally carry or have something in the vehicle now that they normally do not carry.
4. Determine the correct specifications (if possible, check the specifications from two different sources to ensure correct readings).
5. Compensate for the lack of a full gas tank by placing an equal amount of weight in the luggage compartment. (Gasoline weighs 6 lb per gallon [0.7 kg per l]—a 20-gallon gas tank, when full, weighs 120 lb [80 liters weighs 54 kg].)
6. Determine the correct specifications for the *exact* vehicle being checked.

NOTE: Some alignment specifications are published as guidelines for acceptable values for state or local vehicle inspections. Be sure to use the *service* or *set to* specifications.

TECH TIP

Keep the Doors Closed, but the Window Down

An experienced alignment technician became upset when a beginning technician opened the driver's door to lock the steering wheel in a straight-ahead position on the vehicle being aligned. The weight of the open door caused the vehicle to sag. This disturbed the level position of the vehicle and changed all the alignment angles.

The beginning technician learned an important lesson that day: Keep the window down on the driver's door so that the steering wheel and brakes can be locked without disturbing the vehicle weight balance by opening a door. The brake pedal must be locked with a pedal depressor to prevent the wheels from rolling as the wheels are turned during a caster sweep. The steering must be locked in the straight-ahead position when adjusting toe.

READING ALIGNMENT SPECIFICATIONS

There are several methods used by vehicle manufacturers and alignment equipment manufacturers to specify alignment angles.

MAXIMUM/MINIMUM/PREFERRED METHOD. This method indicates the preferred setting for each alignment angle and the minimum and maximum allowable value for each. The alignment technician should always attempt to align the vehicle to the preferred setting.

PLUS OR MINUS METHOD. This method indicates the preferred setting with the lowest and highest allowable value indicated by a negative (−) and positive (+) sign, as in ● **CHART 120–1.** For example, if a camber reading is specified as +1/2 degree with a + and − value of 1/2 degree, it could be written as +1/2 degree ±1/2 degree. The minimum value would be 0 degree (1/2° − 1/2°= 0°) and the maximum value would be +1 degree (+1/2° + 1/2° = 1°). The range would be from 0 to 1 degree.

NOTE: The angle is assumed positive unless labeled with a negative (−) sign in front of the number.

DEGREES, MINUTES, AND FRACTIONS

Specifications are often published in **fractional** or decimal **degrees,** or in degrees and **minutes.** There are 60 minutes (written as 60′) in 1 degree.

Fractions	Decimal Degrees	Minutes-Seconds
1/4°	0.25°	0°15′
1/2°	0.50°	0°30′
3/4°	0.75°	0°45′
1°	1.0°	1° or 60′

To help visualize the amount of these various units, think of decimal degrees as representing money or cents (100 cents = 1 dollar).

0.75 = 75 cents, or 3/4 of a dollar

Minutes can be visualized as minutes in an hour (60′ = 1 hour).

45′ = 3/4 of an hour

Now which is larger, 35 minutes or 0.40 degrees? The larger angle is 35 minutes because this is slightly greater than 1/2 degree, whereas 0.40 minutes is less than 1/2 degree.

	CASTER	CROSS CASTER (LH-RH)	CAMBER	CROSS CAMBER (LH-RH)	TOE (TOTAL IN) DEGREES	STEERING WHEEL ANGLE	THRUST ANGLE
FRONT	+3°±.5°	0°±.75°	+.2° ±.5°	0°±.75°	0°±.3°	0°±3°	–
REAR	–	–	−.3° ±.5°	0°±.75°	+.1° ±.2°	–	0°±.1°

CHART 120–1

This vehicle alignment specification chart indicates the preferred setting with a plus or minus tolerance.

FIGURE 120–9 Using the alignment rack hydraulic jacks, raise the tires off the rack so that they can be rotated as part of the compensating process.

FINDING THE MIDPOINT OF SPECIFICATIONS Many manufacturers specify alignment angles within a range. If you are using equipment that requires a midpoint to be entered, use the following method to determine easily the midpoint of specifications.

Example 1:

Specification: 55′ to 2° 25′

STEP 1 The first step is to determine the specification range or span, which is the total angle value from lowest to highest:

$$\begin{array}{r} 2°\ 25' \\ -55' \\ \hline 1°\ 30'\ \text{Specification range} \end{array}$$

STEP 2 Dividing the specification range by 2 will give the midpoint of the range:

$$\frac{1°30'}{2} = \frac{90'}{2} = 45'$$

STEP 3 To find the midpoint of the specifications, add the midpoint of the range to the smaller specification (or subtract from the larger specification):

$$\begin{array}{r} 45'\ \text{midpoint of range} \\ +55'\ \text{lowest specification} \\ \hline 1°40'\ \text{midpoint of specification} \end{array}$$

Example 2:

Specification: −0.5° to +0.80°

STEP 1 The total range of the specification is determined by adding 0.5 (1/2) to 0.80, totaling 1.30°.

NOTE: Since the lower specification is a negative number, we had to *add* the 0.5 degree to bring the lower range of the specification to zero. Then the total is simply the upper range specification added to the number required to bring the lower end of the range to zero.

STEP 2 Dividing the specification range by 2 gives the midpoint of the range:

$$\frac{1.30°}{2} = 0.65°$$

STEP 3 To find the midpoint of the specification, add the midpoint of the range to the smaller specification:

$$0.65 + (-0.50) = 0.15$$

ALIGNMENT SETUP PROCEDURES

After confirming that the tires and all steering and suspension components are serviceable, the vehicle is ready for an alignment. Setup procedures for the equipment being used must always be followed. Typical alignment procedures include the following:

STEP 1 Drive onto the alignment rack straight and adjust the ramps and/or turn plates so that they are centered under the tires of the vehicle. ● **SEE FIGURE 120–9.**

STEP 2 Use chocks for the wheels to keep the vehicle from rolling off the alignment rack.

STEP 3 Attach and calibrate the wheel sensors to each wheel as specified by the alignment equipment manufacturer. ● **SEE FIGURE 120–10.** The calibration procedure is required whenever the head of the machine is attached to the wheel of the vehicle. All alignment angles and measurements are taken from the readings of the wheel sensors.

Calibration of these wheel sensors is needed for two reasons:

a. *The wheel may be bent.* If the wheel (rim) is bent, even slightly, this small amount of tilt would be read as an angle of the suspension.

NOTE: Compensating or calibrating the wheel sensor for a bent wheel does *not* correct (or repair) the bent wheel! The bent wheel is still present and can result in a shimmy-type vibration.

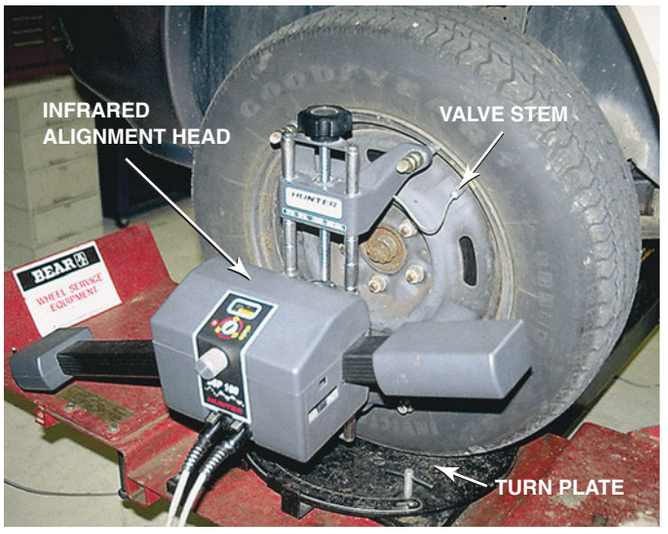

FIGURE 120–10 This wheel sensor has a safety wire that screws to the valve stem to keep the sensor from falling onto the ground if the clamps slip on the wheel lip.

b. *The sensors may not be identically installed on the wheel.* Most sensors use three or four wheel-mounting locations. It is not possible to install all wheel sensors perfectly at the same depth on the wheel in all locations. If a sensor must be removed during the alignment process and reinstalled, it should be recalibrated. Always follow the manufacturer's recommended procedure for compensating the sensors.

STEP 4 Unlock all rack or turn plates.

STEP 5 If raised for compensation, lower the vehicle and jounce the vehicle by pushing down on the front, then rear, bumper. This motion allows the suspension to become centered.

STEP 6 Following the procedures for the alignment equipment, determine all alignment angles.

MEASURING CAMBER, CASTER, SAI, TOE, AND TOOT

CAMBER Camber is measured with the wheels in the straight-ahead position on a level platform. Since camber is a vertical reference angle, alignment equipment reads camber directly.

CASTER Caster is measured by moving the front wheels through an arc inward, then outward, from straight ahead. This necessary movement of the front wheels to measure caster is called *caster sweep.* What the alignment measuring equipment is actually doing is measuring the camber at one wheel sweep and measuring the camber again at the other extreme of the caster sweep. *The caster angle itself is the difference between the two camber readings.*

SAI Steering axis inclination (SAI) is also measured by performing a caster sweep of the front wheels. While this angle can be read at the same time as caster on many alignment machines, most experts recommend that SAI be measured separately from the caster reading. When measuring SAI separately, the usual procedure involves raising the front wheels off the ground and leveling and locking the wheel sensors before performing a caster sweep. The reason for raising the front wheels is to allow the front suspension to extend to its full droop position. When the suspension is extended, the SAI is more accurately determined because the angle itself is expanded.

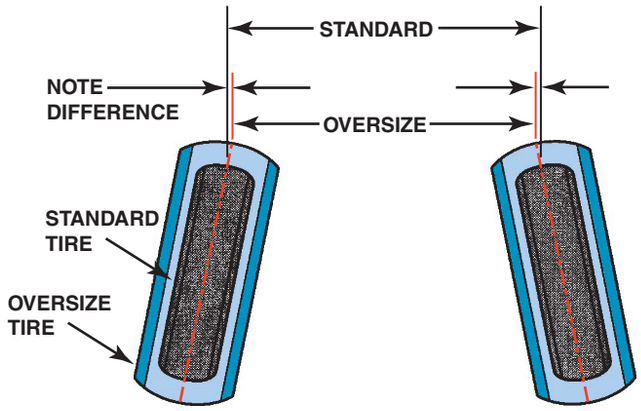

FIGURE 120–11 If toe for an oversize tire is set by distance, the toe angle will be too small. Toe angle is the same regardless of tire size.

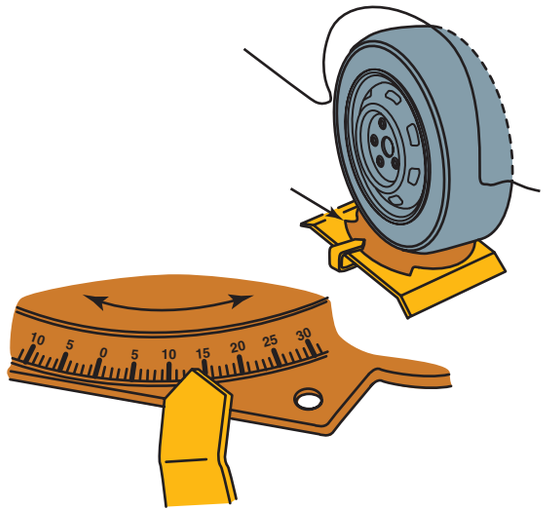

FIGURE 120–12 The protractor scale on the front turn plates allows the technician to test the turning radius by turning one wheel to an angle specified by the manufacturer and observing the angle of the other front wheel. Most newer alignment machines can display turning angle based on sensor readings, and therefore the protractor scale on the turn plate is not needed or used.

TOE Toe is determined by measuring the angle of both front and/or both rear wheels from the straight-ahead (0 degree) position. Most alignment equipment reads the toe angle for each wheel *and* the combined toe angle of both wheels on the same axle. This combined toe is called **total toe.** Toe angle is more accurate than the center-to-center distance, especially if oversize tires are installed on the vehicle. ● **SEE FIGURE 120–11.**

TOOT Toe-out on turns (TOOT) is a diagnostic angle and is normally not measured as part of a regular alignment, but it is recommended to be performed as part of a total alignment check. TOOT is measured by recording the angle of the front wheels as indicated on the alignment machine display or on the front turn plates. ● **SEE FIGURE 120–12.**

If, for example, the inside wheel is turned 20 degrees, then the outside wheel should indicate about 18 degrees on the turn plate. The exact angles are usually specified by the vehicle manufacturer. The turning angle should be checked only after the toe is correctly set. *The turning angle for the wheel on the outside of the turn should not vary more than 1 1/2 degrees from specifications.* For example, if the specification calls for the right wheel to be steered into the turn 20 degrees, the outside wheel should measure 18 degrees. This measurement should be within 1 1/2 degrees (or between 16.5 and 19.5 degrees in this example). If the TOOT is not correct, a bent steering arm is the usual cause. If TOOT is not correct, tire squealing noise is usually noticed while cornering and excessive tire wear may occur.

NOTE: Some front-wheel-drive vehicles use a nonsymmetrical (unequal) turning angle design. This design is found on various makes and models of vehicles to assist in controlling torque steer. The test procedure is the same except that the turning angle specifications include left-wheel and right-wheel angles when turned inward and outward and may be different readings without indicating a problem.

SPECIFICATIONS VERSUS ALIGNMENT READINGS

Secure both the alignment specifications from the manufacturer and the alignment readings and compare the two. Before starting an alignment, the smart technician checks the SAI, included angle, setback, and toe-out on turns to make sure that there is no hidden damage such as a bent spindle or strut that was not found during the prealignment inspection. *Setback is also a diagnostic angle and should be less than 0.5 in. (13 cm or 1/2 degree).* If setback is greater than 0.5 in. (13 cm or 1/2 degree), check the body, frame, and cradle for accident damage or improper alignment.

NOTE: If the SAI or included angle are unequal, suggesting a possible problem such as a bent strut, check the front and rear toe readings. Some alignment equipment cannot show accurate SAI readings if the front or rear toe readings are not within specifications. If the front and rear toe readings are OK and the alignment readings indicate a bent strut, go ahead with the diagnosis and correction as explained later in this chapter.

CHECKING FOR BENT STRUTS, SPINDLES, OR CONTROL ARMS

Even a minor bump against a curb can bend a spindle or a strut housing.

Before attempting to correct an alignment, check all the angles and use the appropriate diagnostic chart to check for hidden damage that a visual inspection may miss.

The chart in ● **CHART 120–2** can be used to determine what is wrong if the alignment angles are known. Simply use the chart that correctly identifies the type of suspension on the problem vehicle. The terms used regarding the specifications in Chart 120–2 include:

At spec	The alignment angle is within specifications.
Over spec	The alignment angle is greater or higher than specified by the manufacturer.
Under spec	The alignment angle is less than or lower than specified by the manufacturer.

TECH TIP

Damage Analysis Tips

To check if a vehicle has been in a collision, technicians should look for the following:

1. Drive the vehicle through a water puddle to see if the tire marks are wider than the tires. If they are, then the front and rear wheels are not tracking correctly.
2. If the setback is out of specifications, then the front of the vehicle may be damaged.
3. If the thrust angle is out of specifications, then rear suspension damage is likely.

CHECKING FRAME ALIGNMENT OF FRONT-WHEEL-DRIVE VEHICLES

Many front-wheel-drive vehicles mount the drive train (engine and transaxle) and lower suspension arms to a subframe or cradle. If the frame is shifted either left or right, this can cause differences in SAI, included angle, setback, and camber. ● **SEE FIGURES 120–13 AND 120–14.** Adjust the frame if SAI and camber angles are different left and right side, yet the included angles are equal.

TYPES OF ALIGNMENTS

There are three types of alignment: geometric centerline, thrust line, and four-wheel alignment.

GEOMETRIC CENTERLINE Until the 1980s, most wheel alignment concerned only the front wheels. Vehicles, such as sports cars, that had independent rear suspensions were often aligned by backing the vehicle onto the alignment rack and adjusting the rear camber and/or toe. This type of alignment is simply an alignment that uses the **geometric centerline** of the vehicle as the basis for all measurements of toe (front or rear). ● **SEE FIGURE 120–15.**

This method is now considered to be obsolete.

DIAGNOSING SAI, CAMBER, AND INCLUDED ANGLE

SLA AND STRUT/SLA SUSPENSIONS

SAI	CAMBER	INCLUDED ANGLE	DIAGNOSIS
Correct	Less than specs	Less than specs	Bent steering knuckle or spindle
Less than specs	Greater than specs	Correct	Bent lower control arm
Less than specs	Greater than specs	Greater than specs	Bent lower control arm and steering knuckle or spindle
Greater than specs	Less than specs	Correct	Bent upper control arm

STRUT SUSPENSIONS

SAI	CAMBER	INCLUDED ANGLE	DIAGNOSIS
Correct	Less than specs	Less than specs	Bent spindle and/or strut
Correct	Greater than specs	Greater than specs	Bent spindle and/or strut
Less than specs	Greater than specs	Correct	Bent control arm or strut tower out at top
Less than specs	Greater than specs	Greater than specs	Bent control arm or strut tower out at top, also bent spindle and/or strut
Less than specs	Less than specs	Less than specs	Bent control arm or strut tower out at top, also bent spindle and/or strut
Greater than specs	Less than specs	Correct	Strut tower in at top
Greater than specs	Greater than specs	Greater than specs	Strut tower in at top and bent spindle and/or bent strut

KINGPIN TWIN I-BEAM SUSPENSION

SAI (KPI)	CAMBER	INCLUDED ANGLE	DIAGNOSIS
Correct	Greater than specs	Greater than specs	Bent spindle
Less than specs	Greater than specs	Correct	Bent I-beam
Less than specs	Greater than specs	Greater than specs	Bent I-beam and spindle
Greater than specs	Less than specs	Correct	Bent I-beam

CHART 120–2

By checking the SAI, camber, and included angle, a damaged suspension component can be determined by using this chart.

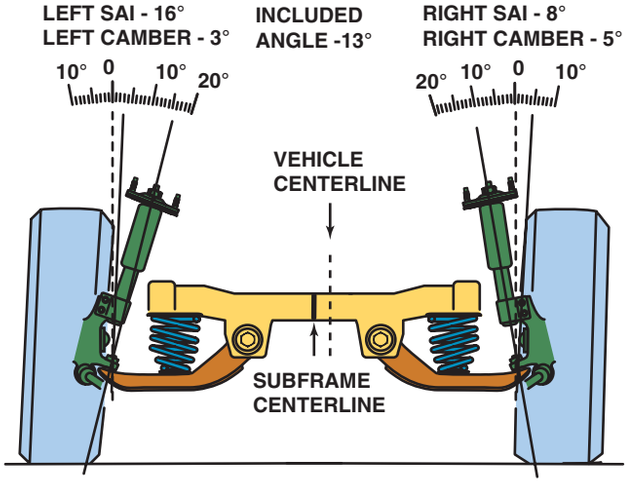

FIGURE 120–13 In this example, both SAI and camber are far from being equal side-to-side. However, both sides have the same included angle, indicating that the frame may be out of alignment. An attempt to align this vehicle by adjusting the camber on both sides with either factory or aftermarket kits would result in a totally incorrect alignment.

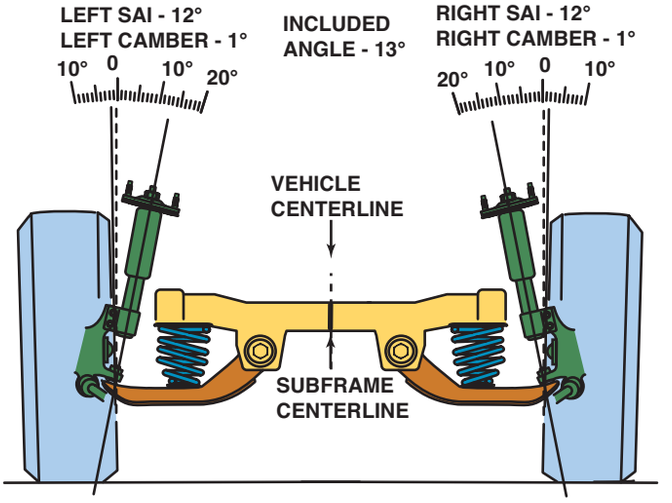

FIGURE 120–14 This is the same vehicle as shown in Figure 120–13, except now the frame (cradle) has been shifted over and correctly positioned. Notice how both the SAI and camber become equal without any other adjustments necessary.

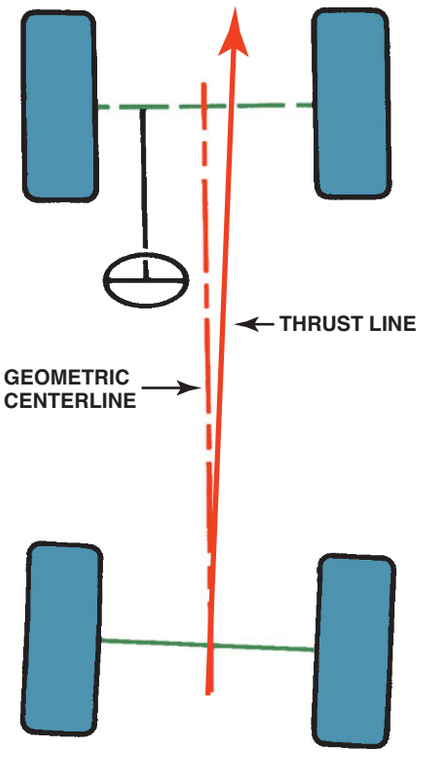

FIGURE 120–15 Geometric-centerline-type alignment sets the front toe readings based on the geometric centerline of the vehicle and does not consider the thrust line of the rear wheel toe angles. (*Courtesy of Hunter Engineering Company*)

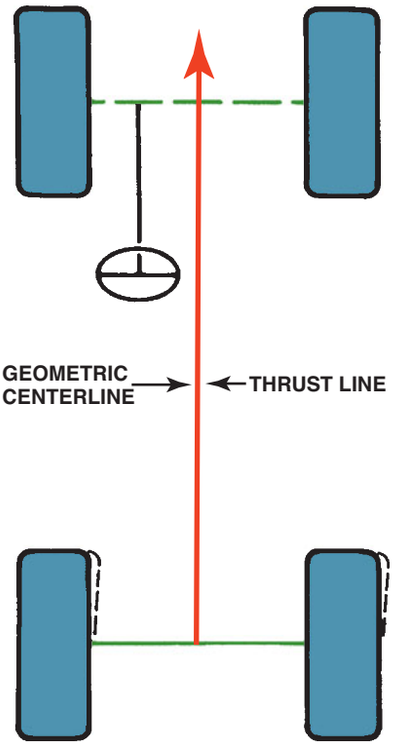

FIGURE 120–17 Four-wheel alignment corrects for any rear-wheel toe to make the thrust line and the geometric centerline of the vehicle both the same. (*Courtesy of Hunter Engineering Company*)

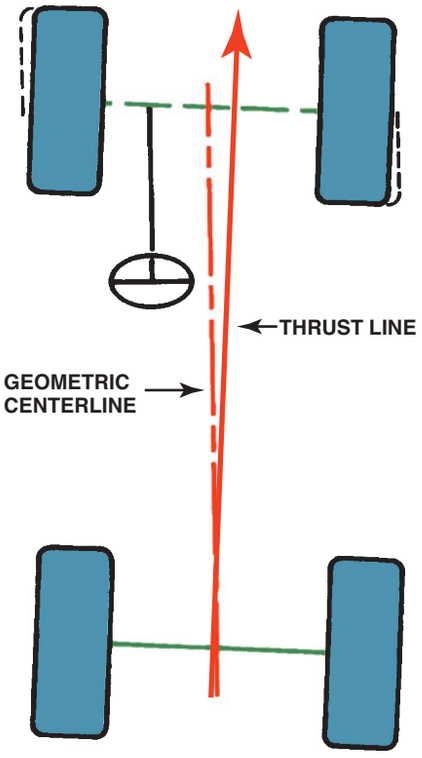

FIGURE 120–16 Thrust line alignment sets the front toe parallel with the rear-wheel toe. (*Courtesy of Hunter Engineering Company*)

THRUST LINE A **thrust line** alignment uses the thrust angle of the rear wheels and sets the front wheels parallel to the thrust line. ● **SEE FIGURE 120–16**

The thrust line is the bisector of rear total toe, or the actual direction in which the rear wheels are pointed. The rear wheels of any vehicle *should* be pointing parallel to the geometric centerline of the vehicle. However, if the rear toe angles of the rear wheels do not total exactly zero (perfectly in a line with the centerline of the vehicle), a thrust condition exists. The front wheels will automatically steer to become parallel to that condition. A crooked steering wheel may also result from an improper thrust condition.

NOTE: It has often been said that while the front wheels steer the vehicle, the rear wheels determine the direction in which the vehicle will travel. Think of the rear wheels as a rudder on a boat. If the rudder is turned, the direction of the boat changes due to the angle change at the rear of the boat.

Thrust line alignment is *required* for any vehicle with a nonadjustable rear suspension. If a vehicle has an adjustable rear suspension, then a four-wheel alignment is necessary to ensure proper tracking.

FOUR-WHEEL ALIGNMENT A **four-wheel alignment** is the most accurate alignment method and is necessary to ensure maximum tire wear and vehicle handling. The biggest difference between a thrust-line alignment and a four-wheel alignment is that the rear toe is adjusted to bring the thrust line to zero. In other words, the rear toe on both rear wheels is adjusted equally so that the actual direction in which the rear wheels are pointed is the same as the geometric centerline of the vehicle. ● **SEE FIGURE 120–17.**

The procedure for a four-wheel alignment includes these steps:

1. Adjust the rear camber (if applicable).
2. Adjust the rear toe (this should reduce the thrust angle to near zero).

3. Adjust the front camber and caster.
4. Adjust the front toe, being sure that the steering wheel is in the straight-ahead position.

SAMPLE ALIGNMENT SPECIFICATIONS AND READINGS

The service technician must know not only all of the alignment angles but also the interrelationship that exists among the angles. As an aid toward understanding these relationships, two examples are presented: Example 1 gives the front wheel angles that are acceptable when compared with the specifications; Example 2 gives four-wheel alignment and readings of a vehicle that are not within specifications.

Example 1: Wheel Alignment

Alignment Specifications

	Left	Right
Camber =	+1/2° ± 1/2°	+1/2° ± 1/2°
Caster =	+1° ± 1/2°	+1° ± 1/2°
Toe (total) =	1/8 in. ± 1/16 in.	

Actual Reading

	Left	Right
Camber =	+1/4°	0°
Caster =	+1°	+1 1/4°
Toe (total) =	1/8 in.	

Answer:

Alignment is perfect:
a. No tire wear
b. No pulling

Explanation:

Camber is within specifications.
Camber is within 1/2-degree difference side-to-side.
Camber is not equal, but there is more camber on the left (1/4 degree) than on the right, thereby helping to compensate for the road crown.
Caster is within specifications.
Caster is within 1/2-degree difference side-to-side.
Caster is not equal, but there is more caster on the right (1/4 degree) than on the left, thereby helping (very slightly) to compensate for road crown.
Toe is within specifications.

Example 2: Four-Wheel Alignment

Specifications

	Left	Right
Front camber =	+1/4° ± 1/2°	0° ± 1/2°
Front caster =	+3° ± 1/2°	+1/2° ± 1/2°
Front toe (total) =	3/16 in. ± 1/16 in.	
Rear camber =	0° ± 1/4°	0° ± 1/4°
Rear toe =	0 in. ± 1/16 in.	

TECH TIP

Ask Yourself These Three Questions

An older technician told a beginning technician that the key to success in doing a proper alignment is to ask yourself three questions about the alignment angles:

Question 1. **"Is it within specifications?"** For example, if the specification reads 1° ±1/2°, any reading between +1/2° and 1 1/2° is within specifications. All vehicles should be aligned within this range. Individual opinions and experience can assist the technician as to whether the actual setting should be at one extreme or the other or held to the center of the specification range.

Question 2. **"Is it within 1/2° of the other side of the vehicle?"** Not only should the alignment be within specifications, but it should also be as equal as possible from one side to the other. The difference between the camber from one side to the other side is called cross camber. Cross caster is the difference between the caster angle from one side to another. Some manufacturers and technicians recommend that this side-to-side difference be limited to just 1/4 degree!

Question 3. **"If the camber and caster cannot be exactly equal side-to-side in the front, is there more camber on the left and more caster on the right to help compensate for road crown?"** Seldom, if ever, are the alignment angles perfectly equal. Sometimes one side of the vehicle is more difficult to adjust than the other side. Regardless of the reasons, if there *has* to be a difference in front camber and/or caster angle, follow this advice to avoid a possible lead or drift problem even if the answers to the first two questions are "yes."

Actual Reading

	Left	Right
Front camber =	−1/2°	−1°
Front caster =	+2 3/4°	+2°
Front toe =	−1/8 in. (toe-out)	
Rear camber =	0°	+1/4°
Rear toe =	1 1/2° (toe-in)	

Answer:

Alignment is incorrect.
a. Left front tire will wear slightly on the inside edge.
b. Right front tire will wear on the inside edge.
c. Vehicle could tend to pull slightly to the left due to the camber difference (may not pull at all due to the pulling effect of the road crown).
d. Vehicle could tend to pull slightly to the right due to the caster difference (3/4 degree more caster on the left).
e. Overall pull could be slight toward the left because it requires four times the caster difference to have the same pulling forces as camber.

FREQUENTLY ASKED QUESTION

How Does Normal Wear Affect the Alignment Angles?

As a vehicle ages, the springs sag and steering and suspension components wear.

- When springs sag the ride height changes and the camber usually is reduced and often becomes negative compared to slightly positive when the vehicle was new in most cases.
- When tie rod ends and other steering components wear, the front wheels tend to toe out.
- Worn suspension components can cause excessive play making the vehicle unstable and cause the tires to wear abnormally.

Alignment alone cannot take the place of worn parts. All an alignment can do is try to compensate for the worn parts.

Toe is the most common angle that needs to be adjusted because any wear in the steering or suspension systems affect the toe.

f. Tires could wear slightly on both the inside edges due to toe-out.
g. The negative camber of the present alignment puts a heavy load on the outer wheel bearing, if RWD, because the load is being carried by the smaller outer wheel bearing instead of the larger inner wheel bearing.

Conclusion:

The vehicle would wear the inside edges of both front tires.
The vehicle may or may not pull slightly to the left.
The vehicle would not act as stable while driving—possible wander.

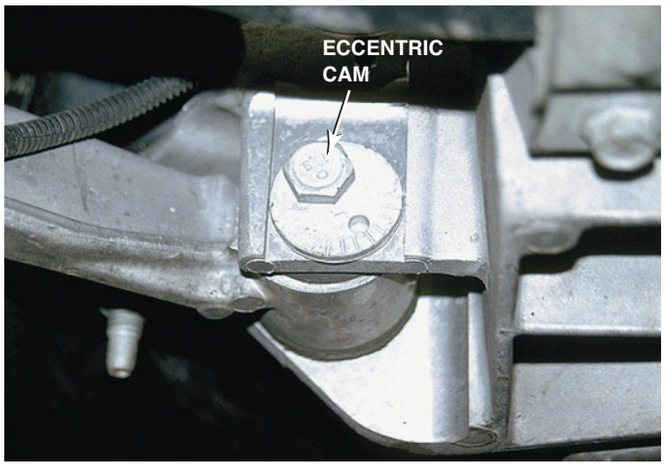

FIGURE 120–18 The rear camber is adjustable on this vehicle by rotating the eccentric cam and watching the alignment machine display.

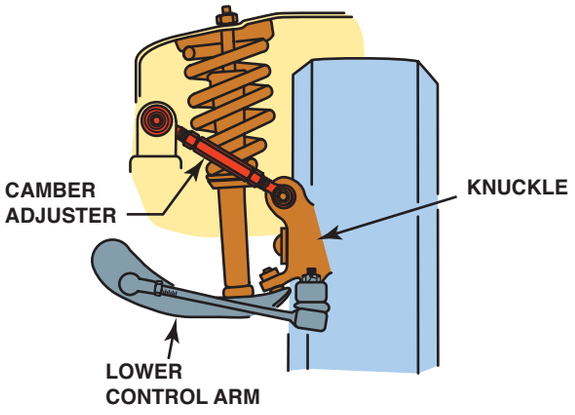

FIGURE 120–19 Some vehicles use a threaded fastener similar to a tie rod to adjust camber on the rear suspension.

ADJUSTING REAR CAMBER

Adjusting rear camber is the first step in the four-wheel alignment process. Rear camber is rarely made adjustable, but can be corrected by using aftermarket alignment kits or shims. If rear camber is not correct, vehicle handling and tire life are affected. Before attempting to adjust or correct rear camber, carefully check the body and/or frame of the vehicle for accident damage, including the following:

1. Weak springs, torsion bars, or overloading (check ride height)
2. Bowed rear axle, trailing arm, or rear control arm
3. Suspension mount or body dimension not in proper location
4. Incorrectly adjusted camber from a previous repair

The cause of the incorrect rear camber could be accident-related and the body or frame may have to be pulled into correct position. ● **SEE FIGURES 120–18 THROUGH 120–20** for examples of various methods used to adjust rear camber.

USING PLASTIC OR METAL ALIGNMENT SHIMS Using plastic or metal alignment shims to correct angles in the rear of the vehicle is relatively simple and includes the following steps:

TECH TIP

The Gritty Solution

Many times it is difficult to loosen a Torx bolt, especially those used to hold the backing plate onto the rear axle on many GM vehicles. ● **SEE FIGURE 120–21.**

A technique that always seems to work is to place some valve grinding compound on the fastener. The gritty compound keeps the Torx socket from slipping up and out of the fastener, and more force can be exerted to break loose a tight bolt. Valve grinding compound can also be used on Phillips head screws as well as other types of bolts, nuts, and sockets.

1. Take alignment readings and determine the change needed.
2. Select proper shims using the easy-to-read chart.
3. Using the template provided, mark and remove tabs to create a proper mounting bolt pattern.
4. Install shim.

ADJUSTING REAR TOE Many vehicle manufacturers provide adjustment for rear toe on vehicles that use an independent rear suspension. Rear toe adjusts the thrust angle. A thrust angle that exceeds 1/2 degree (0.5 degree) on a vehicle with a solid axle is an indication that a component may be damaged or out of place in the rear of the vehicle. Rear toe is often adjusted using an adjustable tie rod end or an eccentric cam on the lower control arm. Check a service manual for the exact method for the vehicle being aligned. Most solid rear axles do not have a method to adjust rear toe except for aftermarket shims or kits. ● **SEE FIGURES 120–22 THROUGH 120–24.**

NOTE: On vehicles equipped with four-wheel steering, refer to the service manual for the exact procedure to follow to lock or hold the rear wheels in position for a proper alignment check.

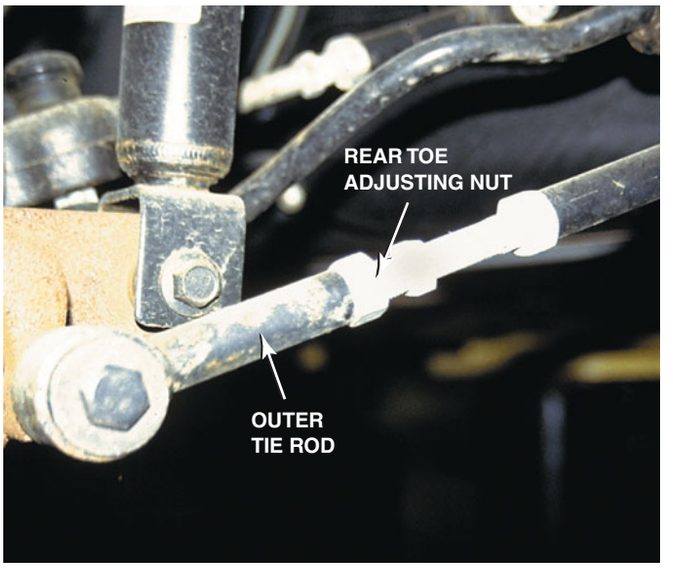

FIGURE 120–22 The rear toe was easily set on this vehicle. The adjusting nuts were easy to get to and turn. Adjusting rear toe is not this easy on every vehicle.

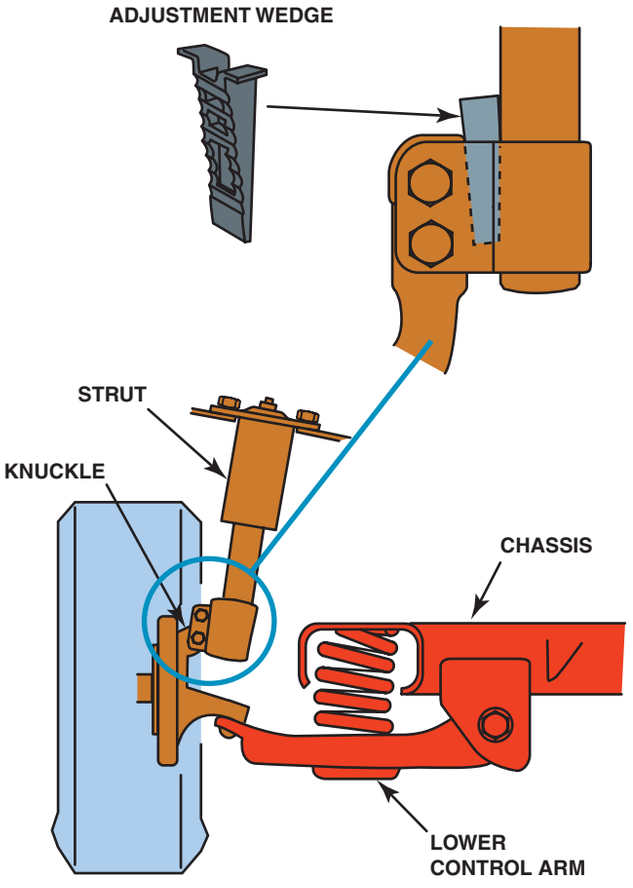

FIGURE 120–20 Aftermarket alignment parts or kits are available to change the rear camber.

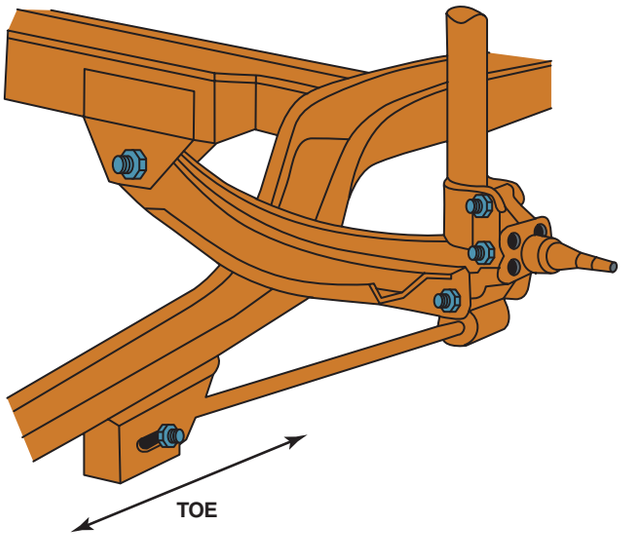

FIGURE 120–23 By moving various rear suspension members, the rear toe can be changed.

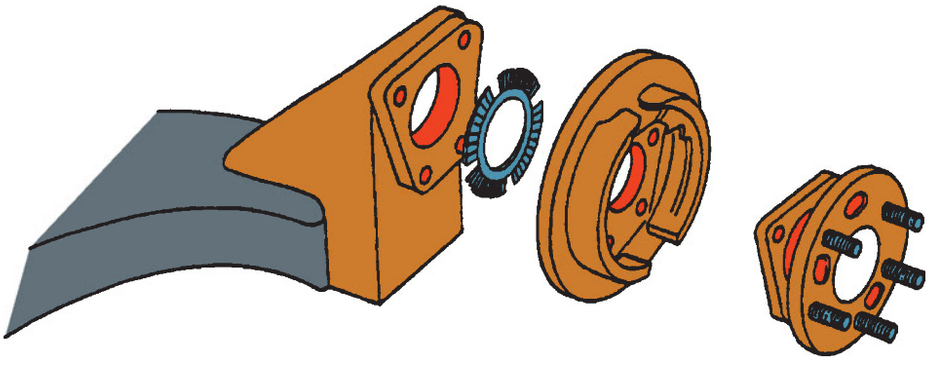

FIGURE 120–21 Full-contact plastic or metal shims can be placed between the axle housing and the brake backing plate to change rear camber, toe, or both. (*Courtesy of Northstar Manufacturing Company, Inc.*)

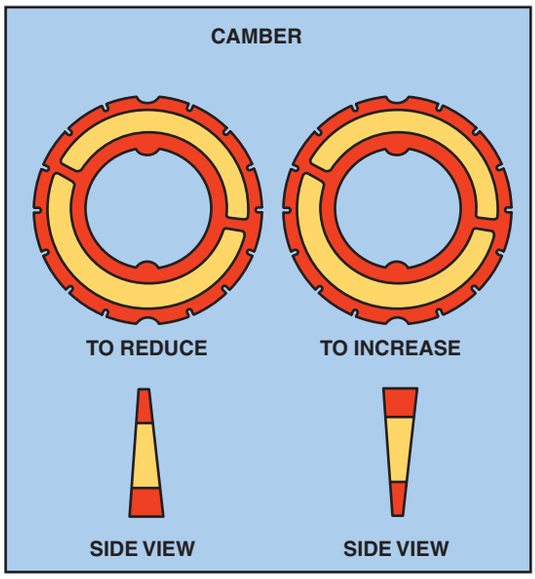

FIGURE 120–24 The use of these plastic or metal shims requires that the rear wheel as well as the hub assembly and/or backing plate be removed. Proper torque during reassembly is critical to avoid damage to the shims.

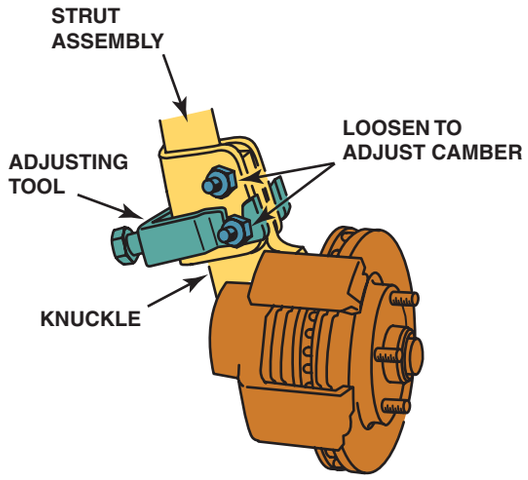

FIGURE 120–25 Many struts allow camber adjustment at the strut-to-knuckle fasteners. Here a special tool is being used to hold and move the strut into alignment with the fasteners loosened. Once the desired camber angle is achieved, the strut nuts are tightened and the tool is removed.

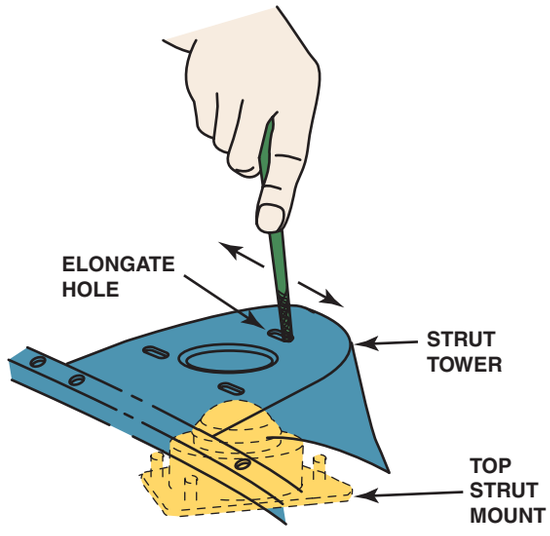

FIGURE 120–26 Some struts require modification of the upper mount for camber adjustment.

GUIDELINES FOR ADJUSTING FRONT CAMBER/SAI AND INCLUDED ANGLE

If the camber is adjusted at the base of the MacPherson strut, camber and included angle are changed and SAI remains the same. ● **SEE FIGURE 120–25.**

If camber is adjusted by moving the upper strut mounting location, included angle remains the same, but SAI and camber change. ● **SEE FIGURE 120–26.**

This is the reason to use the factory alignment methods before using an aftermarket alignment adjustment kit. SAI and included angle should be within 1/2 degree (0.5 degrees) side-to-side. If these angles differ, check the frame mount location before attempting to correct differences in camber. As the frame is changed, camber and SAI change, but the included angle remains the same. Cross camber/caster is the difference between the camber or caster on one side of the vehicle and the camber or caster on the other side of the vehicle.

Alignment Angle	Recommended Maximum Variation
SAI	Within 1/2° (0.5°) side-to-side
Included angle	Within 1/2° (0.5°) side-to-side
Cross camber	Within 1/2° (0.5°) side-to-side
Cross caster	Within 1/2° (0.5°) side-to-side

CAUTION: Do not attempt to correct a pull condition by increasing cross camber or cross caster beyond the amount specified by the vehicle manufacturer.

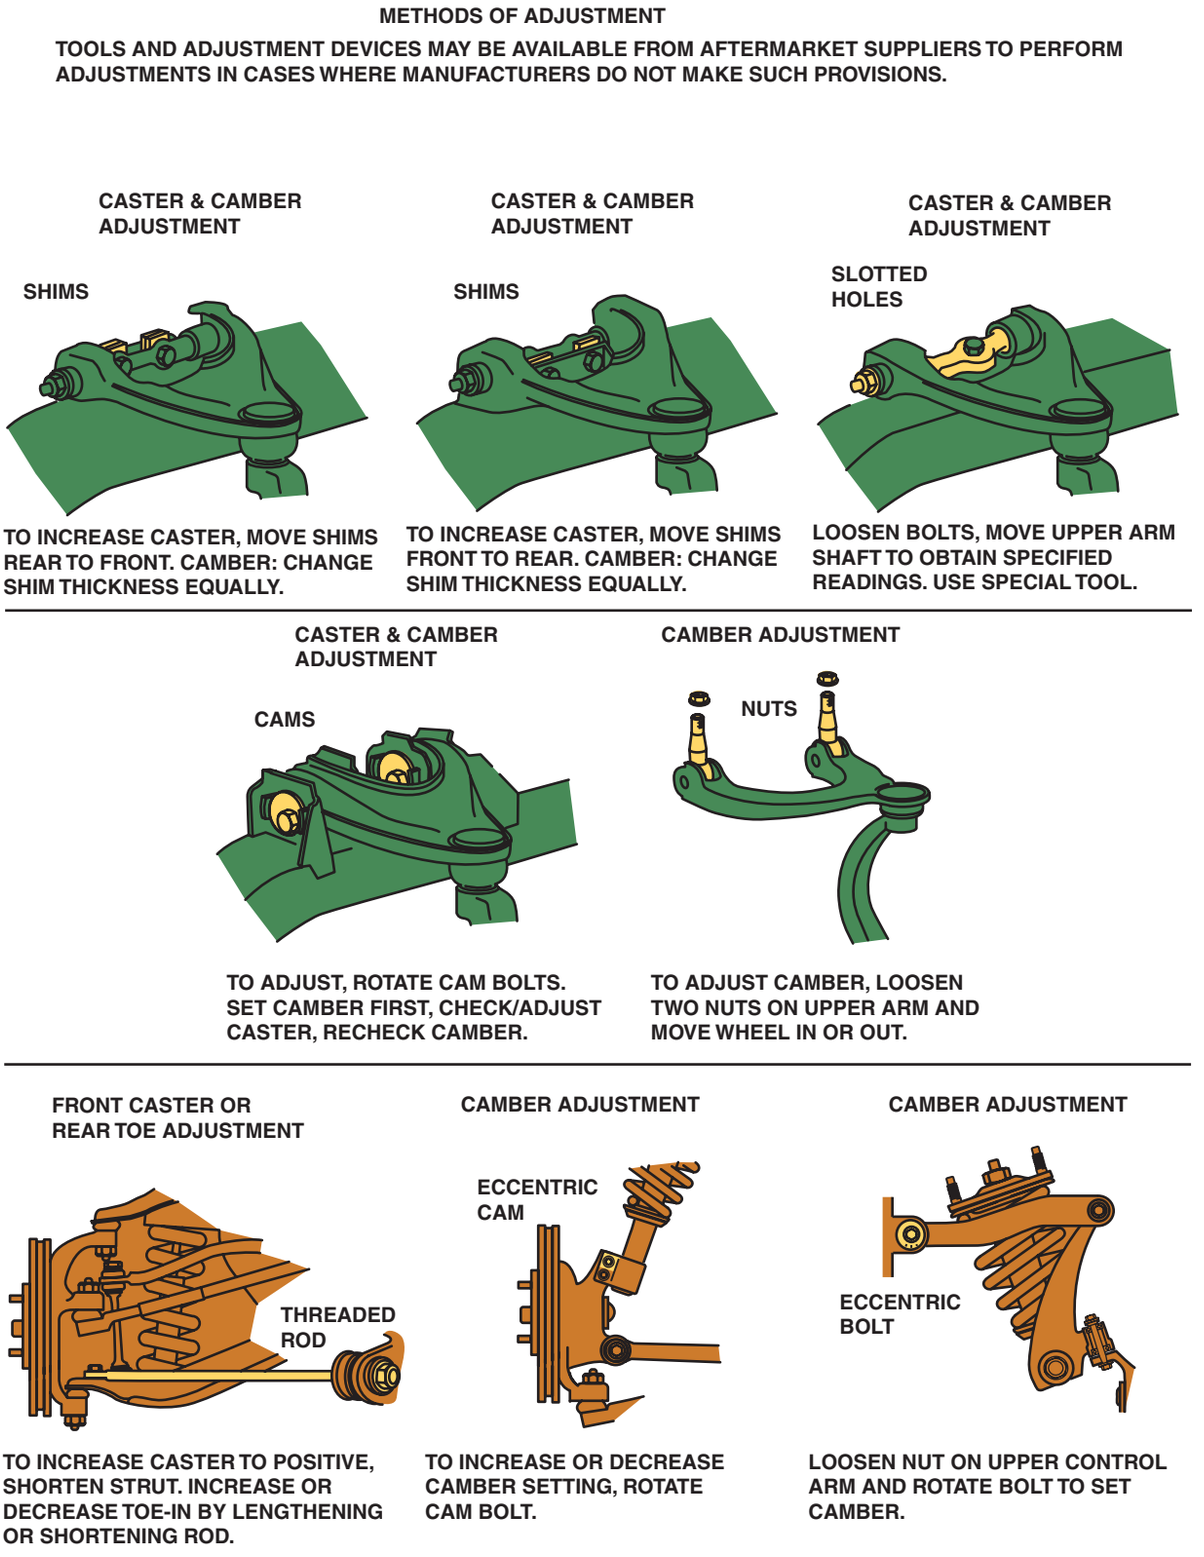

FIGURE 120–27 An example of the many methods that are commonly used to adjust front caster and camber.

FRONT CAMBER/CASTER ADJUSTMENT METHODS

Many vehicles are constructed with only limited camber/caster factory adjustment. ● **SEE FIGURE 120–27** for a summary of which adjustments are *generally* possible for various types of vehicles and suspension systems.

CAUTION: Most vehicle manufacturers warn technicians not to adjust camber by bending the strut assembly. Even though several equipment manufacturers make tools that are designed to bend the strut, most experts agree that it can cause harm to the strut itself.

ADJUSTING FRONT CAMBER/CASTER

Most SLA-type suspensions can be adjusted for caster and camber. Most manufacturers recommend adjusting caster, then camber, before adjusting the toe. As the caster is changed, such as when the strut rod is adjusted as shown in ● **FIGURE 120–28,** the camber and toe also change.

If the camber is then adjusted, the caster is unaffected. Many technicians adjust caster and camber at the same time using shims (● **FIGURES 120–29 AND 120–30**), slots (● **FIGURE 120–31**), or **eccentric cams** (● **FIGURE 120–32**).

Always follow the manufacturer's recommended alignment procedure. For example, many manufacturers include a **shim chart** in their service manual that gives the thickness and location of the shim changes based on the alignment reading. Shim charts are used to set camber and caster at the same time. Shim charts are designed for each model of vehicle. ● **SEE FIGURE 120–33.**

Regardless of the methods or procedures used, toe is always adjusted after all the angles are set because caster and camber both affect the toe.

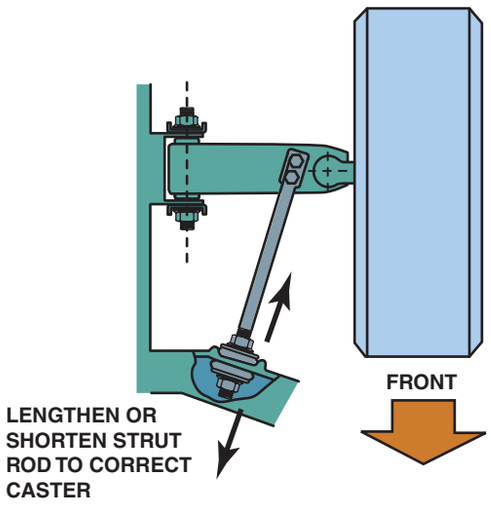

FIGURE 120–28 If there is a nut on both sides of the strut rod bushing, then the length of the rod can be adjusted to change caster.

SETTING TOE

Front toe is the last angle that should be adjusted and is the most likely to need correction. This has led to many sayings in the alignment field:

"Set the toe and let it go."

"Do a toe and go."

"Set the toe and collect the dough."

As wear occurs at each steering joint such as tie rod ends, the forces exerted on the linkage by the tire tend to cause a toe-out condition.

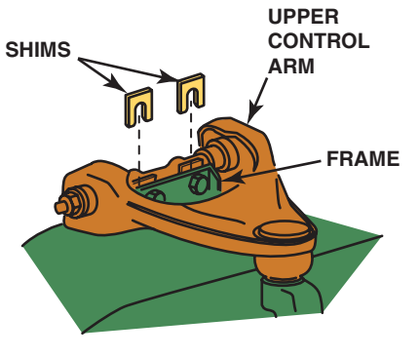

FIGURE 120–30 The general rule of thumb is that a 1/8-in. shim added or removed from both shim locations changes the camber angle about 1/2 degree. Adding or removing a 1/8-in. shim from one shim location changes the caster by about 1/4 degree.

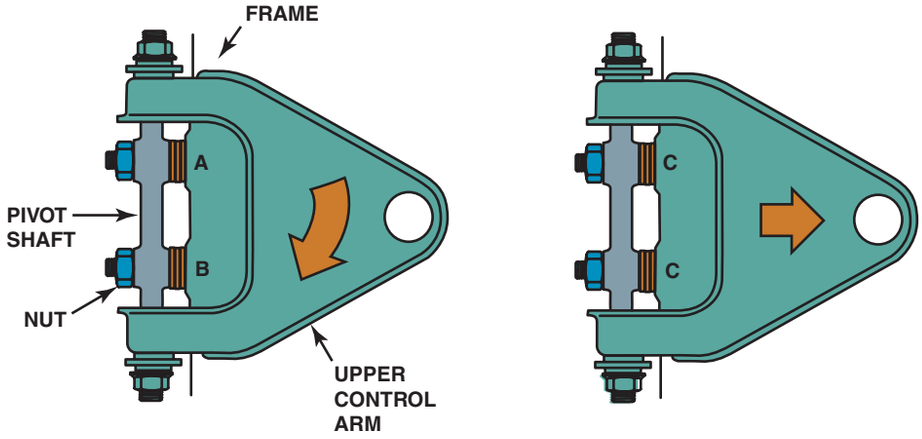

FIGURE 120–29 Placing shims between the frame and the upper control arm pivot shaft is a popular method of alignment for many SLA suspensions. Both camber and caster can be easily changed by adding or removing shims.

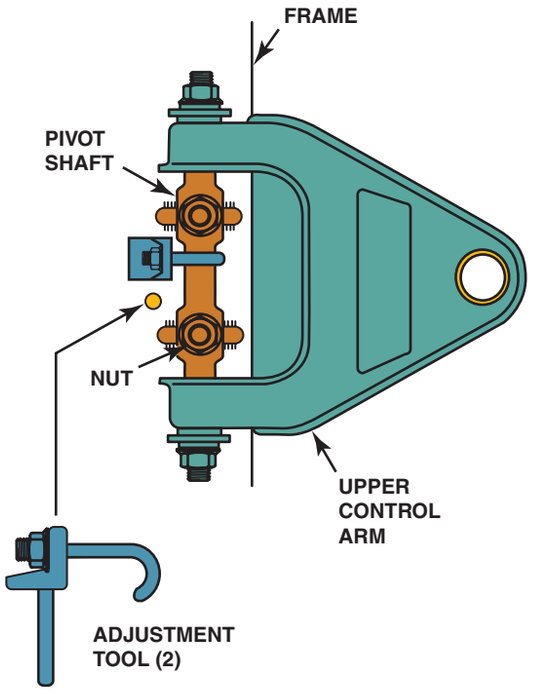

FIGURE 120–31 Some SLA-type suspensions use slotted holes for alignment angle adjustments. When the pivot shaft bolts are loosened, the pivot shaft is free to move unless held by special clamps as shown. By turning the threaded portion of the clamps, the camber and caster can be set and checked before tightening the pivot shaft bolts.

Front-wheel-drive (FWD) vehicles transmit engine power through the front wheels. Many manufacturers of FWD vehicles specify a toe-out setting. This toe-out setting helps compensate for the slight toe-in effect of the engine torque being transferred through the front wheels.

Most newer alignment equipment displays in degrees of toe instead of inches of toe. (See the toe unit conversion chart.) Just remember that positive (+) toe means toe-in and negative (−) toe means toe-out.

Toe Unit Conversions

Units	Conversions			
Fractional inches	1/16 in.	1/8 in.	3/16 in.	1/4 in.
Decimal inches	0.062 in.	0.125 in.	0.188 in.	0.250 in.
Millimeters	1.60 mm	3.18 mm	4.76 mm	6.35 mm
Decimal degrees	0.125°	0.25°	0.375°	0.5°
Degrees and minutes	0°8′	0°15′	0°23′	0°30′
Fractional degrees	1/8°	1/4°	3/8°	1/2°

To make sure the steering wheel is straight after setting toe, the steering wheel *must* be locked in the straight-ahead position while the toe is being adjusted. Another term used to describe steering wheel position is **spoke angle.** To lock the steering wheel, always use a steering wheel lock that presses against the seat and the outer rim of the steering wheel. *Do not* use the locking feature of the steering column to hold the steering wheel straight. Always unlock the steering column, straighten the steering wheel, and install the steering wheel lock. ● **SEE FIGURES 120–34 THROUGH 120–36.**

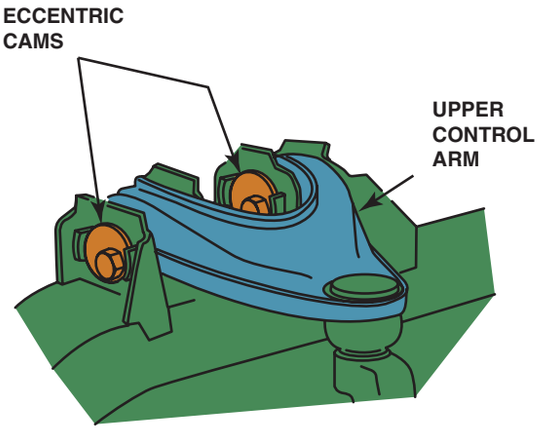

FIGURE 120–32 When the nut is loosened and the bolt on the eccentric cam is rotated, the upper control arm moves in and out. By adjusting both eccentric cams, both camber and caster can be adjusted.

TECH TIP

Race Vehicle Alignment

Vehicles used in autocrossing (individual timed runs through cones in a parking lot) or road racing usually perform best if the following alignment steps are followed:

1. **Increase caster (+).** Not only will the caster provide a good solid feel for the driver during high speed on a straight section of the course, but it will also provide some lean into the corners due to the camber change during cornering. A setting of 5 to 9 degrees positive caster is typical depending on the type of vehicle and the type of course.
2. **Adjust for 1 to 2 degrees of negative camber.** As a race vehicle corners, the body and chassis lean. As the chassis leans, the top of the tire also leans outward. By setting the camber to 1 to 2 degrees negative, the tires will be neutral while cornering, thereby having as much rubber contacting the road as possible.

   NOTE: Though setting negative camber on a street-driven vehicle will decrease tire life, the negative setting on a race vehicle is used to increase cornering speeds, and tire life is not a primary consideration.

3. **Set toe to a slight toe-out position.** When the front toe is set negative (toe-out), the vehicle is more responsive to steering commands from the driver. With a slight toe-out setting, one wheel is already pointed in the direction of a corner or curve. Set the toe-out to −3/8 to −1/2 degree depending on the type of vehicle and the type of race course.

NOTE: The engine must be started and the steering wheel straightened with the engine running to be assured of a straight steering wheel. Lock the steering wheel with the steering lock tool before stopping the engine.

After straightening the steering wheel, turn the tie rod adjustment until the toe for both wheels is within specifications. ● **SEE FIGURE 120–37.**

1. DETERMINE VEHICLE'S CURRENT CASTER AND CAMBER MEASUREMENTS.
2. USING THE CURRENT CASTER READING, READ DOWN THE APPROPRIATE COLUMN TO THE LINES CORRESPONDING TO THE CURRENT CAMBER READING.
3. CORRECTION VALUES WILL BE GIVEN FOR THE FRONT AND REAR BOLTS.
   EXAMPLE: CURRENT READING +1.6° CASTER +0.4° CAMBER. BY READING DOWN THE CHART FROM +1.6° CASTER TO +0.4° CAMBER YOU WILL FIND THAT THE FRONT BOLT REQUIRES AN ADJUSTMENT OF -101 AND THE REAR BOLT REQUIRES AN ADJUSTMENT OF +010.

FIGURE 120–33 Typical shim alignment chart. As noted, 1/8-in. (0.125) shims can be substituted for the 0.120-in. shims; 1/32-in. (0.0625) shims can be substituted for the 0.060-in. shims; and 1/32-in. (0.03125) shims can be substituted for the 0.030-in. shims.

Test drive the vehicle for proper handling and centerline steering. *Centerline steering* is a centered steering wheel with the vehicle traveling a straight course.

CENTERING THE STEERING WHEEL

Centerline steering *should* be accomplished by adjusting the tie rod length on both sides of the vehicle while the toe is set.

CAUTION: Do not attempt to straighten the steering wheel by relocating the wheel on the steering column on a vehicle with two tie rod end adjusters. The steering wheel is positioned at the factory in the center of the steering gear, regardless of type. If the steering wheel is not in the center, then the variable ratio section of the gear will not be in the center as it is designed. Another possible problem with moving the steering wheel from its designed straight-ahead position is that the turning radius may be different for right- and left-hand turns.

STEERING WHEEL REMOVAL

If the steering wheel *must* be removed, first disconnect the airbag wire connector at the base of the steering column. This reduces the chance of personal injury and prevents accidental airbag deployment.

FIGURE 120–34 Many procedures for setting toe specify that the steering wheel be held in the straight-ahead position using a steering wheel lock, as shown. One method recommended by Hunter Engineering sets toe without using a steering wheel lock.

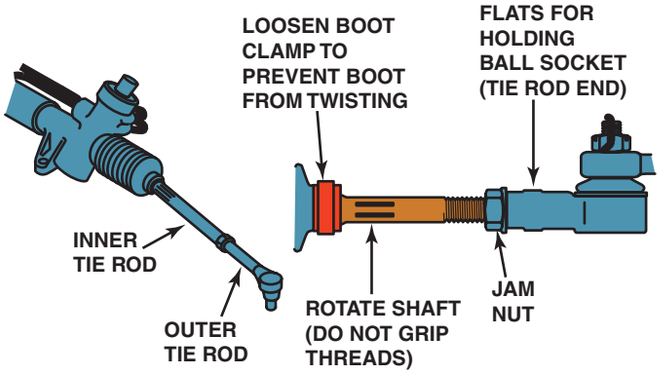

FIGURE 120–35 Adjusting toe by rotating the tie rod on a vehicle equipped with rack-and-pinion steering.

CAUTION: Always follow the manufacturer's recommended procedures whenever working on or around the steering column.

Remove the center section of the steering column by removing the retaining screws, including the inflator module on vehicles equipped with an airbag.

After removal of the airbag inflator module, remove the steering wheel retaining nut. Note the locating marks on the steering wheel and steering shaft. ● **SEE FIGURE 120–38** on page 1446. These marks indicate the proper position of the steering wheel for centerline steering. This means that the steering wheel spoke angle is straight and in line with the centerline position of the steering gear or rack-and-pinion steering unit.

Most steering wheels are attached to the steering shaft with a spline and a taper. After removing the steering wheel nut, use a

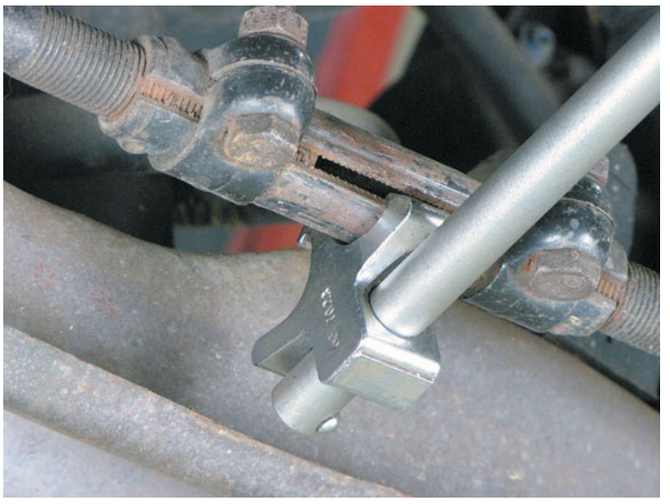

FIGURE 120–37 Special tie rod adjusting tools should be used to rotate the tie rod adjusting sleeves. The tool grips the slot in the sleeve and allows the service technician to rotate the sleeve without squeezing or damaging the sleeve.

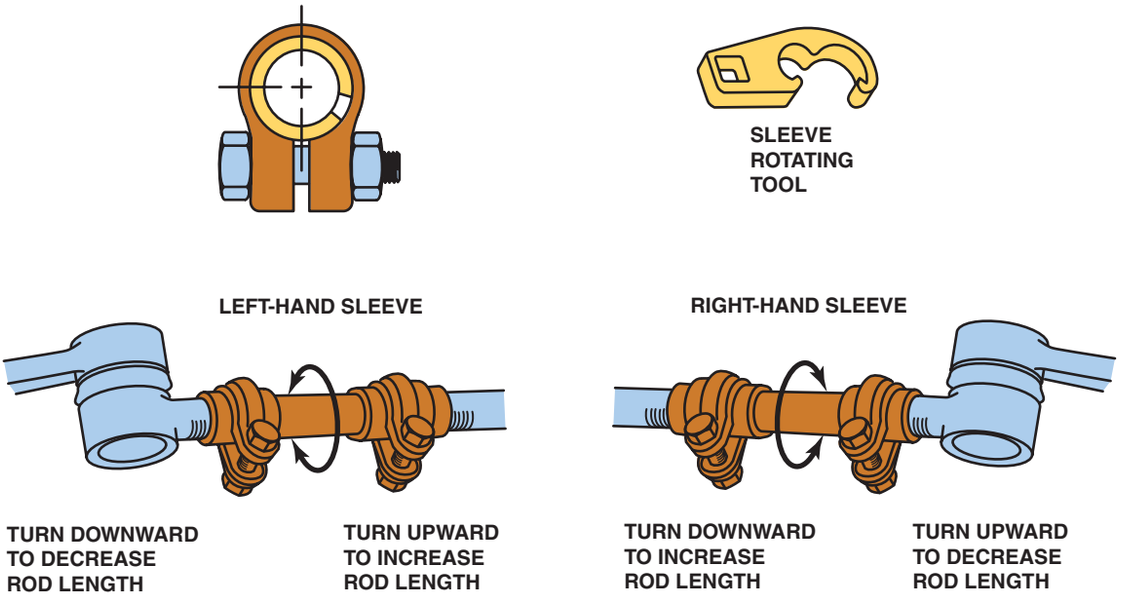

FIGURE 120–36 Toe is adjusted on a parallelogram-type steering linkage by turning adjustable tie rod sleeves. Special tie rod sleeve adjusting tools should be used that grip the slot in the sleeve and will not crush the sleeve while it is being rotated.

TECH TIP

Locking Pliers to the Rescue

Many vehicles use a jam nut on the tie rod end. This jam nut must be loosened to adjust the toe. Because the end of the tie rod is attached to a tie rod end that is movable, loosening the nut is often difficult. Every time force is applied to the nut, the tie rod end socket moves and prevents the full force of the wrench from being applied to the nut. To prevent this movement, simply attach locking pliers (Vise Grips®) to hold the tie rod. Wedge the pliers against the control arm to prevent any movement of the tie rod. By preventing the tie rod from moving, full force can be put on a wrench to loosen the jam nut without doing any harm to the tie rod end.

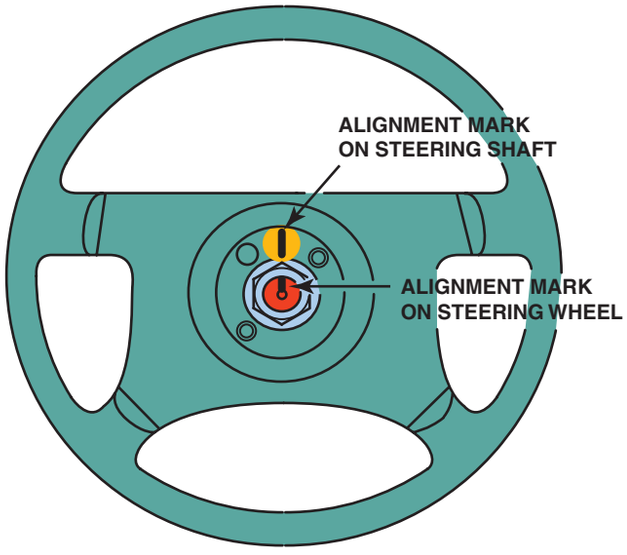

FIGURE 120–38 Most vehicles have alignment marks made at the factory on the steering shaft and steering wheel to help the service technician keep the steering wheel in the center position.

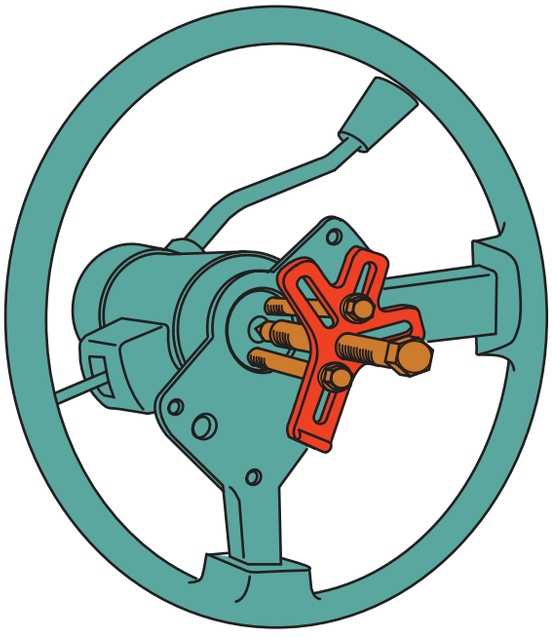

FIGURE 120–39 A puller being used to remove a steering wheel after the steering wheel retaining nut has been removed.

steering wheel puller to remove the steering wheel from the steering shaft. ● **SEE FIGURE 120–39.**

To reinstall the steering wheel, align the steering wheel in the desired straight-ahead position and slip it down over the splines. Install and tighten the retaining nut to specifications.

REAL WORLD FIX

Left Thrust Line, but a Pull to the Right!

A new four-door sport sedan had been aligned several times at the dealership in an attempt to solve a pull to the right. The car had front-wheel-drive and four-wheel independent suspension. The dealer rotated the tires, and it made no difference. The alignment angles of all four wheels were in the center of specifications. The dealer even switched all four tires from another car in an attempt to solve the problem.

In frustration, the owner took the car to an alignment shop. Almost immediately the alignment technician discovered that the right rear wheel was slightly toed-in. This caused a pull to the right. ● **SEE FIGURE 120–40.**

The alignment technician adjusted the toe on the right rear wheel and reset the front toe. The car drove beautifully.

The owner was puzzled about why the new car dealer was unable to correct the problem. It was later discovered that the alignment machine at the dealership was out of calibration by the exact amount that the right rear wheel was out of specification. The car pulled to the right because the independent suspension created a rear steering force toward the left that caused the front to pull to the right. Alignment equipment manufacturers recommend that alignment equipment be calibrated regularly.

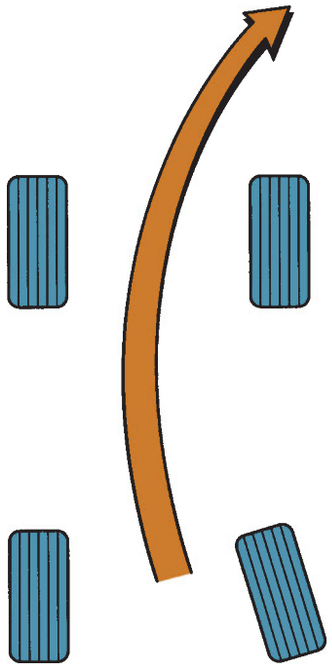

FIGURE 120–40 The toe-in on the right wheel creates a turning force toward the right.

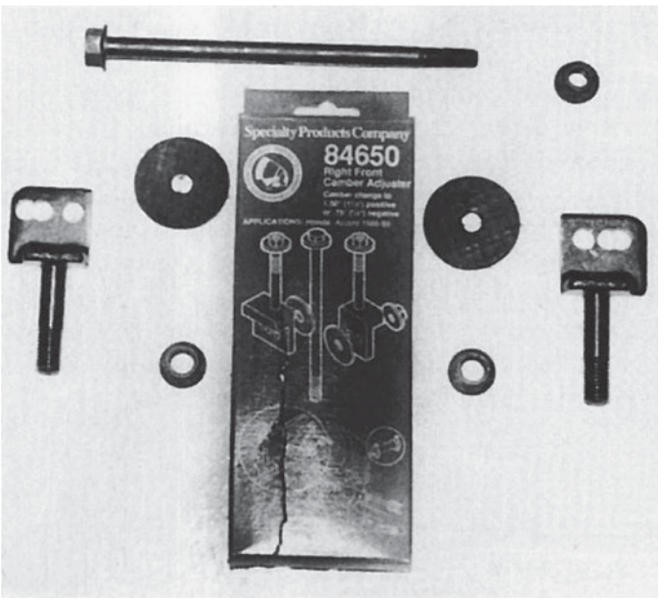
TOLERANCE ADJUSTMENT PROCEDURE

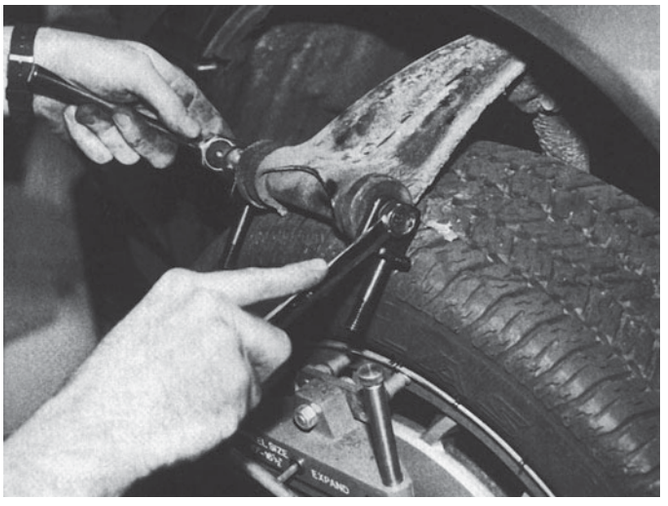
Many vehicles are designed and built without a method to change caster or camber, or both. (All vehicles have an adjustment for toe.) Before trying an aftermarket alignment correction kit, many technicians first attempt to correct the problem by moving the suspension attachment points within the build tolerance. All vehicles are constructed with a slight amount of leeway or tolerance; slight corrections can be made because bolt holes are almost always slightly larger than the bolt diameter, allowing for slight movement. When several fasteners are involved, such as where the powertrain cradle (subframe) attaches to the body of the front-wheel-drive vehicle, a measurable amount of alignment change (often over 1/2 degree) can be accomplished without special tools or alignment kits. The steps for **tolerance adjustment** include the following:

STEP 1 Determine which way the suspension members have to be moved to accomplish the desired alignment—for example, the right front may require more positive camber to correct a pulling or tire wear problem.



STEP 2 Locate and loosen the cradle (subframe) bolts about four turns each. DO NOT REMOVE ANY OF THE BOLTS.

STEP 3 Using prybars, move the cradle in the direction that will result in an improvement of the alignment angles. Have an assistant tighten the bolts as pressure is maintained on the cradle.



STEP 4 Measure the alignment angles and repeat the procedure if necessary.

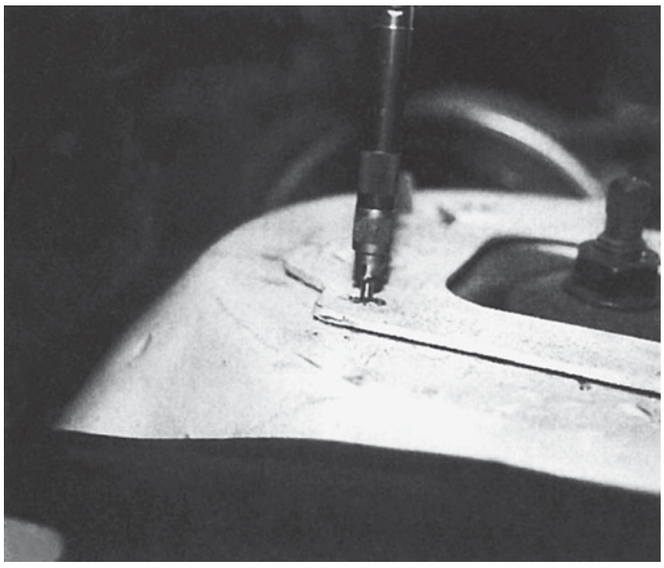
AFTERMARKET ALIGNMENT METHODS

Accurate alignments are still possible on vehicles without factory methods of adjustment by using alignment kits or parts. Aftermarket alignment kits are available for most vehicles. Even when there are factory alignment methods, sometimes the range of adjustment is not enough to compensate for sagging frame members or other normal or accident-related faults. ● **SEE FIGURES 120–41 AND 120–42.**

(a)

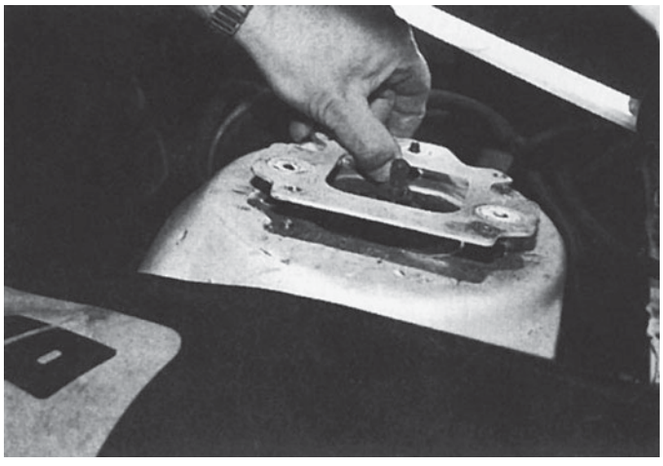
(b)

FIGURE 120–41 (a) Aftermarket camber kit designed to provide some camber adjustments for a vehicle that does not provide any adjustment. (b) Installation of this kit requires that the upper control arm shaft be removed. Note that the upper control arm was simply rotated out over the wheel pivoting on the upper ball joint.



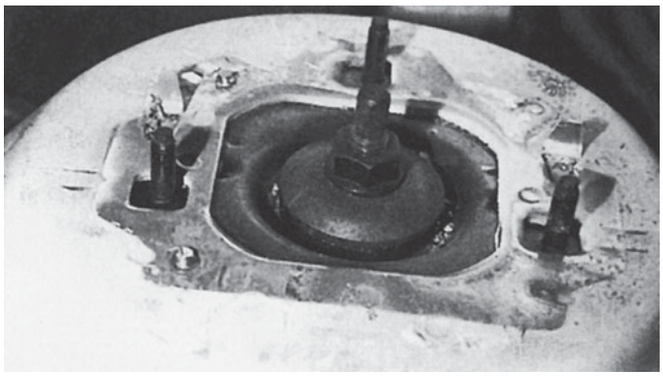
ALIGNING ELECTRONIC-SUSPENSION VEHICLES

When aligning a vehicle equipped with an electronic suspension, several additional steps may be required. Always check service information and read carefully all on-screen instructions on the alignment machine. Some examples of the steps that may be needed include:



- Verify the exact type of electronic suspension. This step could include checking the regular production order (RPO) code.
- Check that the ride height (suspension height) is within factory specifications.
- The steering wheel angle, as well as the radar cruise control sensor, will often need to be recalibrated using a scan tool. This is needed because the steering wheel may be in a different position after the alignment, and the steering wheel position sensor needs to be reset because the rear toe setting was changed. The rear thrust line could also have been changed. The radar cruise control needs to be calibrated to the revised rear thrust angle using a scan tool.

ALIGNING MODIFIED VEHICLES



If different springs were installed which in turn changes the suspension height, or if larger or smaller wheels and tires were installed, many alignment shops would reject doing an alignment. If a shop

(b)

(c)

FIGURE 120–42 (a) The installation of some aftermarket alignment kits requires the use of special tools such as this cutter being used to drill out spot welds on the original alignment plate on a strut tower. (b) Original plate being removed. (c) Note the amount of movement the upper strut bearing mount has around the square openings in the strut tower. An aftermarket plate can now be installed to allow both camber and caster adjustment.

attempted to align a vehicle, handling and tire wear problems were common. Because the ride height is changed from stock factory setting, the following can occur:

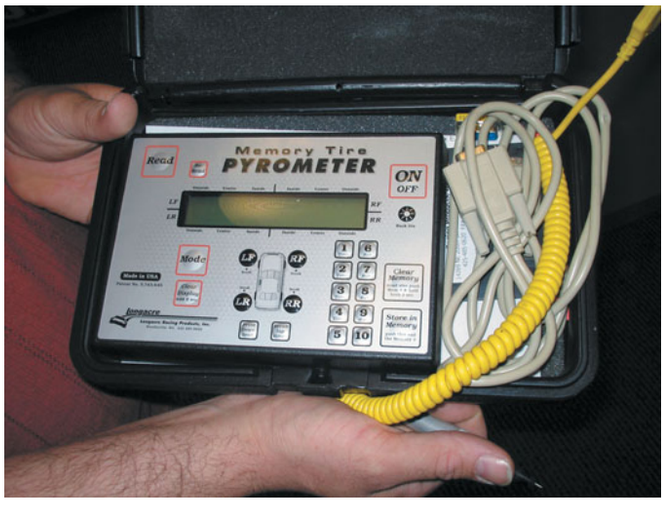

FIGURE 120–43 A typical tire temperature pyrometer. The probe used is a needle that penetrates about 1/4 inch (7 mm) into the tread of the tire for most accurate readings.

1. The steering axis inclination (SAI) is now incorrect.
2. Because the steering linkage and the control arms are no longer parallel, bump steer can occur. Bump steer causes the vehicle to dart to one side when a wheel hits a bump.
3. Because the ride height changed, camber and toe also changed. The camber change is often enough to prevent it from being able to be adjusted to within specifications.

Alignment alone will not correct these concerns. To allow for proper handling, the following aftermarket kits and parts are available:

- **Camber kits**—These kits usually include a replacement control arm or offset cam, which provides additional camber adjustment.
- **Bump steer kits**—A bump steer kit can include a modified steering arm or rack-and-pinion steering gear repositioning components.

The kits available can be found listed on the alignment screen of many newer alignment machines, such as the Hunter Engineering Company's WinAlign Tuner Custom Alignment for Modified Vehicles. During part of this alignment, the technician has to select one of two options:

- Maximum tire wear
- Maximum handling

Therefore, the technician has to determine from the customer which of these two parameters are most important. After the alignment, the instructions often state that the vehicle should be driven and then the temperature of the tires measured and recorded. Using a tire pyrometer, be sure to measure the temperature of each tire at the following locations for each tire:

- Approximately 1.5 inches (38 mm) from the outside edge of the tire in the tread rubber
- In the middle of the tread
- Approximately 1.5 inches (38 mm) from the inside edge of the tire in the tread rubber

The temperatures are then typed into the alignment machine, and the program calculates the final alignment settings. ● **SEE FIGURE 120–43.**

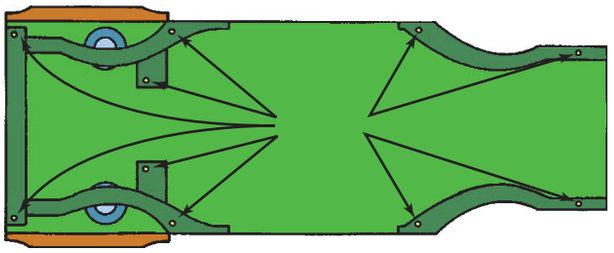

FIGURE 120–44 Jig holes used at the assembly plant to locate suspension and drivetrain components. Check service information for the exact place to measure and the specified dimensions when checking for body or frame damage.

TECH TIP

TSBs Can Save Time

Technical service bulletins (TSBs) are issued by vehicle and aftermarket manufacturers to inform technicians of a situation or technical problem and give the corrective steps and a list of parts needed to solve the problem.

TSBs are often released by new vehicle manufacturers to the dealership service department. They usually concern the current-year vehicle of a particular model. While many of these TSBs concern minor problems covering few vehicles, many contain very helpful solutions to hard-to-find problems.

Most TSBs can be purchased directly from the manufacturer, but the cost is usually very high. TSBs can also be purchased through aftermarket companies that are licensed and available on a web site. Go to the National Automotive Service Task Force (NASTF) web site (www.NASTF.org) for a list of the web addresses for all vehicle manufacturer's sites where TSBs can be purchased directly. Factory TSBs can often save the technician many hours of troubleshooting.

HIDDEN STRUCTURAL DAMAGE DIAGNOSIS

Many accidents result in hidden structural damage that can cause alignment angles to be out of specification. If alignment angles are out of specification tolerances, then accident damage should be suspected. Look for evidence of newly replaced suspension parts, body work, or repainted areas of the body. While a body and/or frame of a vehicle can be straightened, it must be done by a knowledgeable person using body-measuring equipment.

The first thing that must be done is to determine a *datum plane. Datum* means a basis on which other measurements can be based. The datum plane is the horizontal plane.

However, most alignment technicians do not have access to body/frame alignment equipment. The service technician can use a common steel rule to measure several points of the vehicle to determine if the vehicle is or is not damaged or needs to be sent to a frame shop for repair.

FRAME/BODY DIAGONALS If the frame or body is perfectly square, then the diagonal measurements should be within 1/8 in. (3 mm) of each other. ● **SEE FIGURE 120–44.**

While there are specified measurement points indicated by the manufacturer, the diagonal measurements can be made from almost any point that is repeated exactly on the other side, such as the center of a bolt in the suspension mounting bracket.

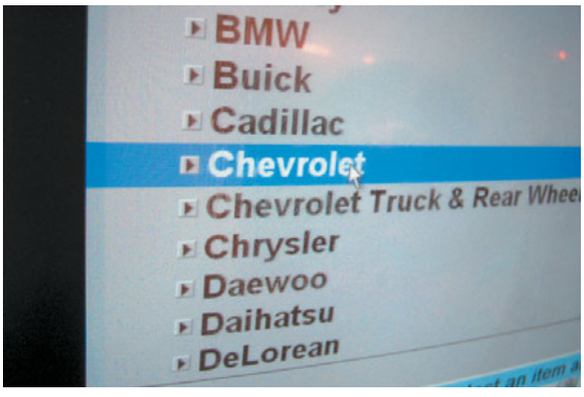
ALIGNMENT GUIDE

The following chart lists common alignment problems and their probable causes.

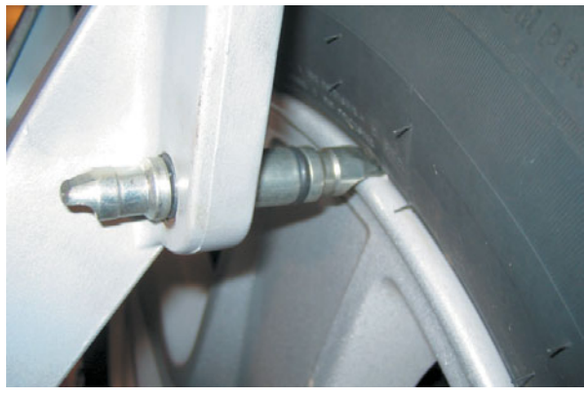
Symptom-Based Alignment Guide

Problems	Probable Causes
Pull left/right	Uneven tire pressure, tire conicity, mismatched tires, unequal camber, unequal caster, brake drag, setback, suspension/frame sag, unbalanced power assist, bent spindle, bent strut, worn suspension components (front or rear), rear suspension misalignment.
Incorrect steering wheel position	Incorrect individual or total toe, rear wheel misalignment, excessive suspension or steering component play, worn rack-and-pinion attachment bushings, individual toe adjusters not provided.
Hard steering	Improper tire pressure, binding steering gear or steering linkage, low P/S fluid, excessive positive caster, lack of lubrication, upper strut mount(s), worn power steering pump, worn P/S belt.
Loose steering	Loose wheel bearings, worn steering or suspension components, loose steering gear mount, excessive steering gear play, loose or worn steering coupler.
Excessive road shock	Excessive positive caster, excessive negative camber, improper tire inflation, too wide wheel/tire combination for the vehicle, worn or loose shocks, worn springs.
Poor returnability	Incorrect camber or caster, bent spindle or strut, binding suspension or steering components, improper tire inflation.
Wander/ instability	Incorrect alignment, defective or improperly inflated tires, worn steering or suspension parts, bent spindle or strut, worn or loose steering gear, loose wheel bearings.
Squeal/scuff on turns	Defective or improperly inflated tires, incorrect turning angle (TOOT), bent steering arms, excessive wheel setback, poor driving habits (too fast for conditions), worn suspension or steering parts.
Excessive body sway	Loose or broken stabilizer bar links or bushings, worn shocks or mountings, broken or sagging springs, uneven vehicle load, uneven or improper tire pressure.
Memory steer	Binding steering linkage, binding steering gear, binding upper strut mount, ball joint, or kingpin.
Bump steer	Misalignment of steering linkage, bent steering arm or frame, defective or sagged springs, uneven load, bent spindle or strut.
Torque steer	Bent spindle or strut, bent steering arm, misaligned frame, worn torque strut, defective engine or transaxle mounts, drive axle misalignment, mismatched or unequally inflated tires.

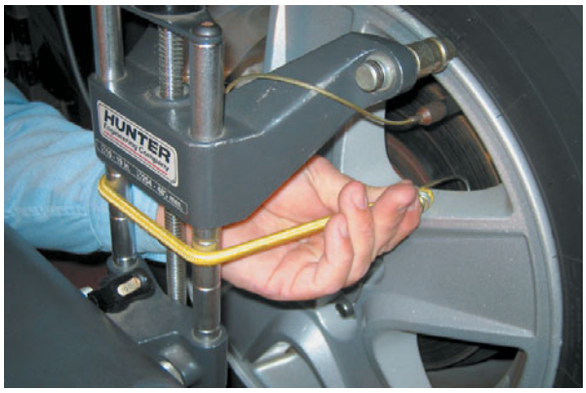
1 Begin the alignment procedure by first driving the vehicle onto the alignment rack as straight as possible.



2 Position the front tires in the center of the turn plates. These turn plates can be moved inward and outward to match a vehicle of any width.

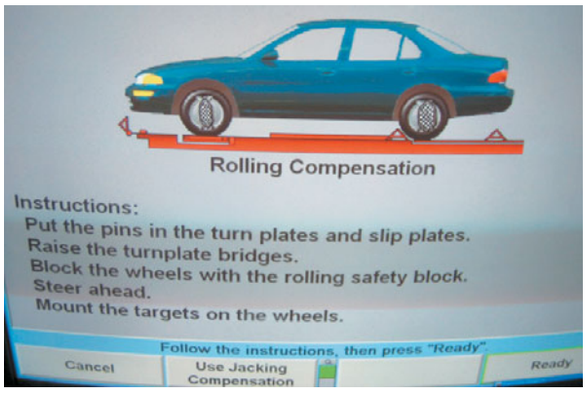


3 Raise the vehicle and position the alignment rack following the rack manufacturer's instructions.



4 Check and adjust tire pressures and perform the prealignment checks necessary to be assured of proper alignment.

5 Select the exact vehicle on the alignment machine.



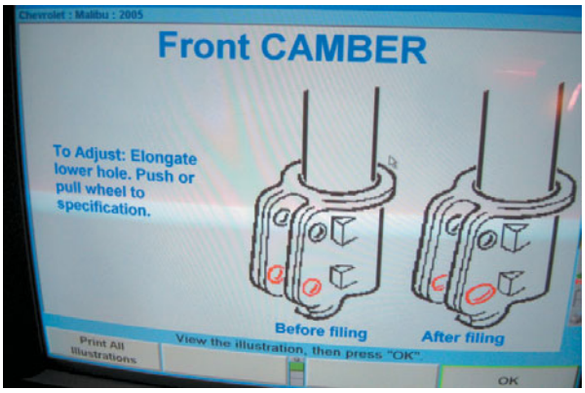
6 Securely mount the alignment heads or target wheels.

7 If mounting a transmitter-type alignment head, be sure to attach the retaining wire to the tire valve.

8 After installation of the heads, follow the specified procedure for compensation, which allows accurate alignment readings.

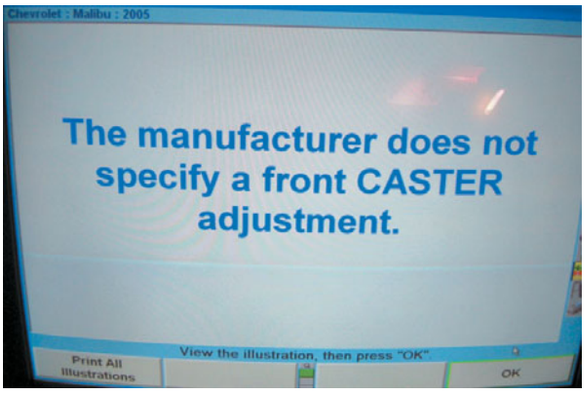
9 Rolling compensation is used on machines that use lasers and wheel targets.

10 An alignment reading is displayed even though caster has not yet been measured. The readings marked in red indicate that they are not within specifications.



11 Before performing a caster sweep, install a brake pedal depressor to keep the front wheels from rotating when the steering wheel is turned.

12 Perform the caster sweep by turning the front wheels inward, and then outward following the instructions on the screen.



CONTINUED ▶

13 Most alignment machines will display where to make the alignment correction and will often include drawings and live-action videos that show the procedure.

14 The rear toe is being adjusted by rotating the eccentric cam on the lower control arm while watching the display.

15 The alignment machine display indicates that front caster is not a factory-adjustable angle.

16 Adjusting the front toe on this vehicle involves loosening the jam nut (left wrench) and rotating the tie rod using the right wrench.

17 One last adjustment of the left front toe is needed to achieve a perfect alignment. The final alignment reading can be printed and attached to the work order.

18 After disconnecting all of the attachments, reinstalling the valve caps, and removing the steering wheel holder, the vehicle should be test driven to check for proper alignment before returning it to the customer.

REVIEW QUESTIONS

1. List 10 prealignment checks that should be performed before the wheel alignment is checked and/or adjusted.
2. Describe the difference between a lead (drift) and a pull.
3. Explain the causes and possible corrections for torque steer.
4. Explain the causes and possible corrections for memory steer.
5. List the necessary steps to follow for a four-wheel alignment.

CHAPTER QUIZ

1. If the tie rod ends become worn, which angle is most affected?
   a. Camber **c.** Toe
   b. Caster **d.** SAI
2. Technician A says that a vehicle will pull (or lead) to the side with the most camber (or least negative camber). Technician B says that a vehicle will pull (or lead) to the side with the most positive caster. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Technician A says that the front toe determines the thrust angle. Technician B says that the rear toe angle determines the thrust angle. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. Strut rods, if they are adjustable, can be used to adjust which angle?
   a. Toe **c.** Caster
   b. Camber **d.** Toe-out on turns
5. If metal shims are used for alignment adjustment in the front, they adjust _____.
   a. Camber **c.** Toe
   b. Caster **d.** Both a and b
6. Which angle is largest?
   a. 0.55 degrees **c.** 45 minutes
   b. 1/4 degree **d.** 1/2 degree

Use the following information to answer question 7:

Specifications:	Min.	Preferred	Max.
Camber (degree)	0	1.0	1.4
Caster (degree)	.8	1.5	2.1
Toe (inch)	−.10	.06	.15
Results:	**L**	**R**	
Camber (degree)	−.1	.6	
Caster (degree)	1.8	1.6	
Toe (inch)	1.12	+.12	

7. The vehicle above will _____.
   a. Pull toward the right and feather-edge both tires
   b. Pull toward the left
   c. Wear the outside of the left tire and the inside of the right tire
   d. None of the above

Use the following information to answer questions 8 and 9:

Specifications:	Min.	Preferred	Max.
Camber (degree)	−1/4	+1/2	1
Caster (degree)	0	+2	+4
Toe (inch)	−1/16	1/16	3/16
Results:	**L**	**R**	
Camber (degree)	−0.3	−0.1	
Caster (degree)	3.6	1.8	
Toe (inch)	−1/16	+1/32	

8. The vehicle above will _____.
   a. Pull toward the left
   b. Pull toward the right
   c. Wander
   d. Lead to the left slightly
9. The vehicle above will _____.
   a. Wander
   b. Wear tires, but will not pull
   c. Will pull, but not wear tires
   d. Pull toward the left and cause feather-edge tire wear
10. Which alignment angle is most likely to need correction and cause the most tire wear?
    a. Toe
    b. Camber
    c. Caster
    d. SAI/KPI

CLUTCHES

OBJECTIVES: After studying Chapter 121, the reader will be able to: • Prepare for ASE Manual Drive Train and Axles (A3) certification test content area "A" (Clutch Diagnosis and Repair). • List the parts that are included in the clutch system. • Describe how the clutch works. • Explain the importance of proper clutch pedal freeplay. • List the steps necessary to replace a clutch. • Describe the characteristic noise each clutch component part makes when defective.

KEY TERMS: Belleville spring 1458 • Bushing 1455 • Candlestick 1461 • Clutch disc 1454 • Coil spring clutch 1458 • Cushioning spring 1457 • Front bearing retainer 1455 • Lever style (pressure plate) 1458 • Marcel spring 1457 • Pilot bearing 1455 • Pressure plate 1454 • Quill 1455 • Quill shaft 1461 • Release bearing 1454 • Slave cylinder 1455 • Throwout bearing 1454 • Torsional dampers 1457

PURPOSE AND FUNCTION OF A CLUTCH

The clutch assembly is located between the engine and the transmission/transaxle. The purpose and function of a clutch include the following:

- To disconnect the engine from the transmission/transaxle to permit the engine to remain running when the vehicle is stopped and to permit the transmission/transaxle to be shifted
- To connect and transmit engine torque to the transmission/transaxle

NOTE: The term *transmission* refers to rear-wheel-drive vehicles and the term *transaxle* usually refers to front-wheel-drive vehicles that have a differential built into the unit. A separate differential is used with a transmission.

- To dampen and absorb engine impulses and drive train vibration
- To provide a smooth engagement and disengagement between the engine and the transmission/transaxle

COMPONENT PARTS AND OPERATION OF A CLUTCH ASSEMBLY

A clutch assembly consists of a **clutch disc** that is splined to the input shaft of the transmission/transaxle. When the driver depresses the clutch pedal, a **throwout bearing** (**release bearing**) is forced against the fingers of the **pressure plate.** The pressure plate is bolted to and rotates with the flywheel. ● **SEE FIGURE 121–1.** When force is exerted on the center of the pressure plate, the pressure is released from the clutch disc that has been forced against the engine flywheel. With

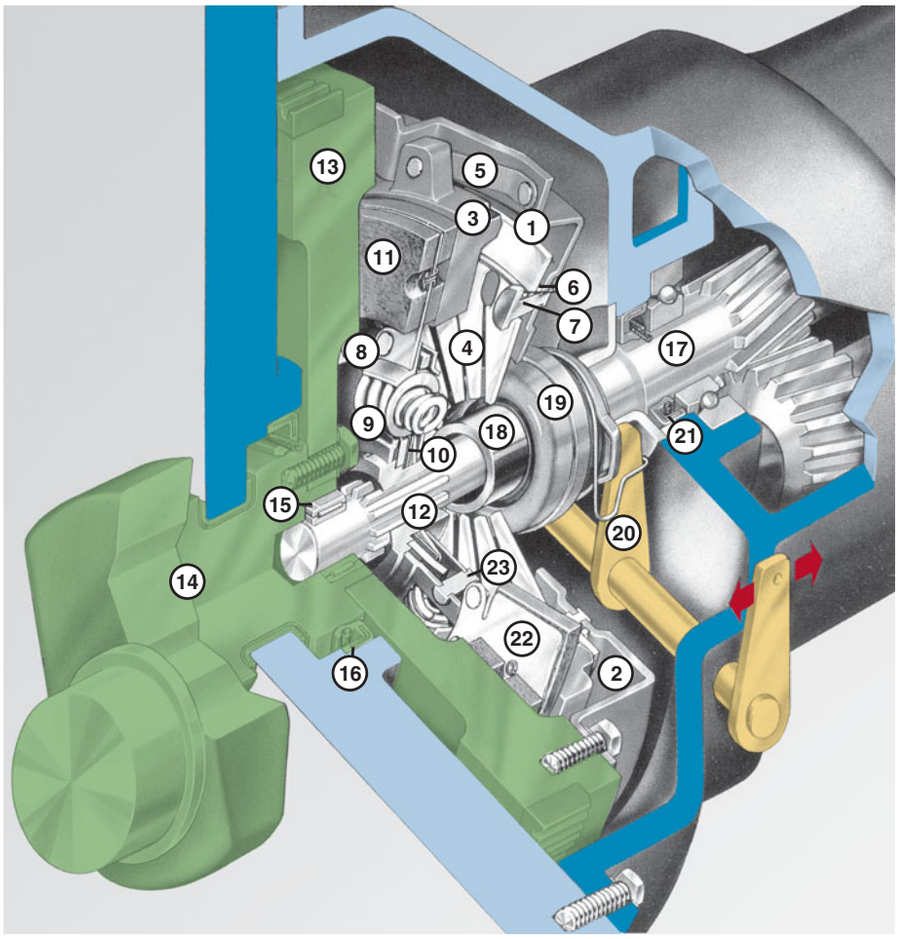

FIGURE 121–1 Typical automotive clutch assembly showing all related parts. (*Courtesy of LUK*)

the pressure removed from the clutch disc, the engine can be operated without transferring torque to the transmission/transaxle. This also permits the transmission/transaxle to be shifted because a shift cannot be made if the transmission/transaxle is transferring engine torque.

When the driver reduces force on the clutch pedal, the pedal return spring and the pressure plate spring combine to return the clutch pedal to its at-rest position (clutch-engaged position). When the clutch pedal moves up, the pressure on the throwout bearing is released and the force against the pressure plate spring(s) is released allowing the force of the pressure plate to clamp the clutch disc tightly between the flywheel and the pressure plate. ● **SEE FIGURE 121–2.**

Additional related parts include the **pilot bearing** (or **bushing**) that supports the front of the transmission input shaft. ● **SEE FIGURE 121–3.** The throwout bearing is often supported and rides on the transmission/transaxle **front bearing retainer** (also called the **quill**).

NOTE: Most front-wheel-drive transaxles do not use a pilot bearing.

To summarize:

- When the clutch pedal is up, the clutch is engaged.
- When the clutch pedal is down, the clutch is disengaged.

CLUTCH PEDAL LINKAGE

There are three methods of transferring the force of the driver's foot to the throwout (release) bearing, including:

- **Levers and rods.** Through a series of levers and rods, the release fork is forced against the throwout bearing. This method was commonly used on many older vehicles.
- **Cable operation.** A cable is used similar to a brake cable used on a bicycle. ● **SEE FIGURE 121–4.**
- **Hydraulic.** A small master cylinder and a **slave cylinder** located near the throwout bearing is a very common method of connecting the clutch pedal to the release fork on vehicles equipped with a manual transmission. ● **SEE FIGURES 121–5 AND 121–6.**

CLUTCH DISC

The clutch disc is round with a splined center hole that slips over the splines of the input shaft of the transmission/transaxle. Friction material is riveted to both sides of the clutch disc—one side touches the flywheel of the engine and the other side touches the friction surface of the pressure plate.

Friction material is either woven or molded from a mixture of other materials. Woven materials are softer and help cushion clutch engagement, but they may not last as long as molded materials.

Friction materials operate in high heat and pressure. For many years, asbestos was the most common material used in both clutch and brake linings. However, it is no longer used because inhaling tiny particles of asbestos causes lung damage. Today, clutch friction material may contain paper, cotton, and bits of copper or brass wire with resin holding the mixture together.

CAUTION: Always take precautions when working around clutch lining material and assume that it contains asbestos. These precautions should include wetting the friction disc before removal and preventing any dust from the lining from becoming airborne.

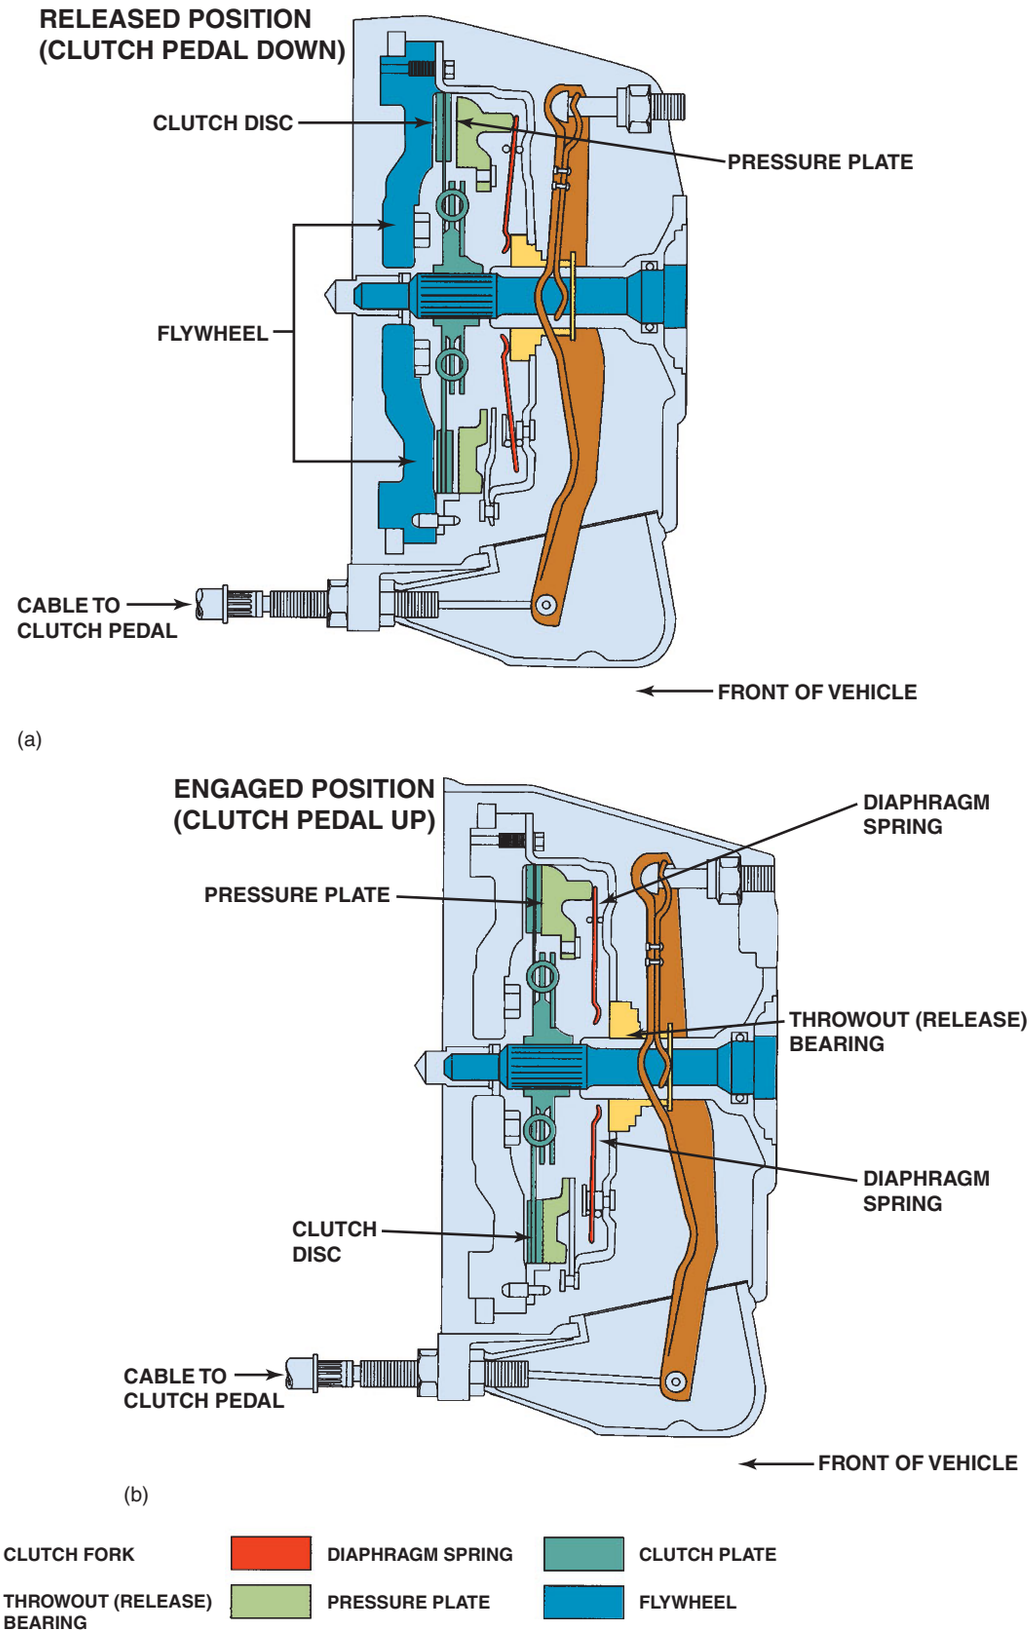

FIGURE 121–2 (a) When the clutch is in the released position (clutch pedal depressed), the clutch fork is applying a force to the throwout (release) bearing, which pushes on the diaphragm spring, releasing the pressure on the friction disc. (b) When the clutch is in the engaged position (clutch pedal up), the diaphragm spring exerts force on the clutch disc, holding it between the flywheel and the pressure plate.

HIGH-PERFORMANCE CLUTCH DISC Another type of friction material is a ceramic and metallic mixture. This creates a hard, long-lasting lining, but is more expensive and does not cushion clutch engagement as much as a softer lining. Instead of a full circle of softer friction material, the disc may have only a few segments or buttons of this ceramic-metallic material. Clutches that use these discs, which are sometimes called "button clutches," are found in racing applications where strength and durability are a greater concern than smooth engagement. ● **SEE FIGURE 121–7.**

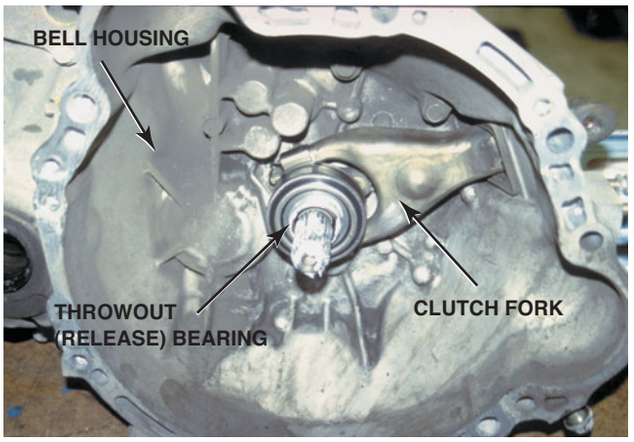

FIGURE 121–3 The transmission has just been removed. Note that this type of transmission incorporates the bell housing, which was therefore removed at the same time as the transmission. The clutch fork and throwout (release) bearing also came off together. All that remained attached to the engine was the flywheel, clutch disc, and pressure plate.

FIGURE 121–6 A typical clutch master cylinder and reservoir mounted on the bulkhead on the driver's side of the vehicle. Brake fluid is used in the hydraulic system to operate the slave cylinder located on the bell housing.

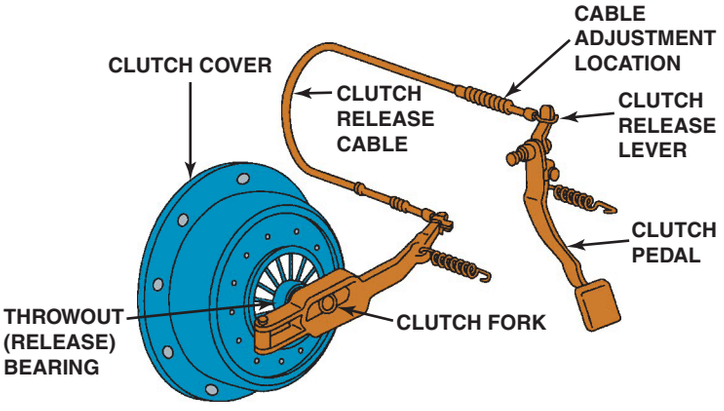

FIGURE 121–4 A typical cable-operated clutch.

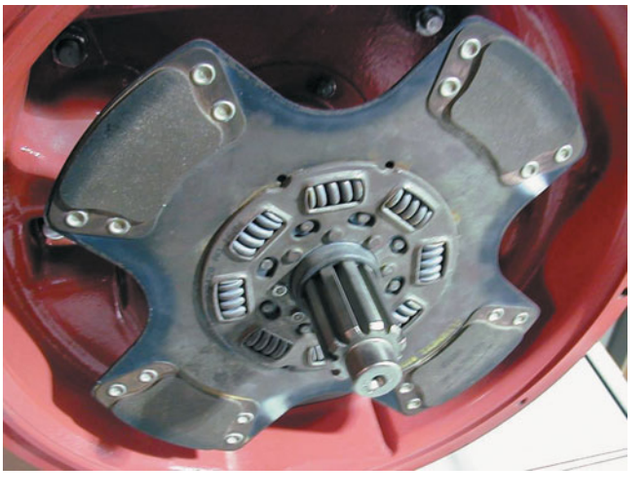

FIGURE 121–7 A racing or high-performance clutch disc lacks the features of a stock clutch disc that help provide smooth engagement.

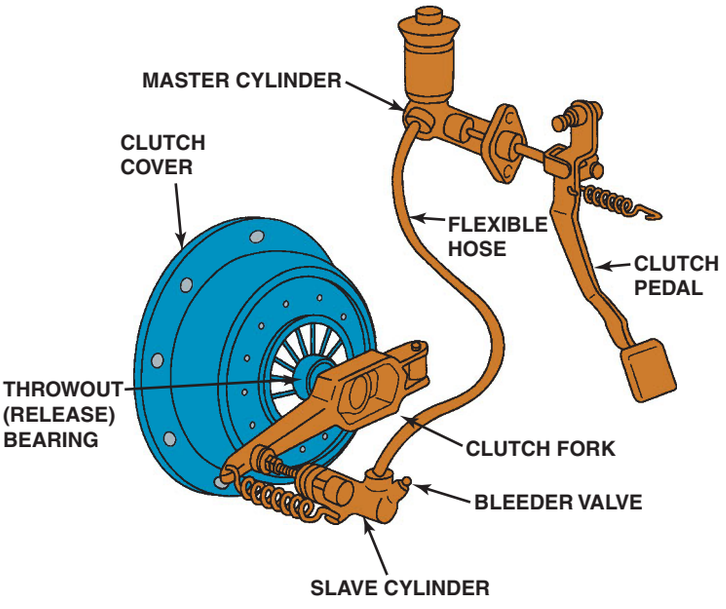

FIGURE 121–5 A hydraulic clutch linkage uses a master cylinder and a slave cylinder.

STOCK CLUTCH DISC Around the center hub of the clutch disc are **torsional dampers** that absorb the initial shock of engagement and help dampen engine-firing in pulses being transmitted into and through the transmission/transaxle. ● **SEE FIGURE 121–8.** The torsional dampers are either coil springs or are made of rubber. In the space between the friction surfaces is a wavy spring steel material called a **cushioning spring** or **marcel spring.** ● **SEE FIGURE 121–9.** The marcel spring also helps to absorb the initial shock of engagement and allows for a smooth engagement of the clutch.

FIGURE 121–8 A typical stock clutch friction disc that uses coil spring torsional dampers.

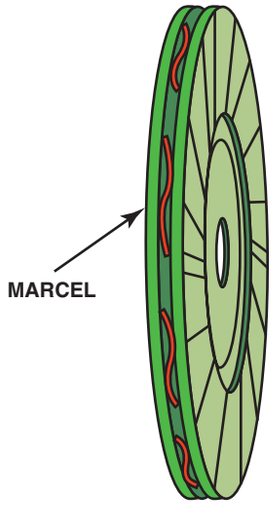

FIGURE 121–9 A marcel is a wavy spring that is placed between the two friction surfaces to cushion the clutch engagement.

HINT: The larger center hub section of the disc must be installed with the thicker portion facing the pressure plate. ● **SEE FIGURE 121–10.**

PRESSURE PLATES

The purpose of the pressure plate is to exert a force on the clutch disc so that engine torque can be transmitted from the engine to the transmission/transaxle. The required strong clamping force is provided by pressure plate spring(s). However, a strong pressure plate spring force must be released by the force of the driver's foot to disengage the clutch. Most pressure plates today are made of stamped steel with a nodular cast iron driving plate. A smooth, machined area on one side forms the friction disc contact surface. When the clutch engages, spring force pushes the pressure plate toward the flywheel so the friction disc is clamped between the flywheel and the pressure plate. Engine torque flows through the clutch to the transmission input shaft. Three or four drive straps or clips connect the pressure plate to the clutch cover. These spring-steel straps or clips help hold the pressure plate away from the flywheel when the clutch disengages. Several styles of pressure plates have been used, including

- **Coil spring style.** This style of pressure plate uses coil springs and three or four release arms. A coil-spring-style pressure plate is also called the **lever style** because it uses levers to compress the coil springs. ● **SEE FIGURE 121–11.**
- **Diaphragm spring style.** This style is the most commonly used pressure plate design. One large, round, spring-steel spring is used to apply even force on the clutch disc called a **Belleville spring**. ● **SEE FIGURE 121–12.** These tend to be smaller

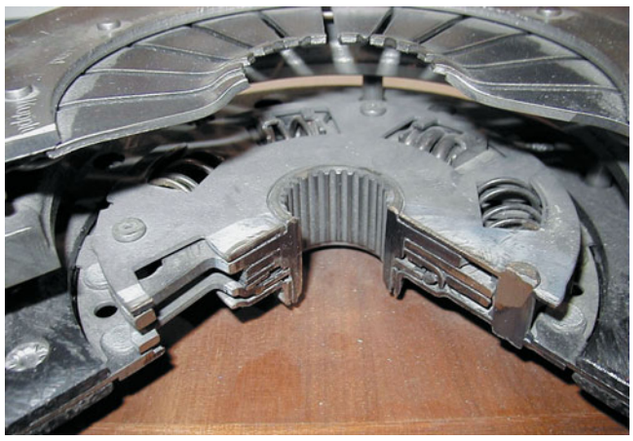

FIGURE 121–10 Cutaway of the center section of a clutch plate showing the various layers of steel plates used in the construction.

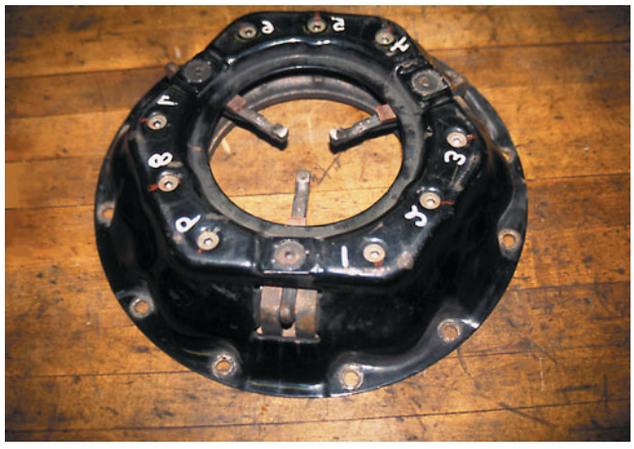

FIGURE 121–11 A coil spring (lever style) clutch pressure plate.

FIGURE 121–12 Typical diaphragm-style pressure plate that uses a Belleville spring.

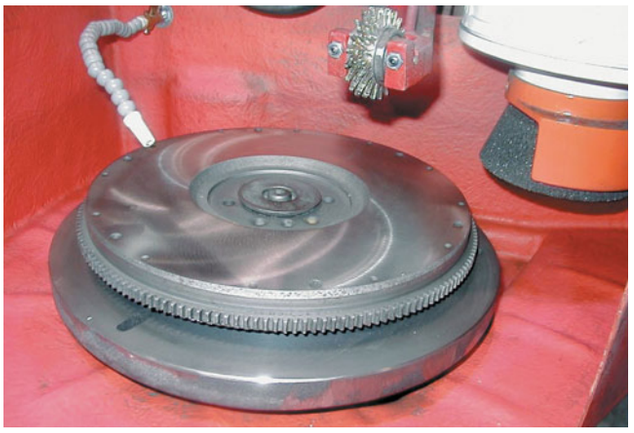

FIGURE 121–13 A flywheel after it has been machined (ground) to provide the correct surface finish for the replacement clutch disc.

FIGURE 121–14 The starter motor will spin but the engine will not crank if the ring gear on the flywheel is broken.

assemblies, weigh less, and have fewer parts than coil spring assemblies. The one-piece diaphragm spring does the job of all the release levers and coil springs in a coil spring clutch.

The driver must push harder on the clutch pedal to disengage a **coil spring clutch** than to disengage a comparable diaphragm spring design. The pedal effort for a coil spring clutch increases the farther down the pedal is pushed. The pedal effort for a diaphragm spring clutch decreases during the second half of pedal travel.

As the friction disc wears, coil springs expand and lose some of their clamping force. In contrast, the design of the diaphragm spring tends to increase its clamping force as the friction disc wears to half its original thickness. Then, as the friction disc continues to wear, the clamping force of the spring gradually returns to its original level. This happens without any obvious change in clutch pedal effort.

In many cases, aftermarket clutch parts manufacturers supply a diaphragm spring pressure plate assembly when an original coil spring assembly must be replaced. If so, carefully compare the new pressure plate to the old one to make sure it is the correct replacement. Physical characteristics, such as dimensions and bolt-hole patterns, must be identical for the assembled clutch to operate properly. Check that the inner edges of the diaphragm spring fingers are the same height as the release levers on the original unit.

FLYWHEELS

The engine flywheel serves four basic purposes:

- Smoothes out or dampens engine power pulses.
- Absorbs some of the heat created by clutch operation.
- Provides the connection point for the starter motor to crank the engine.
- Provides the application surface for the clutch friction disc.

A flywheel is heavy, or has a large mass, which creates inertia. This inertia acts upon crankshaft rotation to smooth out or dampen engine power pulses. On a running engine, the crankshaft speeds up as a cylinder fires, then slows due to internal engine friction until the next cylinder fires. The inertia provided by the flywheel mass tends to keep crankshaft speed more constant.

Whenever friction exists between two moving parts, heat is generated. The flywheel absorbs some of the heat created by clutch operation by acting as a heat sink for the clutch friction disc.

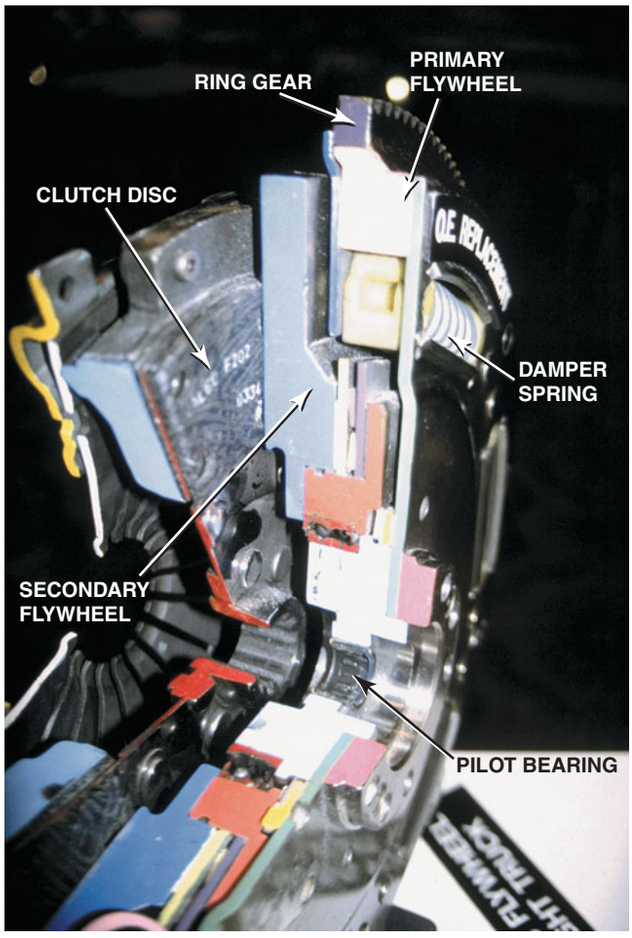
An external ring gear is pressed or welded onto the flywheel along its outer circumference. When the starter motor is engaged, the starter-drive gear meshes with the flywheel ring gear. Through gear reduction, the flywheel transfers starter motor rotation to the crankshaft to crank the engine.

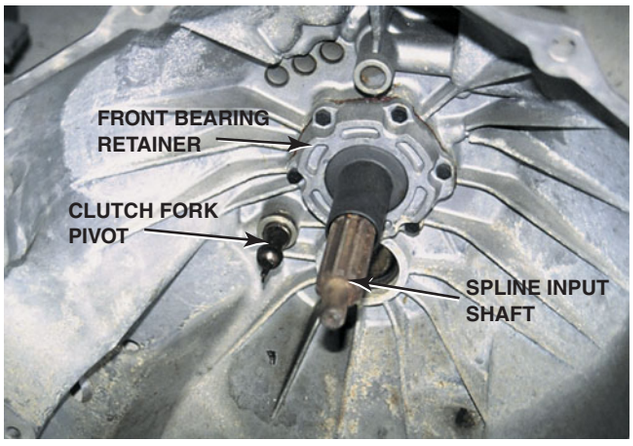
The face on the transmission side of the flywheel has a smooth, machined area that creates the application surface for the clutch friction disc. This surface must be properly finished to allow adequate slippage as the clutch engages and disengages, and to prevent slippage when the clutch is engaged. ● **SEE FIGURE 121–13.**

The flywheel is constructed of cast iron and attaches to the end of the engine crankshaft. The carbon content of the cast iron (about 3%) provides a suitable surface for the clutch disc. The carbon, in the form of graphite, acts as a lubricant to provide a smooth engagement of the clutch. Often the ring gear can be replaced separately without having to replace the flywheel in the event of a failure, as shown in ● **FIGURE 121–14.** The pilot bearing is often installed in the center of the flywheel (or in the end of the crankshaft) to support the end of the input shaft of the transmission.

DUAL-MASS FLYWHEELS. Some vehicles, especially high-performance vehicles and vehicles equipped with diesel engines, use a dual-mass flywheel. The purpose of a dual-mass flywheel is to dampen engine vibrations and keep them from being transmitted to the passenger compartment through the transmission and shift linkage. A dual-mass flywheel consists of two separate flywheels attached with damper springs, friction material, and ball bearings to allow some movement between the primary and secondary flywheel. By allowing a very slight amount of movement between the two flywheels, the damper absorbs engine torque peaks and normal vibration to provide smoother drive train operation. The damper assembly is completely sealed, because it also contains a fluid or lubricant, typically silicone-based, which also helps absorb vibration and transmit torque. Typically, the two flywheels twist out of phase with each other by up to about 60 degrees to absorb torsional oscillations. The starter ring gear mounts on the primary flywheel. Power from the starter motor does not have to flow through the damper assembly to reach the engine crankshaft. The ring gear and pilot bearing are usually attached to the primary flywheel, and the clutch friction surface is usually the secondary flywheel. ● **SEE FIGURE 121–15.**

NOTE: If the dual-mass flywheel fails, the symptom is the same as a slipping clutch. The torque-limiting friction material connecting the primary and secondary flywheels can fail. This failure requires the replacement of the flywheel assembly.





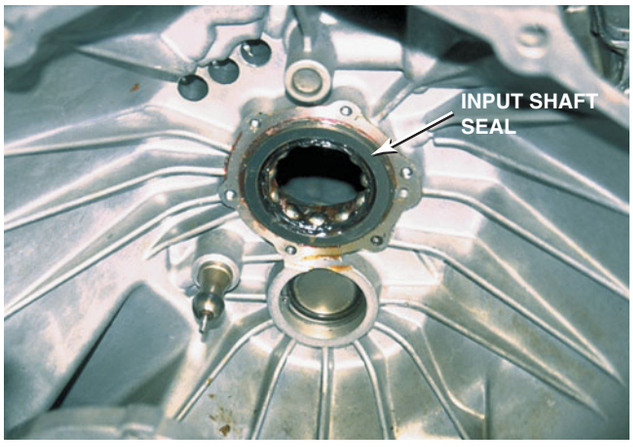


FIGURE 121–15 A cutaway of a dual-mass flywheel used on a Ford diesel pickup truck.

(a)

(b)

FIGURE 121–16 (a) Before replacing the clutch, the bell housing should be cleaned and the clutch fork pivot lightly lubricated. (b) The input shaft seal should also be replaced to prevent the possibility of getting transmission lubricant on the friction surfaces of the clutch.

TECH TIP

Shim It or Replace It

Whenever replacing a clutch, most experts agree that the flywheel should be removed from the engine and resurfaced. When material is removed from the surface of the flywheel, the geometry (relationship) of the clutch parts changes because the pressure plate is now closer to the rear of the engine by the amount removed from the flywheel. Ask your parts supplier for a shim equal in thickness to the amount of material removed during resurfacing. Generally, these round shims are available in 0.020" to 0.100" thicknesses. The shim is installed between the crankshaft flange and the flywheel. If a shim is not used, the flywheel may have to be replaced to properly restore proper clutch operation and service life.

TECH TIP

Repair the Oil Leaks Before Replacing the Clutch

If engine oil or transmission lube gets onto the friction surface of the clutch, the clutch will chatter when engaged. This grabbing and releasing of the clutch is not only harmful to the drive train (transmission, driveshaft, etc.) but also is disturbing to the driver when the vehicle vibrates and shakes while driving. To avoid the possibility of a chattering clutch, always repair oil leaks as soon as possible. Rocker (valve) cover gaskets, intake manifold gaskets, oil galley plugs, rear main seals, as well as the input shaft seal on the transmission/transaxle itself can all lead to clutch contamination. ● **SEE FIGURE 121–16.**

PILOT BEARING OR BUSHING

The transmission input shaft goes all the way from the transmission, through the clutch assembly, to the engine. Transmission bearings support the transmission end of the shaft. Depending on the length of the input shaft, it may also need a pilot bearing or bushing to support it at the engine end.

A front-wheel-drive vehicle with a stepped flywheel, compact clutch assembly, and a transaxle that has a short input shaft that may not reach all the way to the flywheel. This design does not need a pilot bushing or bearing to support the engine end of the input shaft. ● **SEE FIGURE 121–17.**

Other designs, such as a rear-wheel-drive vehicle with a flat flywheel, have a much longer transmission input shaft. At the engine, the transmission input shaft rests inside a small bore in the flywheel or crankshaft flange. The pilot bearing or bushing, which is pressed into this bore, supports the engine end of the input shaft and provides

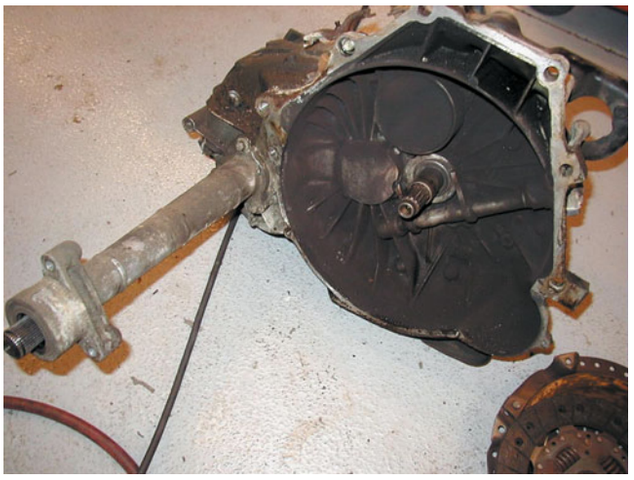

FIGURE 121–17 A transaxle assembly has been removed to replace the clutch. Note the short input shaft. This vehicle did not use a pilot bearing (bushing).

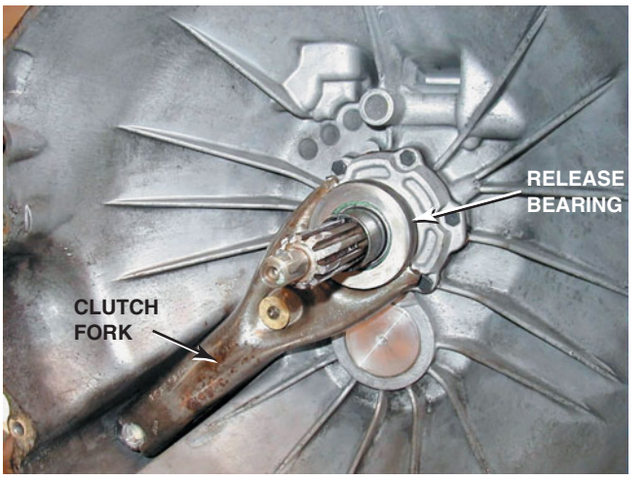

FIGURE 121–18 The clutch pedal linkage moves the clutch fork, which then applies a force against the release bearing, which then releases the clamping force the pressure plate is exerting on the clutch disc.

REAL WORLD FIX

The Mazda Pickup Truck Story

The driver of a Mazda pickup truck complained that it was difficult to shift the manual transmission into first gear and reverse. The hydraulic clutch system was checked and bled and seemed to be operating as designed. A defective clutch was not suspected because the clutch did not slip. The problem continued to worsen. Finally, when the driver had trouble shifting into all gears, the technician decided that the transmission had to be removed and the clutch inspected. When the transmission was removed, the clutch assembly including the pressure plate, throwout bearing, and clutch disc all appeared to be worn but not enough to cause any trouble. Then the pilot bearing was inspected. The needle bearings were broken. The input shaft of the transmission is supported by the pilot bearing located in the center of the flywheel. Apparently, what had happened was that the pilot bearing failed and the pieces of the bearing kept the input shaft to the transmission rotating whenever the engine was running whether or not the clutch was depressed or released. The technician replaced the pilot bearing and the other clutch components at the request of the owner and everything worked perfectly.

a low-friction surface for the shaft to ride on. This keeps the shaft and friction disc perfectly aligned with the flywheel and pressure plate.

The pilot bearing or bushing rotates with the crankshaft when the engine is running. At times, the input shaft does not rotate when the engine is running. The pilot bearing or bushing lowers the friction between these two moving parts. Some pilot bearings use ball bearings while other applications use a caged-needle bearing. The outer race of the bearing is pressed into the crankshaft or flywheel. The input shaft slides freely into the inner race. Pilot bushings are usually a sintered metal sleeve pressed into the bore in the crankshaft flange.

Always follow the manufacturer's transmission/transaxle lubrication instructions. Excess lubricant leaks out onto the clutch friction disc, which causes clutch slippage and early failure. Too little lubricant leads to noisy operation and input shaft damage.

Replacement pilot bearings may need to be packed before installation. Sometimes, the bottom of the bore behind the bearing is also packed with grease. Other pilot bearings are permanently lubricated at the factory. Prelubricated bearings have an oil seal to hold the lubricant. If only one side is sealed, that side faces the transmission when installed.

Some pilot bushings need to be soaked in oil before installation. Others have a permanent lubricant built into the bushing material. With this type, adding another lubricant actually increases friction, by preventing the permanent lubricant from doing its job.

RELEASE BEARING The throwout (release) bearing is attached to the clutch fork and rides on the fingers of the pressure plate. The clutch operating system moves the clutch release bearing when the driver presses or releases the clutch pedal. Most systems move the release bearing toward the flywheel to disengage the clutch. ● **SEE FIGURE 121–18.** However, some systems have a pull-type mechanism that moves the bearing away from the flywheel to disengage the clutch. The release bearing presses against the diaphragm spring fingers or coil spring levers. This takes spring force off the pressure plate so that it no longer clamps the friction disc against the flywheel.

The diaphragm spring fingers or coil spring levers rotate at crankshaft speed, but the clutch operating system is a part of the vehicle chassis and does not rotate. The release bearing is the point where the fixed, stationary clutch operating system meets the rapidly spinning clutch assembly. ● **SEE FIGURE 121–19.**

RELEASE BEARING CONSTRUCTION Most clutch release bearings are ball bearings. The bearing absorbs a thrust load when its outer race presses against the diaphragm spring fingers or coil spring levers. When the outer race contacts the spring fingers or levers, it must rotate with them at engine crankshaft speed. The inner bearing race is pressed onto an iron hub, or sleeve. In some designs, the inner bearing race and sleeve are machined as one piece. The inner bearing race and sleeve are stationary and do not spin when the outer race spins.

RELEASE BEARING INSTALLATION The transmission front bearing retainer has a long, hollow tube extending toward the engine. The release bearing sleeve slides on the outer surface of this tube, which is commonly called the quill, **quill shaft,** or **candlestick.**

In a typical system, the outside of the release bearing sleeve has grooves or raised flat surfaces that fit into the clutch release

FIGURE 121–19 The release bearing rubs against the tips of the diaphragm spring.

FREQUENTLY ASKED QUESTION

What Part Causes What Noise and When?

Many service technicians try to determine which part causes noise before the clutch assembly is removed from the vehicle. Start your noise analysis by starting the engine with the manual transmission in neutral and the clutch engaged (foot off the clutch pedal). If you hear a growl or grinding sound, the cause is the input shaft bearing in the transmission.

If you are hearing a chirping noise, slowly depress the clutch pedal. If the noise stops, the problem is lack of lubrication at the fork and pivot. If the noise gets louder as you depress the clutch, the throwout (release) bearing is the problem.

The pilot bearing is the cause of a squealing noise if the sound changes as the clutch pedal is depressed or released. The sound will be loudest when the difference in speed between the engine and the input shaft is greatest.

fork. A snap ring, spring clips, or lock pins secure the release bearing to the release fork. The clutch operating system pivots the release fork back and forth when the driver presses and releases the clutch pedal. The pivoting motion of the fork slides the release bearing away from or toward the engine to engage or disengage the clutch.

TYPES OF RELEASE BEARINGS If the clutch operating system self-adjusts, then there is no clearance between the release bearing outer race and the diaphragm spring fingers or coil spring levers. The release bearing outer race constantly turns at engine crankshaft speed. This is called a constant-running release bearing. In some self-adjusting systems, a snap ring holds the outer race to the spring fingers. This design is typical of pull-type clutch operating systems that move away from the flywheel to disengage the clutch.

If the clutch operating system does not self-adjust, then there must be some clearance between the release bearing outer race and the spring fingers when the clutch is engaged. The outer race does not contact the spring fingers and so it does not turn. As the driver depresses the clutch pedal, the release bearing moves into contact with the fingers and the outer race begins to rotate with them. This type of release bearing is not designed to rotate constantly. If the clutch is not adjusted properly and there is no clearance, the release bearing spins constantly and wears out quickly.

REAL WORLD FIX

Best to Double-Check Your Parts Before Installation

A beginning technician installed a new clutch in a Chevrolet S-10 pickup truck. After the transmission was installed and the driveshaft connected, the technician started the engine to check the operation of the clutch with the truck still on the lift and off the ground. The drive wheels never turned even though the clutch was released. It was almost as if the clutch disc was left out completely although the clutch pedal felt normal.

The transmission was removed and the clutch parts inspected. Everything looked okay until the technician slid the clutch disc over the splines of the transmission input shaft. The diameter of the hole in the clutch disc was a lot larger than the diameter of the shaft. The clutch also simply revolved without even touching the input shaft. Obviously, the technician received the wrong clutch disc from the parts department. The experienced technician explained that not only should all parts be carefully inspected before installation but that the clutch disc should have been slid over the splines of the input shaft to check for any possible burrs that could prevent the clutch disc from disengaging.

RELEASE BEARING LUBRICATION The ball bearing portion of the release bearing is usually permanently lubricated and sealed during manufacture. This part of the bearing should not be lubricated during service.

The sleeve, or quill shaft, often needs lubrication during clutch service. Typically, a thin film of high-temperature grease coats the sliding surfaces. Always follow the manufacturer's recommendations for release bearing lubrication, and avoid overlubricating. As with pilot bearings, too much lubricant here can lead to early clutch failure.

CLUTCH PROBLEM DIAGNOSIS

If the clutch is slipping, it cannot transfer engine torque to the transmission or drive wheels. A common method used to check for a slipping clutch is the following:

1. Drive the vehicle to a safe location where it can be accelerated safely.
2. Rapidly accelerate the vehicle in first or second gear and rapidly shift the transmission into a higher gear.

The engine speed should drop as the clutch is released after selecting a higher gear. If the clutch is slipping, the engine speed will either rise or not drop after the clutch pedal is released (clutch is engaged).

Another common problem with a clutch is that it sometimes will not fully disengage. The following symptoms will occur if there

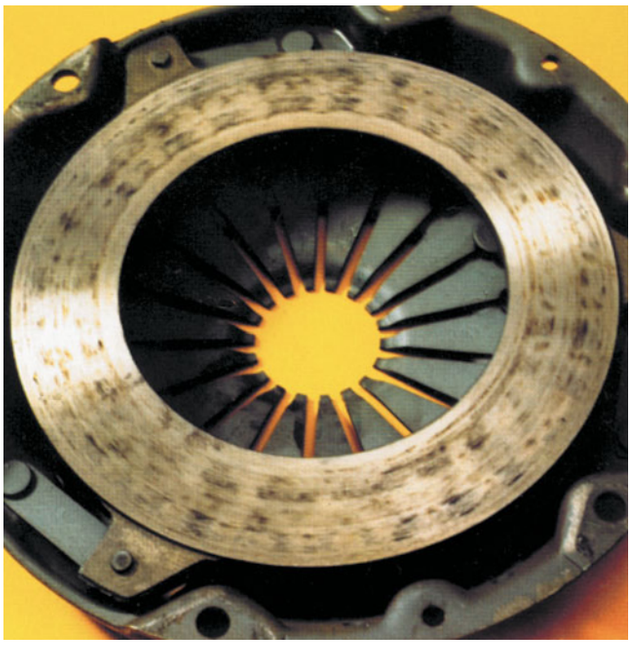

FIGURE 121–20 Heavy chatter marks on the pressure plate indicate that oil or grease has gotten onto the clutch facing. (*Courtesy of LUK*)

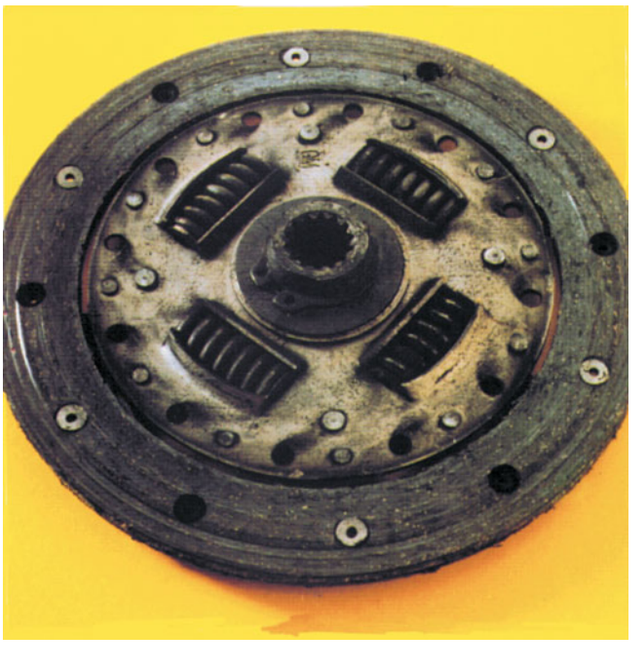

FIGURE 121–22 Friction material (facing) worn down to the rivets. Normal wear can cause this or improper clamping force from a defective pressure plate. (*Courtesy of LUK*)

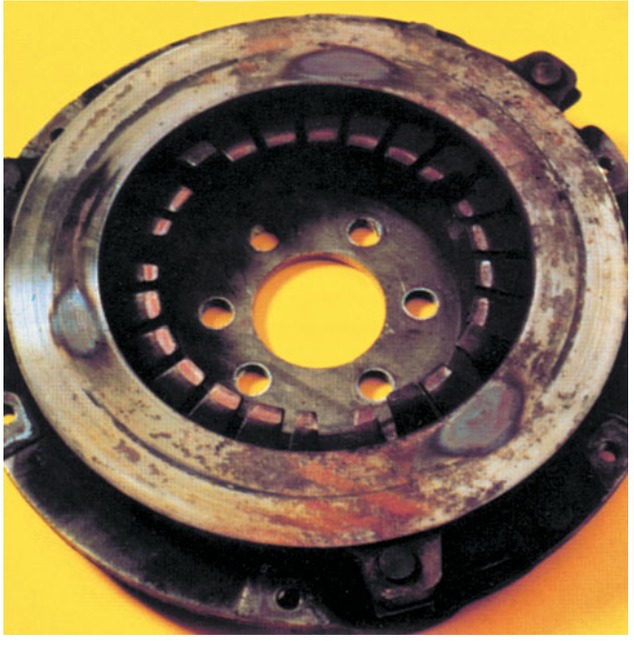

FIGURE 121–21 Hot spots on the pressure plate indicate that this clutch has been slipping or that oil/grease has gotten onto the clutch facing. (*Courtesy of LUK*)

FIGURE 121–23 Friction material (facing) only makes contact with the flywheel on the inner and outer edge. The likely cause is that the flywheel was not resurfaced or replaced during a previous repair. (*Courtesy of LUK*)

is a fault in the clutch or in the linkage or hydraulic system that could prevent the clutch from being fully disengaged:

- The transmission will be difficult (or impossible) to shift into reverse.
- The transmission will be difficult (or impossible) to shift between forward gears.

● **SEE FIGURES 121–20 THROUGH 121–28** for examples of worn clutch components.

SAFETY TIP

Disconnect the Battery Before Work Begins

It is always a safe idea to disconnect the negative (−) battery cable before performing major work to the vehicle as a safety precaution.

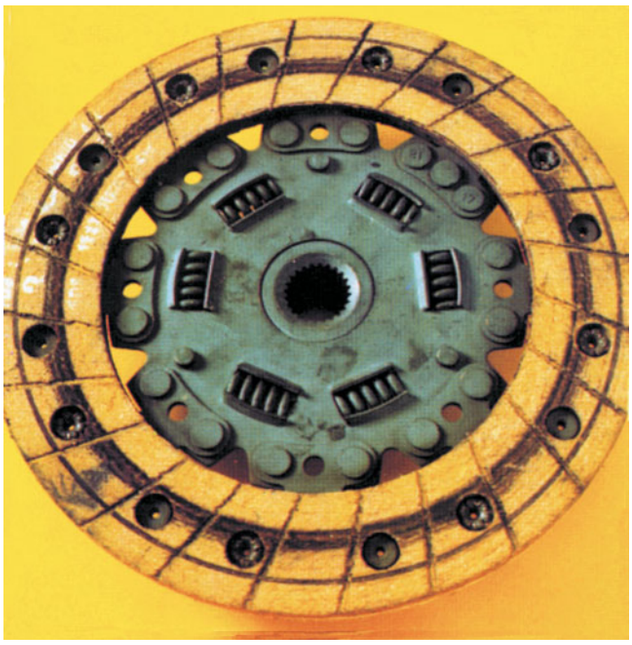

FIGURE 121–24 Deep scoring in the friction material (facing) on the flywheel side indicates that the flywheel was not resurfaced or replaced during a previous repair. (*Courtesy of LUK*)

FIGURE 121–26 A destroyed torsional damper is usually caused by driving at too low an engine speed, which would cause too much strain on the torsional damper. (*Courtesy of LUK*)

FIGURE 121–25 A broken cushion segment caused by movement between the engine and transmission. The most likely cause is a missing or defective pilot bearing. (*Courtesy of LUK*)

FIGURE 121–27 A worn down or broken diaphragm is often caused by a faulty release bearing or a linkage problem that keeps the clutch from fully releasing. (*Courtesy of LUK*)

CLUTCH REPLACEMENT

The clutch replacement for a typical rear-wheel-drive vehicle includes the following steps.

1. Hoist the vehicle safely and mark and remove the driveshaft. This step ensures that the driveshaft will be reinstalled correctly and in phase.
2. Disconnect the shift linkage, speedometer connections, and reverse light switch connection as well as the clutch linkage or cable or slave cylinder.
3. Support the transmission with a transmission jack and then remove the rear crossmember and bell housing bolts.
4. Carefully move the transmission toward the rear. Try to keep the transmission level to avoid causing damage to the pilot bearing or clutch components. A slight wiggling of the transmission is usually necessary to allow the input shaft to slide over the spline of the clutch disc.

FIGURE 121–28 Rusting hub splines indicate that the transmission shaft was not lubricated, which can cause the clutch to not disengage correctly. (*Courtesy of LUK*)

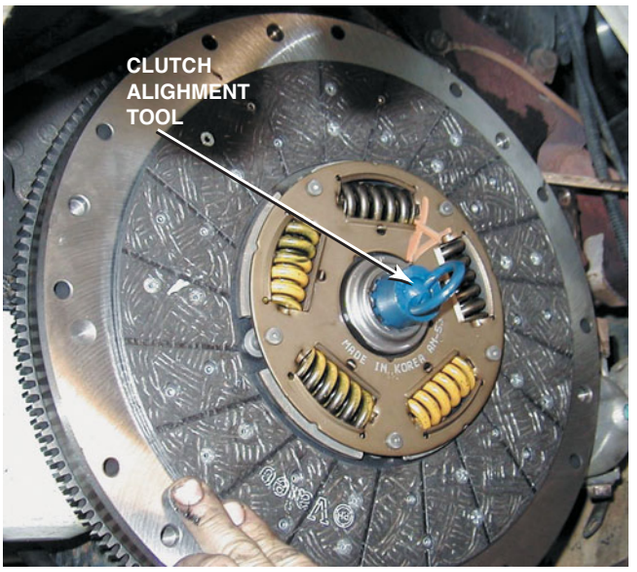

FIGURE 121–29 A clutch alignment tool is inserted into the pilot bearing and over the splines of the clutch disc to keep the disc properly centered before installing the pressure plate. After the pressure plate has been installed and torqued to factory specifications, the alignment tool can be removed because the pressure plate spring force holds the friction disc tightly against the flywheel.

5. After the transmission has cleared the clutch, it can be lowered and inspected before being reinstalled after the clutch assembly has been replaced.
6. Mark the pressure plate and flywheel if they are to be reused to allow them to be reinstalled in the same location to maintain assembly balance.
7. Remove the clutch pressure plate retaining bolts, and remove the clutch assembly including the release bearing, pressure plate, and clutch disc.
8. Clean and inspect the flywheel.

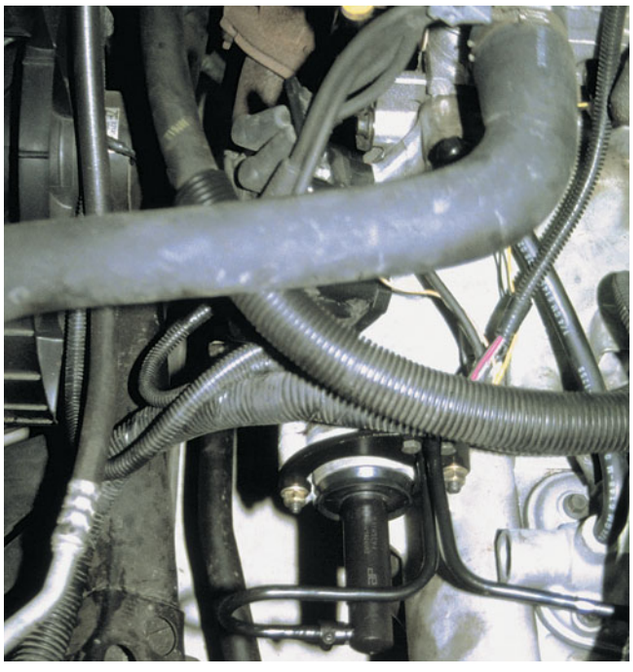
NOTE: Most experts recommend that the flywheel be removed and resurfaced. Always use new flywheel bolts and torque to factory specifications.

9. Replace or lightly lubricate the pilot bearing/bushing.
10. Install the clutch disc and pressure plate using an aligning tool to center the clutch disc and then torque the pressure plate bolts to factory specifications. ● **SEE FIGURE 121–29**.
11. Inspect the clutch release lever and replace if necessary.
12. Attach the replacement release bearing and install the transmission and torque the retaining bolts to factory specifications.
13. Reconnect the clutch linkage and place the transmission into high gear and have an assistant depress the clutch pedal. Grasp the output shaft and turn it with your hand.
    a. The transmission output shaft should be easy to rotate if the clutch is fully disengaged with the clutch pedal held down. ● **SEE FIGURE 121–30**.
    b. If the output shaft cannot be rotated, double-check that the clutch linkage and clutch is correctly installed.
14. Reinstall the rear crossmember and torque the retaining bolts to factory specifications.
15. Reconnect the shift linkage, speedometer, and reverse light connections.

FIGURE 121–30 To check that the clutch is properly installed before replacing all of the components, try to turn the output shaft with the transmission in gear and the clutch pedal depressed by an assistant.

16. Install the driveshaft and torque the U-joint retaining fastener to factory specifications.
17. Lower the vehicle and test-drive it to verify correct clutch operation.

CLUTCH PEDAL ADJUSTMENT



As the clutch disc wears, the pressure plate moves closer to the flywheel. This causes the clutch to engage when the clutch pedal is higher and higher. Eventually, the clutch will start to slip if the

FIGURE 121–31 The clutch slave cylinder is often corroded because of moisture absorbed by the brake fluid used in the hydraulic clutch. This slave cylinder was disassembled to see if it could be overhauled rather than replaced.

(a)

(b)

FIGURE 121–32 (a) The replacement hydraulic clutch for a Saturn includes the master cylinder (shown) with the line and the slave cylinder as an assembly. The assembly is even filled with brake fluid! Do not open the master cylinder cap on this unit because Saturn did not provide any method of bleeding air out of the system. (b) The slave cylinder attaches to the bell housing of the transaxle.

TECH TIP

Check for Bulkhead Flex

Many cable-operated clutch linkage problems are caused by flexing of the bulkhead (firewall) as the clutch pedal is depressed. This movement of the bulkhead can cause the clutch to slip. To prevent unnecessary clutch repairs, have an assistant observe the bulkhead near the clutch cable while the clutch pedal is depressed. If there is movement of the sheet metal bulkhead, add reinforcing steel plate to the area.

linkage is not adjusted to compensate for the normal wear. Most hydraulic clutch linkage is self-adjusting and does not require any adjustment in normal service. Most lever type clutch linkage must be adjusted for proper clutch free pedal setting. Some cable-operated clutches are either self-adjusting or are adjusted easily. For example, one style of clutch linkage is adjusted by simply pulling upward on the clutch pedal until it stops. Some cable-operated clutch linkage is adjusted either at the bulkhead (firewall) where the cable exits the passenger compartment or at the clutch fork. Follow the adjustment procedures specified for the exact vehicle being serviced.

Most adjustment procedures specify a clutch pedal freeplay of 0.5 to 1.0 inch. Freeplay is the distance the clutch pedal can be depressed without encountering any noticeable resistance. This slight amount of freeplay assures that the clutch is fully engaged and not partially engaged as could occur if there is no freeplay in the pedal linkage.

BLEEDING THE HYDRAULIC CLUTCH

If the hydraulic system has been opened to replace either a clutch slave cylinder or master cylinder or both, air has to be bled from the system. ● **SEE FIGURES 121–31 AND 121–32.** Fill the master

cylinder with DOT 3 brake fluid and open the bleeder valve at the slave cylinder. Gravity should force the brake fluid to flow downward, expelling any trapped air that may be in the system. When brake fluid starts to drip from the bleeder valve, close the bleeder valve and check the clutch for normal operation. Sometimes depressing the clutch pedal slowly as an assistant opens the bleeder valve at the slave cylinder will force any trapped air out of the system. This is called *manual bleeding* and should be repeated as necessary until the normal operation of the clutch returns.

NOTE: Most technicians who are experienced in clutch service know that some vehicles are extremely difficult to bleed. Often it is necessary to use special service tools to either vacuum bleed or pressure bleed the system.

CLUTCH SYMPTOM GUIDE

CLUTCH SLIPS Possible causes:

1. Clutch is worn or out-of-adjustment.
2. Clutch disc has oil on the surface.
3. Flywheel height is out-of-specifications.

CLUTCH GRABS Possible causes:

1. Clutch disc has oil on the surface.
2. Clutch linkage is binding.

CLUTCH NOISES Possible causes:

1. Pilot bearing is defective or worn.
2. Release bearing is defective or worn.

CLUTCH REPLACEMENT

1 The first step in the process of replacing the clutch on this Chevrolet S-10 pickup truck is to remove the negative battery cable.

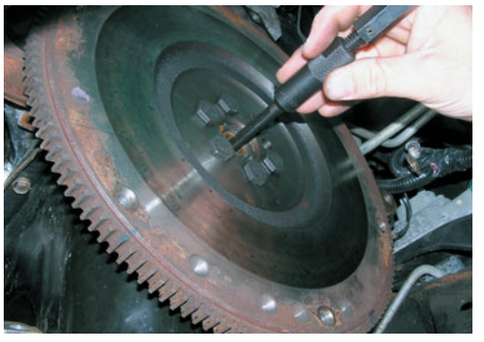
2 Remove the shifter mechanism inside the vehicle. This step may involve removing the center console and other components.

3 Mark and then remove the driveshaft.

4 Remove the exhaust pipe if needed. It was needed in this case, according to service information.

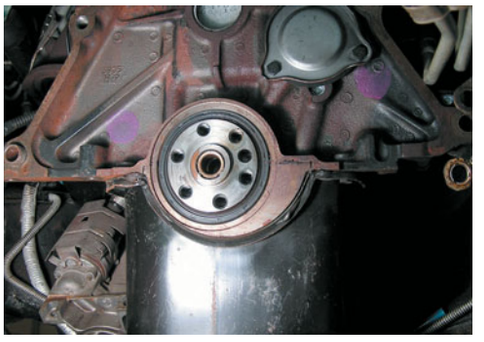
5 Remove the transmission mount fasteners.

6 Using a transmission jack, support the transmission and remove the bell housing bolts.



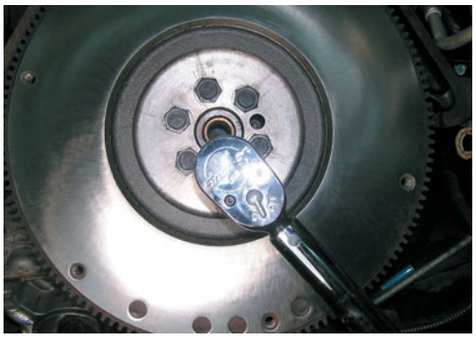
7 A view of the bell housing and throwout bearing as the transmission assembly is removed from the engine.

8 Removing the fasteners holding the pressure plate to the flywheel.



9 Removing the pressure plate and clutch disc.

10 Using a special puller, remove the pilot bearing.



11 The flywheel is being removed to be refinished or replaced as needed.

12 With the flywheel removed, check to see if the rear main seal is leaking and replace if needed.

CONTINUED ▶

13 Installing a reconditioned flywheel and torquing new bolts to factory specifications.

14 Installing a new pilot bearing and lubricate as per instructions in service information.

15 Using a pilot tool to align the clutch disc with the pilot bearing through the center opening of the pressure plate.

16 Installing the transmission assembly with a new throwout bearing.

17 Bleeding the air from the hydraulic clutch circuit.

18 Finish the clutch replacement by reinstalling all components removed and check for proper operation.

REVIEW QUESTIONS

1. List the parts of a typical clutch assembly.
2. Describe what happens when the driver depresses the clutch pedal.
3. Describe how to determine which of the following is the cause of a noise: pilot bearing, throwout (release) bearing, and input shaft bearing.
4. Explain why a dual-mass flywheel is used on some vehicles.
5. What is meant by clutch pedal freeplay?

CHAPTER QUIZ

1. Technician A says that too much clutch pedal freeplay can cause the clutch to slip during acceleration. Technician B says that too little clutch pedal freeplay can cause the clutch to slip. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. The engine speed increases when the driver depresses the accelerator pedal and releases the clutch pedal, but the vehicle does not move. Technician A says the clutch may be defective. Technician B says the dual-mass flywheel may be defective. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
3. A growling noise is heard only when the driver exerts force on the clutch pedal. No noise is heard when the clutch pedal is up. Technician A says the pilot bearing is defective. Technician B says the input shaft bearing is defective. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. Which part does *not* rotate when the engine is running and the clutch is depressed?
   a. Clutch disc **c.** Pressure plate
   b. Pilot bearing **d.** Flywheel
5. The clutch pedal freeplay is less than specifications. Technician A says that the clutch may slip during hard acceleration. Technician B says that the clutch will "grab" when the clutch pedal is close to the floor when the clutch is engaged. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
6. What part is often *not* used on a front-wheel-drive vehicle with a manual transaxle?
   a. Flywheel **c.** Clutch fork
   b. Throwout (release bearing) **d.** Pilot bearing
7. Most hydraulic clutch systems use what hydraulic fluid?
   a. Mineral (hydraulic) oil **c.** DOT 3
   b. SAE 80W-90 **d.** ATF
8. A clutch is chattering when engaged. Technician A says that too much clutch freeplay is the cause. Technician B says that oil or grease may be on the friction disc. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
9. A manual transmission is difficult to shift or get into gear, especially reverse. Technician A says that the clutch may not be fully releasing. Technician B says that too much clutch pedal freeplay could be the cause. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. Two technicians are discussing bleeding a hydraulic clutch. Technician A says to open the bleeder and allow the fluid to gravity bleed. Technician B says to have an assistant slowly depress the clutch pedal as the bleeder valve is opened at the slave cylinder to bleed the air out of the system. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 122

MANUAL TRANSMISSIONS/ TRANSAXLES

OBJECTIVES: After studying Chapter 122, the reader will be able to: • Prepare for the ASE Manual Drive Train and Axles (A3) certification test content area "B" (Transmission Diagnosis and Repair) and content area "C" (Transaxle Diagnosis and Repair). • Explain how to calculate gear ratios. • Name the parts of a typical manually shifted transmission/transaxle. • Describe how the synchronizer assembly allows for smooth, clash-free shifting. • Describe the different types of lubricants that may be used in a manual transmission/transaxle. • Diagnose a difficult-to-shift manual transmission/transaxle. • Describe the service and overhaul procedures for manual transmission and transaxles.

KEY TERMS: Axis 1472 • Back taper 1480 • Bell housing 1476 • Bevel gear 1473 • Blocker ring 1477 • Cluster gears 1476 • Cluster shaft 1476 • Clutch 1476 • Constant-mesh gear 1482 • Counter gears 1476 • Countershaft 1476 • Direct drive 1474 • Drive gear 1473 • Driven gear 1473 • Extension housing 1476 • External gears 1472 • Fifth gear 1481 • Final drive assembly 1482 • First gear 1480 • Fourth gear 1481 • Front bearing retainers 1476 • Gear reduction 1474 • Helical gear 1472 • Hypoid gear set 1473 • Hub 1477 • Input shaft 1476 • Internal ring gears 1473 • Keys 1477 • Lay shaft 1476 • Main drive pinion assembly 1476 • Main gear 1476 • Main shaft 1476 • Neutral 1480 • Output shaft 1476 • Overdrive 1474 • Pinion gear 1473 • Quill 1476 • Reverse 1482 • Second gear 1481 • Sliding reverse gear 1482 • Sliding sleeve 1477 • Springs 1477 • Spur gear 1472 • Stop ring 1477 • Synchronizer assemblies 1477 • Synchronizer keys 1478 • Synchronizer ring 1477 • Third gear 1481 • Transmission case 1476

THE NEED FOR A TRANSMISSION

A vehicle requires a lot of torque to start off and to climb hills, yet it does not require as much torque to move on level ground. The source of the torque is the engine. Torque is a twisting or turning force that is exerted on the input shaft of a transmission/transaxle. An engine produces increasing torque as its speed increases up to a certain point where the torque output starts to decrease. Therefore, to get a vehicle moving or to accelerate up a hill, it is desirable to use a transmission that allows the engine speed to be increased even though the vehicle speed may be low. Using gears allows the engine speed to increase at low vehicle speeds yet still permits the engine speed to drop at higher speeds to save fuel and reduce exhaust emissions.

For example,

- First gear: Vehicle speed is low, engine speed is high.
- Second gear: Vehicle speed increases, engine speed decreases as shift is made.
- Third gear: Vehicle speed continues to increase, engine speed is kept in a narrow range.
- Fourth gear: Again, the vehicle speed is increasing, yet engine speed is about the same as in third gear.

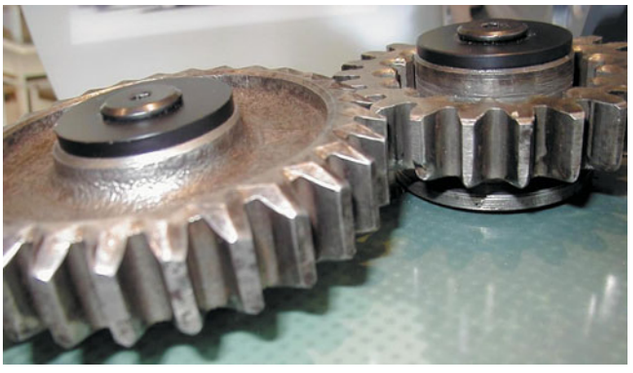


FIGURE 122–1 Spur gears have straight-cut teeth.

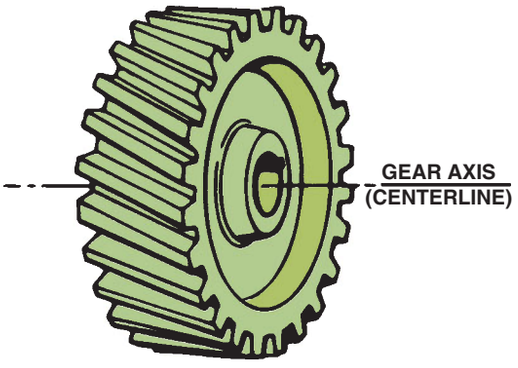

FIGURE 122–2 The teeth of a helical gear are cut at an angle to the gear axis.

GEAR TYPES

The simplest type of gear is the **spur gear.** ● **SEE FIGURE 122–1.** A spur gear consists of a gear blank with straight-cut teeth around its entire circumference. All gear teeth lie parallel to the centerline, or **axis,** of the gear. The teeth are shaped so they can mesh without slippage with a second spur gear's teeth positioned along a parallel axis.

Spur gear design permits 1.5 to 2.5 gear teeth to mesh at a time. The gear teeth make contact with each other over their full width at the same instant. The fact that the gear teeth are in full contact increases the strength of the gear, but also causes spur gear operation to be noisy. Due to their strength, most heavy-duty truck transmissions use spur gears.

A **helical gear,** although similar to a spur gear, has its teeth cut at an angle to the axis of the gear. ● **SEE FIGURE 122–2.** This enables more teeth, 2.5 to 3.5, to mesh at a time than the spur gear. Additionally, the angle allows the teeth to mesh gradually, rather than all at once. As a result, helical gears run quieter than spur gears. Helical gears, however, have two disadvantages. Each gear pushes against its shaft parallel to its axis. Special bearings are needed to protect the gearbox from this type of axial, or thrust, loading. Furthermore, because of the increased contact area, helical gears create more friction than spur gears. ● **SEE FIGURE 122–3.**

Spur and helical gears have gear teeth on their outside circumference and, for this reason, are called **external gears.** This

? FREQUENTLY ASKED QUESTION

What Is the Difference Between a Transmission and a Transaxle?

A transmission is used on rear-wheel-drive vehicles, whereas a transaxle is usually used on front-wheel-drive vehicles. A vehicle equipped with a transmission uses a separate differential to split the torque equally to the drive wheels. A transaxle includes a differential assembly. In a transaxle, the differential, sometimes called the *final drive unit,* is incorporated in the construction of the transmission.

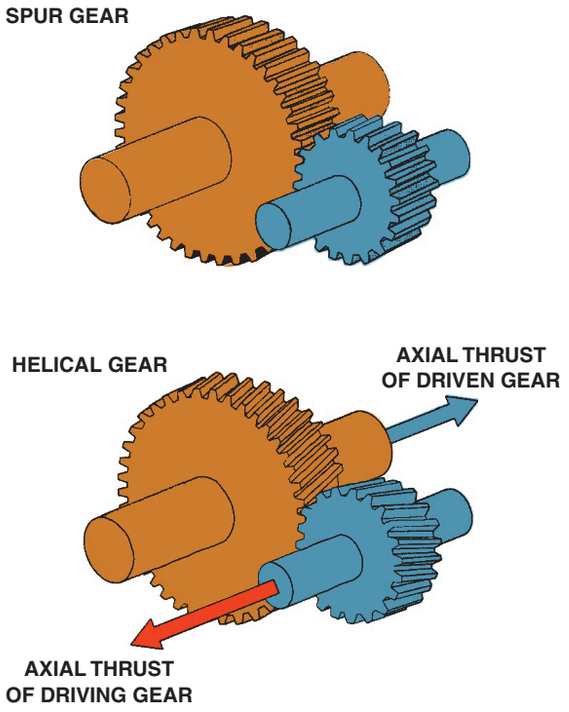

FIGURE 122–3 A spur gear has straight-cut teeth. This design is very strong and is used where strength is important. Spur gears are noisy during operation. Helical-cut gears, on the other hand, operate quietly but create a force in line with the axis of the gears due to the angle of the gear teeth.

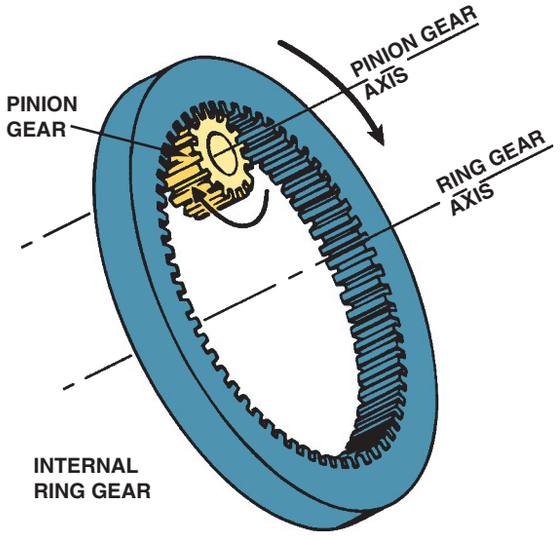

FIGURE 122–4 A pinion gear meshed with an internal ring gear rotates in the same direction around a parallel axis of rotation.

type of gear is the most commonly used in manual transmissions and transaxles.

Gears having teeth along the inside circumference are called **internal ring gears.** ● **SEE FIGURE 122–4.** The teeth of an internal ring gear may be spur or helical teeth. An internal ring gear may mesh with a smaller external gear designed to rotate as it travels around the inside of the internal ring gear. This type of external gear is called a **pinion gear** because of its smaller diameter.

When an external gear meshes with an internal ring gear, both gears rotate in the same direction, but when an external gear meshes with another external gear, the gears rotate in opposite directions as shown in ● **FIGURE 122–5.**

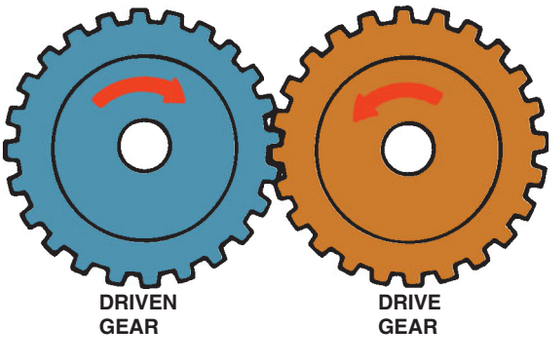

FIGURE 122–5 When two external gears mesh, they rotate in opposite directions.

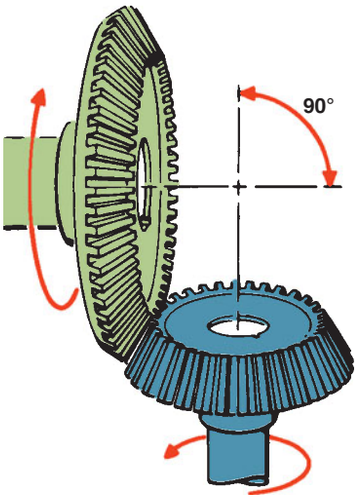

FIGURE 122–6 Bevel gears are often used to change the direction of rotation and are typically used in differentials.

BEVEL GEARS

The teeth of a **bevel gear** are cut at an angle to the outside gear surface. Simple bevel gears have straight-cut teeth similar to those on a spur gear. ● **SEE FIGURE 122–6.** Special gears used in a differential, called spider gears, are a common example of the simple bevel gear.

HYPOID GEARS

Hypoid gear sets have gear teeth that are curved much like the teeth of a spiral bevel gear. The pinion gear is offset below the centerline of the ring gear as shown in ● **FIGURE 122–7.** This design provides maximum gear tooth contact for strength, gradual tooth engagement, and quiet operation. Hypoid gears are generally available only as a matched set.

Hypoid gears are commonly used as the final drive gears in rear axles where load-carrying ability and low noise are important. The offset pinion allows the driveshaft to be positioned lower in the vehicle, reducing the size of the hump in the vehicle's interior.

GEAR RATIOS

When one gear turns another, the speed that the two gears turn in relation to each other is the gear ratio. Gear ratio is expressed as the number of rotations the **drive gear** must make in order to rotate the **driven gear** through one revolution. To obtain a gear ratio, simply

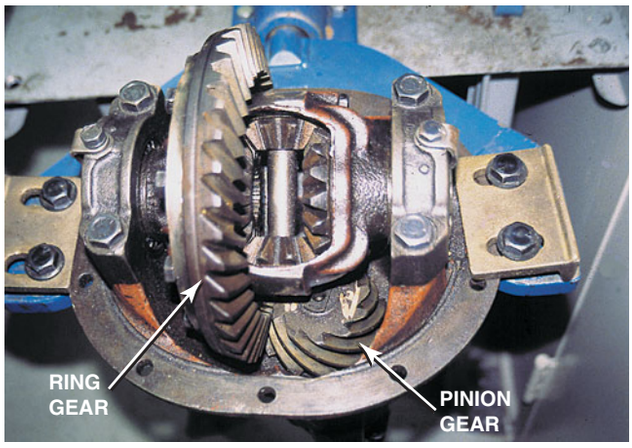

FIGURE 122–7 A differential uses a hypoid gear set to provide a change in the direction of torque and for gear reduction (torque increases) to the drive wheels.

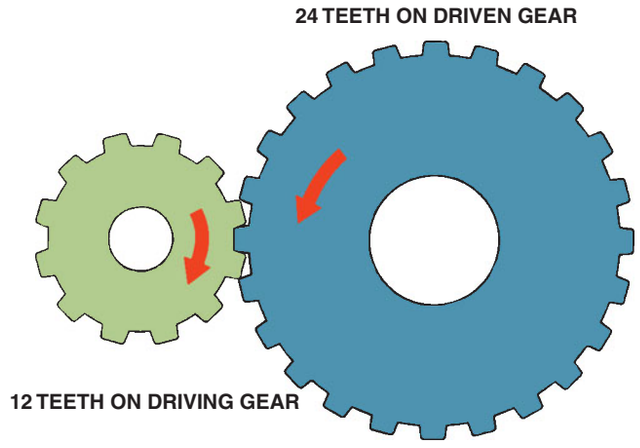

FIGURE 122–8 Gear ratio is determined by dividing the number of teeth of the driven (output) gear (24 teeth) by the number of teeth on the driving (input) gear (12 teeth). The ratio illustrated is 2:1.

divide the number of teeth on the driven gear by the number of teeth on the drive gear. Gear ratios, which are expressed relative to the number one, fall into three categories:

- Direct drive
- Gear reduction
- Overdrive

A gear ratio, is determined by dividing the number of teeth on the driven gear (output) by the number of teeth on the driving gear (input). ● **SEE FIGURE 122–8.**

$$\frac{\text{Number of teeth on the driven gear (24)}}{\text{Number of teeth on the driving gear (12)}} = 2{:}1$$

The gear ratio represents the number of turns of the input gear to one turn of the output gear. A transmission/transaxle usually uses two pairs of gears to achieve each gear ratio, and there may be four, five, or six forward gears plus reverse. When two pairs of gears are used to create a gear, simply multiply the two ratios together to get the gear ratio.

A low first-gear (high numerical) ratio creates a high amount of torque applied to the drive wheels to get the vehicle moving. To summarize what is occurring if the engine speed is constant:

First gear:

- Output shaft speed is a lot lower than engine speed.
- Output torque is a lot higher than the engine is producing.

Fifth gear:

- Output shaft speed is faster than the engine speed.
- Output torque is lower than the engine is producing.

DIRECT DRIVE If two meshed gears are the same size and have the same number of teeth, they will turn at the same speed. Since the drive gear turns once for each revolution of the driven gear, the gear ratio is 1:1; this is called a **direct drive.** When a transmission is in direct drive, the engine and transmission turn at the same speed.

GEAR REDUCTION If one gear drives a second gear that has three times the number of teeth, the smaller drive gear must travel three complete revolutions in order to drive the larger gear through one rotation. ● **SEE FIGURE 122–9.** Divide the number of teeth on the driven gear by the number of teeth on the drive gear and you get a 3:1 gear ratio (pronounced three to one). This type of gear

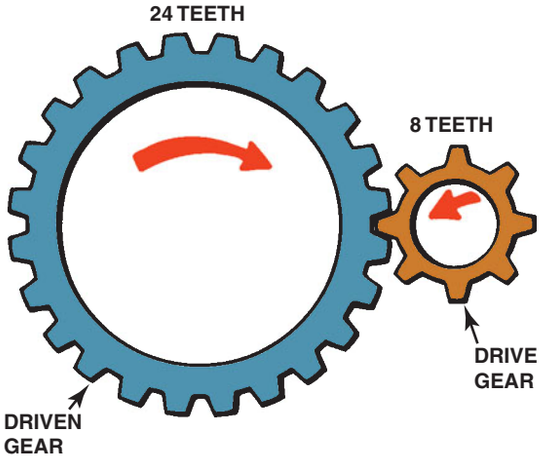

FIGURE 122–9 This gear combination provides a gear reduction of 3:1.

arrangement, where driven gear speed is slower than drive gear speed, provides **gear reduction.** Gear reduction may also be called underdrive as drive speed is less than, or under, driven speed. Both terms mean the same thing and use is a matter of preference.

Gear reduction is used for the lower gears in a transmission. First gear in a transmission is called "low" gear because output speed, not gear ratio, is low. Low gears have numerically high gear ratios. That is, a 3:1 gear ratio is a lower gear than those with a 2:1 or 1:1 gear ratio. These three ratios taken in order represent a typical upshift pattern from low gear (3:1), to second gear (2:1), to third gear (1:1).

OVERDRIVE **Overdrive** is the opposite of a gear reduction condition and occurs when a driven gear turns faster than its drive gear. For the gears shown in ● **FIGURE 122–10,** the driven gear turns three times for each turn of the drive gear. The driven gear is said to overdrive the drive gear. For this example, the gear ratio is 0.33:1. Overdrive ratios of 0.65:1 and 0.70:1 are typical of those used in automotive applications.

NOTE: Ratios always end in one with a colon in between. Therefore, the first number is less than one if it is an overdrive ratio and greater than one if it is a gear reduction ratio.

IDLER GEARS A gear that operates between the drive and driven gears is called a floating gear, or idler gear. ● **SEE FIGURE 122–11.** Idler gears do not affect the speed relationship between the drive

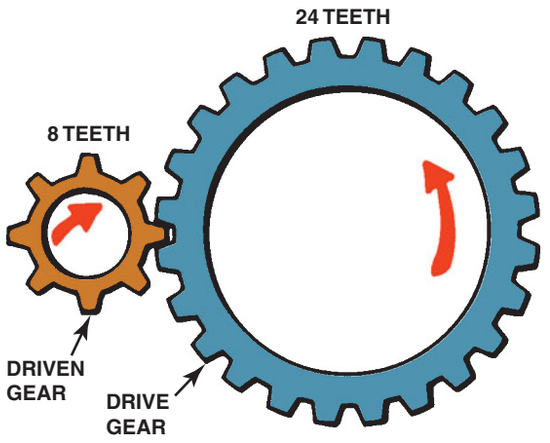

FIGURE 122–10 This gear combination provides an overdrive ratio of 0.33:1.

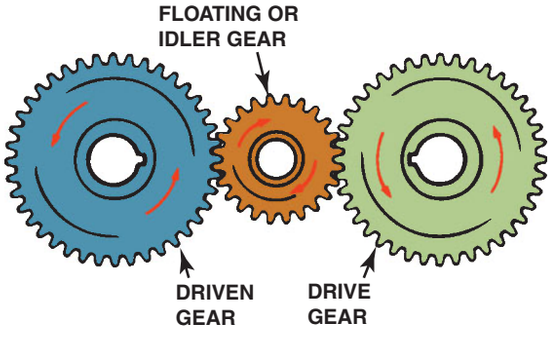

FIGURE 122–11 Idler gears affect the direction of rotation in a gear train, but not the final drive ratio.

and driven gears, although they do affect the direction of rotation. Reverse gear on a manual transmission often uses an idler gear to change the direction of rotation.

When a drive and driven gear mesh directly, they rotate in opposite directions. When an idler gear is installed between the drive and driven gears, both drive and driven gears rotate in the same direction.

TORQUE, SPEED, AND POWER

Torque is a twisting force commonly expressed in pound-feet (lb-ft) or Newton-meters (N-m). Gears apply torque much like a wrench does; each tooth of a gear is actually a lever. On a gear with a 2-foot radius, applying a force of 10 pounds to one gear tooth exerts 20 lb-ft of torque on the center of the shaft to which the gear attaches. ● **SEE FIGURE 122–12.**

TORQUE AND SPEED RELATIONSHIP Torque and speed have an inverse relationship: as one goes up, the other goes down. With a constant input speed, transmission torque decreases as output speed increases. The opposite also applies assuming a constant input speed, transmission torque increases as output speed decreases.

TORQUE MULTIPLICATION Levers can be used to increase or multiply torque. For example, a wheel that is too heavy for a person to turn by muscle power alone turns easily when that same

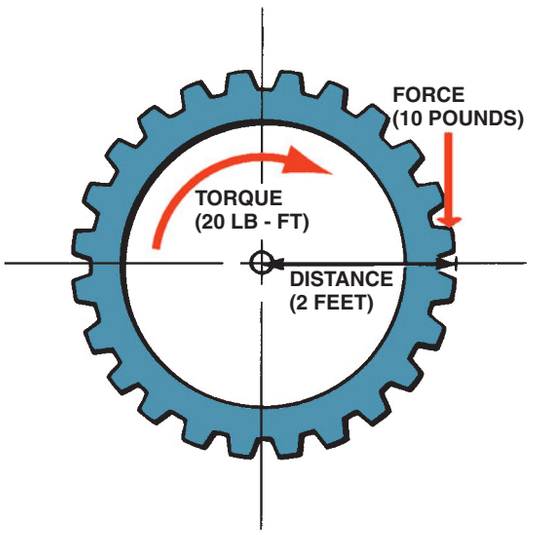

FIGURE 122–12 Gears apply torque in the same way a wrench applies torque—the force applied multiplied by the distance from the center of the gear equals the torque.

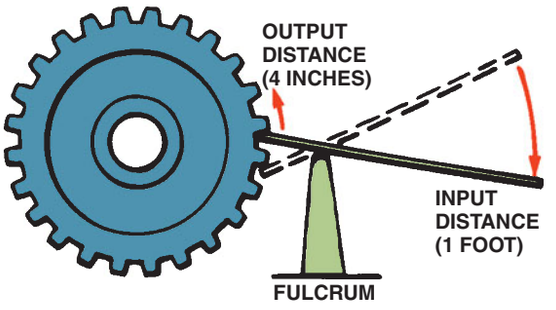

FIGURE 122–13 A lever can be used to multiply torque, but it does so at the expense of distance or speed.

person uses a lever and fulcrum to multiply the applied force. ● **SEE FIGURE 122–13.** The force, or torque, increases at one end, but the lever must be moved a greater distance at the opposite end to obtain the increase in force. Either distance or speed must always be given up in order to increase, or multiply, torque.

When two gears of the same diameter are meshed, the driven gear will turn at the same speed as the drive gear. Since there is no difference in speed, there is no difference in torque between the two gears.

If the drive gear is one-third the diameter of the driven gear, it must rotate three times for each rotation of the larger gear. This means that the larger gear will turn three times slower than the smaller gear. At the same time, the larger gear will exert three times the torque of the smaller gear. When speed decreases, torque increases. Torque multiplication and gear ratios are directly related. When a gear system is in reduction, there is more torque available at the driven gear, but less speed. When the gear system is in overdrive, there is less torque available at the driven gear, but greater speed.

ENGINE TORQUE CHARACTERISTICS The torque curve of an engine shows how much torque is available at different points within a range of engine speeds.

Because of these characteristics, torque multiplication must be provided between the crankshaft and drive axles to enable a vehicle to begin moving from a standstill and to accelerate at low speeds. Once engine RPM rises beyond the torque peak, a change in gear ratio brings engine speed back within the most efficient torque producing range.

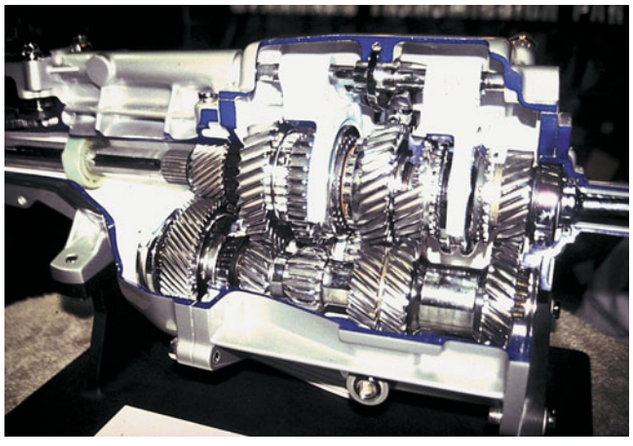

FIGURE 122–15 Cutaway of a six-speed manual transmission showing all of its internal parts.

FREQUENTLY ASKED QUESTION

What Is Meant by a 77 mm Transmission?

The size (77 mm or about 3 inches) is the distance between the center of the input shaft and the center of the countershaft. The greater this distance, the larger the transmission and the more torque it is capable of handling due to the larger gears.

TRANSMISSION CONSTRUCTION

A transmission is usually constructed of cast aluminum machined to accept the internal parts and strong enough to be a structural member of the drive train. The front of the transmission attaches to a separate **bell housing** or includes the bell housing as part of the casting of the transmission itself. At the front of the transmission (toward the engine) is the **front bearing retainer** (sometimes called the **quill**) that supports the clutch throwout (release) bearing and usually houses the front grease seal. The rear of the transmission usually includes a separate casting called the **extension housing.** The center housing is usually referred to as the **transmission case.** ● **SEE FIGURE 122–14.**

The **input shaft** is splined to the clutch disc and is also referred to as the **main gear, clutch gear,** or **main drive pinion assembly.** ● **SEE FIGURE 122–15.** The **main shaft,** also called the **output shaft,** is splined at the end and transmits engine torque to the drive shaft (propeller shaft) through a yoke and universal shaft.

All manual transmissions/transaxles use a **countershaft** (also called a **lay shaft** or **cluster shaft**) to provide the other set of gears necessary to achieve the changes in gear ratios. The gears on the countershaft are called **cluster gears** or **counter gears.**

TORQUE FLOW THROUGH A MANUAL TRANSMISSION

The engine torque is applied to the input shaft when the clutch is engaged (clutch pedal up). This torque is applied to the main gear, which is in constant mesh with the countershaft gear.

HINT: The fact that the countershaft is revolving any time the clutch is engaged makes transmission noise diagnosis easier.

The engine torque is multiplied by the ratio difference between the main gear and the cluster gear. The engine torque is then transferred and multiplied again when first gear is in mesh with the corresponding first gear on the main (output) shaft. Again, the torque is

FIGURE 122–16 Notice that the countershaft and the main shaft both use gears of increasing size that mesh together.

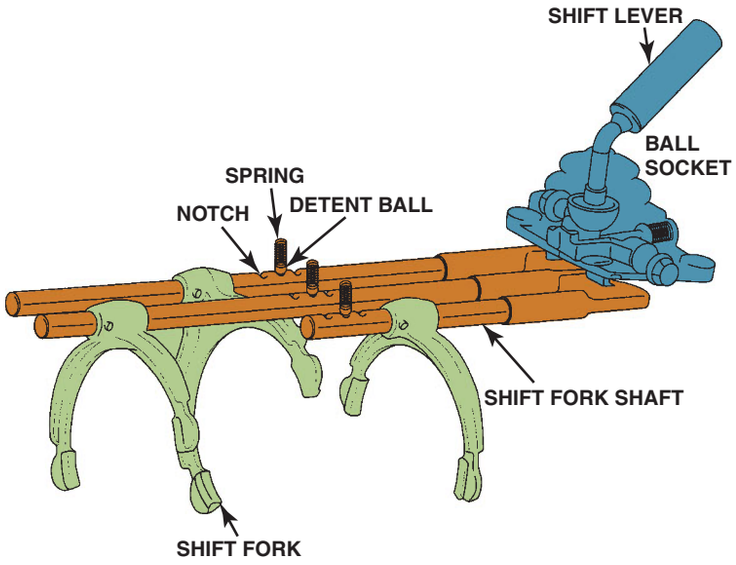

FIGURE 122–17 A typical shift mechanism showing the shift detents designed to not only give the driver a solid feel when shifting but also to prevent two gears from being selected at the same time. The shifter also prevents shifting into reverse except from the neutral position.

multiplied by the ratio difference between the two gears. The engine torque then is applied to the drive wheels through the driveshaft, differential, and drive axles.

SPEED GEARS

All gears on the countershaft are permanently attached to the shaft. When the countershaft rotates, all gears on the countershaft rotate. The input shaft gear is also part of the input shaft. However, the gears on the main shaft are free to move on the shaft and are connected to the main shaft through the synchronizer hub when a shift is made. The gears that rotate on the main shaft are called *speed gears* and are free to rotate on a film of oil or on bearings.

HINT: When assembling the main shaft and the countershaft, just remember that each shaft should look like a Christmas tree (tapered downward from the top). When installed in the transmission, these two "Christmas trees" are meshed together with the small gear end of one shaft meshing with the large gear end of the other shaft. ● SEE FIGURE 122–16.

SYNCHRONIZER PARTS AND OPERATION

Most vehicles today in a manually shifted transmission use a floor-mounted shifter to change gears. The shifting lever either moves cables that transfer the shifting motion to the transmission or transaxle or move the shift forks directly. Inside the transmission/transaxle are shift forks that control shifts between two gears, such as first and second or second and third. Interlocks either in the shifter linkage itself or inside the transmission/transaxle prevent the accidental selection of reverse except when shifting from neutral and also prevent selecting two gears at the same time. ● **SEE FIGURE 122–17.**

Synchronizers are used in manual transmissions/transaxles to make shifting easier. To synchronize means to make two or more events occur at the same time. When the driver depresses the clutch pedal, torque is no longer being transmitted to the input shaft and the drive wheels are "driving" the main shaft of the transmission/transaxle. To achieve a clash-free (no grinding sound) shift, the two gears to be meshed must be rotating at the same speed. The detents and interlocks hold the shift mechanism in position.

The real "shifting" in a synchromesh transmission takes place in the **synchronizer assemblies,** not the gears. Most synchronizer assemblies ride on the output shaft between two gears. A synchronizer assembly is named for the gears on either side of it, which are the two speeds that it engages. For example, a five-speed transmission with constant-mesh reverse uses a 1–2 synchronizer, 3–4 synchronizer, and a 5-reverse synchronizer.

SYNCHRONIZER CONSTRUCTION Although there are a number of design variations, all are similar and include a hub, a **sliding sleeve,** a **stop ring,** (or **blocker rings** or **synchronizer ring**), **keys,** and **springs.** In addition, the tapered cone and coupling teeth machined on the speed gear are part of the synchronizer assembly. ● **SEE FIGURE 122–18.** In a typical synchronizer:

- Splines attach the center **hub** of the synchronizer to the output shaft, so the hub and output shaft rotate together. There are also splines machined on the outer circumference of the hub.
- An outer sliding sleeve rides on the external hub splines with enough clearance so that it slides freely. The splines on the sleeve also match the small coupling teeth of the stop ring and speed gear. Coupling teeth are also called engagement

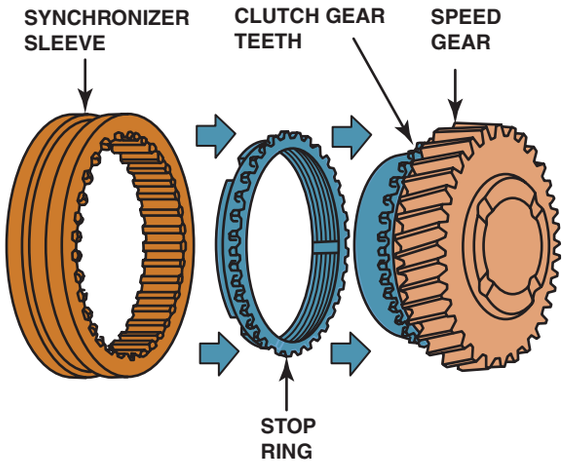

FIGURE 122–18 The shifter fork fits into the groove of the synchronizer sleeve. When a shift is made, the sleeve is moved toward the speed gear. The sleeve presses the stop ring (synchronizer ring) against the cone area of the speed gear. The friction between the stop ring and the speed gear causes the speed of the two to become equal, permitting the sleeve to engage the gear clutch teeth of the speed gear. When this engagement occurs, the shift is complete.

FIGURE 122–19 Typical synchronizer assembly.

or clutch teeth. The sleeve is splined to the hub, so it rotates with the output shaft.

- A **stop ring** sits between the speed gear and the sleeve. The coupling teeth on the stop ring match those on both the sleeve and the speed gear. The stop ring also has a tapered cone to match the cone machined on the speed gear.
- Small, spring-loaded detent keys, also called **synchronizer keys** or **struts,** ride in slots on the outer sleeve. The stop ring has slots to match these keys. This allows the stop ring to rotate slightly, relative to the sleeve, before the keys hit the sides of their slots and stop the stop ring. As the sleeve moves, the synchronizer keys move with it, which pushes the blocking ring onto the tapered cone of the speed gear.

SYNCHRONIZER OPERATION

When the outer sliding sleeve is centered on the hub, the synchronizer is in its neutral position—it does not contact either of the speed gears. ● **SEE FIGURE 122–19.** To shift into gear, the driver disengages the clutch and moves the shift linkage. The shift linkage, which is described later in this chapter, pushes the sleeve toward one of the speed gears. As the sleeve moves, the detent keys help guide the stop ring toward the speed gear. This causes the ring cone to slide onto the tapered cone of the speed gear.

The speed gear is turning because it is in constant mesh with a countershaft gear. However, the gear may not be turning at the same speed as the synchronizer assembly even though both are on the same shaft. When the clutch is disengaged, the engine is no longer driving the transmission, so there is no torque applied to the input shaft, and the countershaft, or cluster gear, simply freewheels. As the shift is made, the stop ring acts as a brake to slow down the gear so that its speed matches the speed of the synchronizer assembly. That is, it synchronizes the shift. This matched speed allows the internal hub splines to easily engage the coupling teeth on the stop ring and speed gear. When the clutch disengages, the crankshaft drives the input shaft, which drives the countershaft, which drives the output shaft through the selected gear.

The synchronizer goes through three stages during a shift:

1. As the shift is selected, the sliding sleeve moves towards the speed gear. If the speeds of the sliding sleeve (main shaft) and the speed gear (counter shaft) are not identical, the speed difference will cause the tapered cone to "mis-align" the teeth of the sleeve, the stop ring, and the speed gear. This "blocks" the shift. Now, the tapered teeth of the sliding sleeve push against the teeth of the stop ring, which in turn pushes the stop ring tapered surface up against the tapered surface of the speed gear. This causes the speed gear to either speed up or slow down based on the difference between the main shaft speed (hub) and the counter gear speed (speed gear). When the speeds are equal, the thrust is released on the tapered surface which now allows the "alignment" of the sliding sleeve teeth, the stop ring teeth and the speed gear teeth which allows the shift to be completed. ● **SEE FIGURE 122–20.**
2. The sleeve overcomes the force of the detent key springs as the shift linkage continues to move it toward the gear. This allows the stop ring to relax and move slightly so that the sleeve splines begin to engage the coupling teeth on the stop ring. At this point, the coupling teeth on the stop ring and the speed gear may not line up with each other. However, friction continues to build between the ring and the cone, so the gear continues to slow down.
3. Once the sleeve, stop ring, and gear are all turning at the same speed, it takes just a small movement between the stop ring and gear to align the coupling teeth and allow the sleeve to slip completely over both sets. The speed gear is now locked to the output shaft through the synchronizer stop ring and sleeve. ● **SEE FIGURE 122–21.**

Synchronizer stop rings are a simple type of clutch, called a cone clutch for the shape of the mating surfaces. Some manufacturers refer to the synchronizer action as "clutching."

Synchronizer sleeves and hubs are gear-quality steel. Stop rings are a softer metal—usually brass, copper, or a sintered metal—to absorb the friction of synchronizer operation. The tapered cone is relieved, that is grooves are machined into its contact surface. These grooves serve two purposes; they

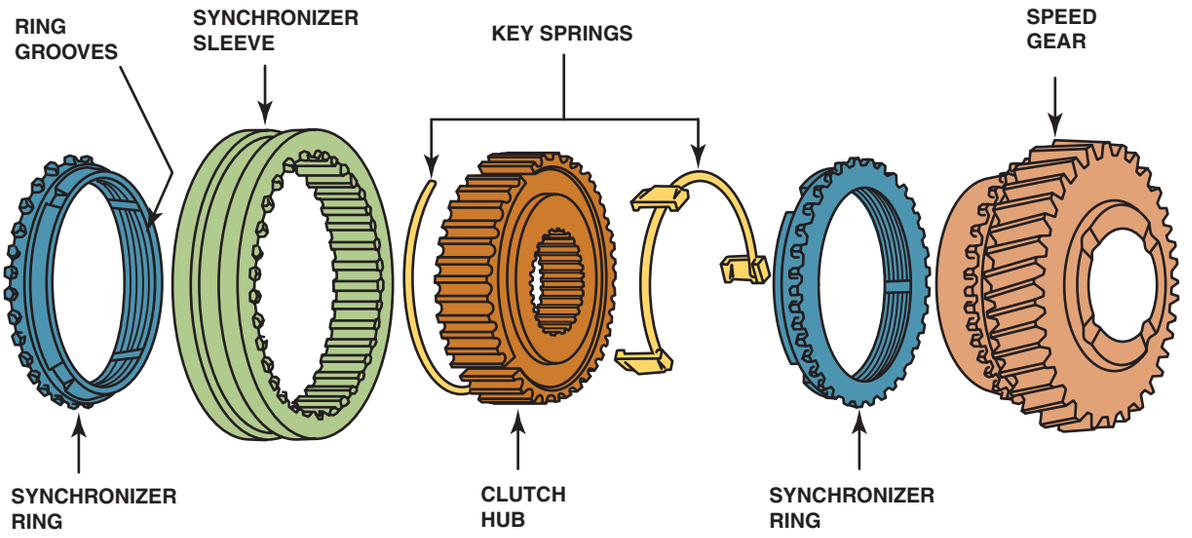

FIGURE 122–20 Synchronizer keys are attached to the clutch hub and push against the synchronizer ring when the sleeve is being moved during a shift. Notice the grooves on the synchronizer ring. These grooves prevent lubricating oil from becoming trapped between the ring and the cone surface of the speed gear. The grooves also help the ring release from the cone surface when a shift is made out of a gear.

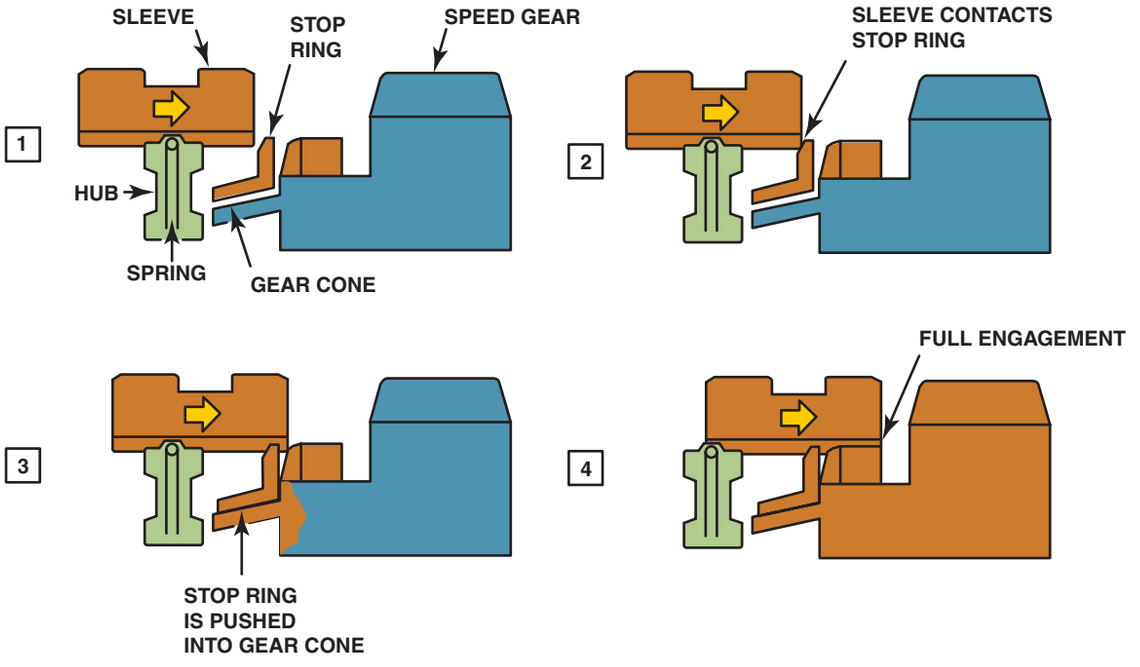

FIGURE 122–21 A shift sequence starts when the shift fork is moved by the driver, (1) applying a force on the sleeve that moves it toward the speed gear. (2) The sleeve and the inserts contact the stop ring (blocking ring). (3) The synchronizer ring (stop ring) engages the cone on the speed gear, causing both assemblies to reach the same speed. (4) The shift is completed when the internal teeth of the sleeve mesh with the gear clutch teeth of the speed gear.

FREQUENTLY ASKED QUESTION

What Do the Keys Do?

The keys are there to limit the amount of rotation of the ring from 1/2 tooth misaligned in the forward direction, to 1/2 tooth misaligned in the "coast" direction so that both upshifts and downshifts can be made. The detent key springs are designed to "push up" on the keys which have a "bump" on them that aligns with a notch in the inside center of the sliding sleeve. This upward pressure tends to keep the sliding sleeve in the neutral position and prevents unwanted movement toward another unwanted gear.

- Channel excess lubricant out from between the two pieces for better contact.
- Retain a small amount of lubricant. This decreases wear when the cone clutch must slip slightly during coupling tooth alignment.

The internal splines on the synchronizer sleeve and the coupling gear teeth on stop rings and speed gears have a special shape that works to hold the gear engaged once the driver releases the shift lever. The ends of the gear teeth are chamfered, giving them a triangular shape. These pointed ends allow easier sleeve-to-gear alignment as the angles tend to center the splines between the teeth.

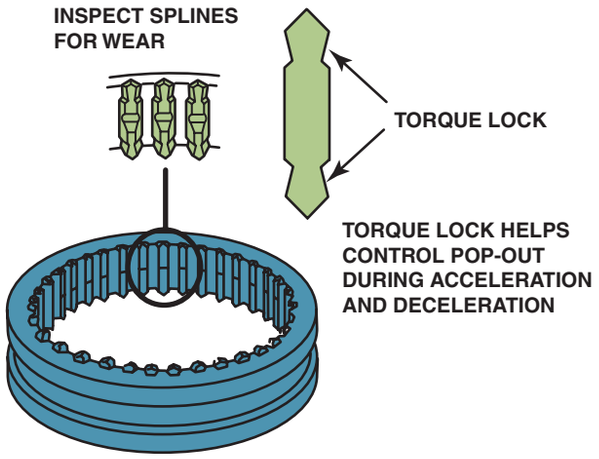

FIGURE 122–22 Before reassembling the transmission/transaxle, carefully inspect the splines on the synchronizer sleeves for wear. The shape of the splines helps prevent the transmission/transaxle from jumping out of gear during acceleration and deceleration.

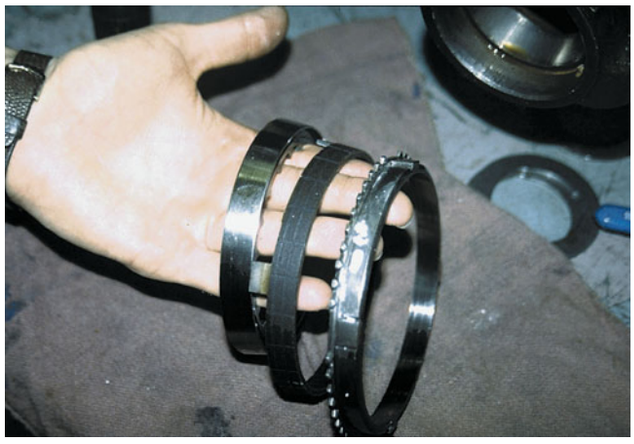

FIGURE 122–23 A three-piece synchronizer assembly. This type of synchronizer uses two cones, which helps achieve a smooth shift with less driver effort. Many newer transmissions/transaxles use a paper lining similar to that of the clutches in an automatic transmission. The transmissions/transaxles that have these paper linings must use automatic transmission fluid (ATF) for proper operation and long life.

Once aligned, a back taper machined behind the chamfered end of the teeth and splines tends to keep the sleeve in place until the linkage pushes the sleeve away for another shift. **Back taper** is an angle cut opposite to the chamfer so that spline or tooth narrows just behind the chamfered end. ● **SEE FIGURE 122–22.** The back taper creates resistance to motion to keep the splines from sliding off the coupling teeth. This is especially important when there is no torque load, such as coasting, to help keep the parts meshed. Worn back taper may cause the transmission to jump out of gear, usually when the throttle is released.

Some synchronizer stop rings have friction material on the cone surface. This paper friction material is the same as used on automatic transmission clutch plates, and provides a smoother synchronizing action than metal-to-metal contact. A manual transmission with paper stop rings must use automatic transmission fluid (ATF). Other lubricants damage the paper ring surface. ● **SEE FIGURE 122–23.**

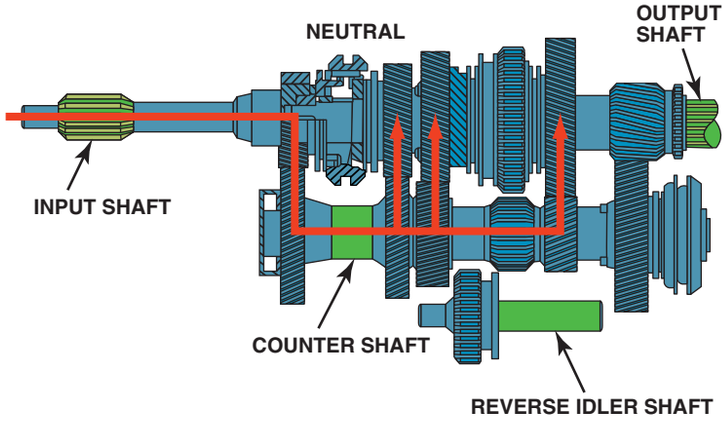

FIGURE 122–24 In neutral, the input shaft and the countershaft are rotating if the clutch is engaged (clutch pedal up), but no torque is being transmitted through the transmission.

FIVE-SPEED TRANSMISSION TORQUE FLOW

This section describes how power is transmitted through a typical five-speed transmission. Although minor differences exist among different designs, the basic pattern of torque flow, also called power flow, is similar for most gearboxes. The concept of torque flow, or torque transfer, is the same for any transmission, regardless of the number of gear ratios available. The differences are in how the parts assemble and where they are located in the transmission.

FIVE-SPEED TRANSMISSION A five-speed transmission has six gear sets that provide five forward speeds and one reverse speed. Either a sliding gear or constant-mesh gears may be used for reverse. All forward gears are the constant-mesh type. The Borg-Warner T5 manual transmission serves as an example of a contemporary five-speed design. In addition to reverse, the T5 provides three gear reduction ratios (first, second, and third), direct drive (fourth), and an overdriven ratio (fifth). A sliding idler gear is used to change output shaft direction and provide reverse.

NEUTRAL. In **neutral,** all of the synchronizer sleeves are centered on their hubs as shown in ● **FIGURE 122–24.** Note that in this and the following illustrations the reverse idler shaft and sliding gear have been repositioned for clarity. In actuality, the assembly is positioned so it meshes with the reverse gears of the countershaft and output shaft simultaneously.

With the clutch engaged, the drive gear of the input shaft turns the cluster gear, or countershaft. The speed gears are driven by the cluster gears, but rotate freely, on the output shaft. The output shaft may turn if the vehicle is moving or coasting, but no engine torque being transferred through the transmission.

FIRST GEAR. In **first gear,** the shift linkage slides the 1–2 synchronizer sleeve rearward toward the first speed gear. ● **SEE FIGURE 122–25.** The synchronizer assembly locks the speed gear to the output shaft.

With the clutch engaged, the input shaft drives the countershaft, delivering engine torque to the gearbox. Torque transfers from the first counter gear to the first speed gear, which drives the output shaft through the 1–2 synchronizer hub splines. Torque flows through the transmission in gear reduction at the first gear ratio.

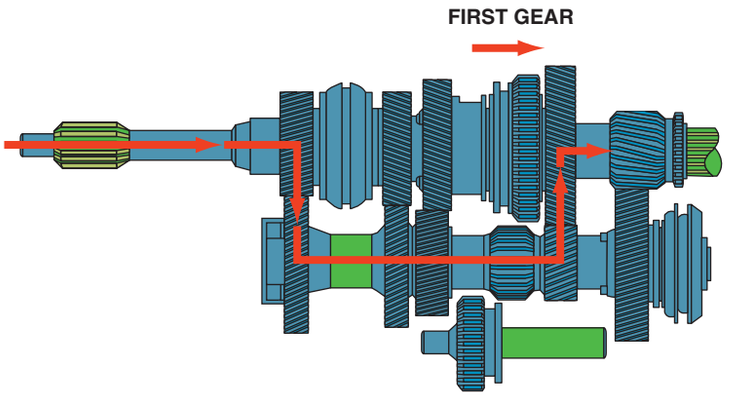

FIGURE 122–25 In first gear, the 1–2 synchronizer sleeve is moved rearward, locking the first speed gear to the output shaft. Torque is transmitted from the input shaft to the countershaft and then to the output shaft.

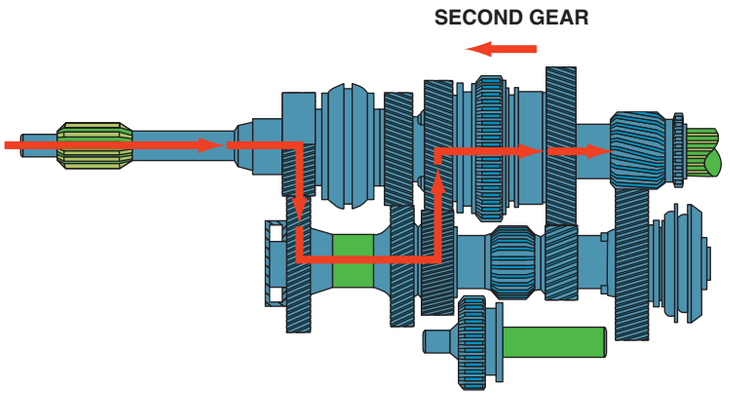

FIGURE 122–26 In second gear, the 1–2 synchronizer sleeve is moved forward, which locks the second speed gear to the output shaft.

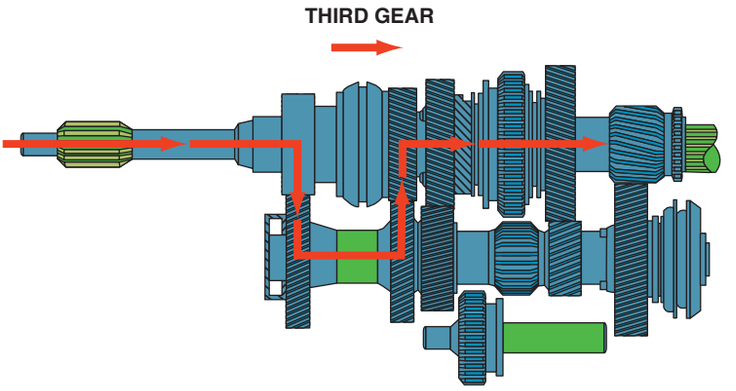

FIGURE 122–27 To achieve third gear, the shaft linkage first centers the 1–2 synchronizer sleeve and then moves the 3–4 synchronizer sleeve rearward, locking third speed gear to the output shaft.

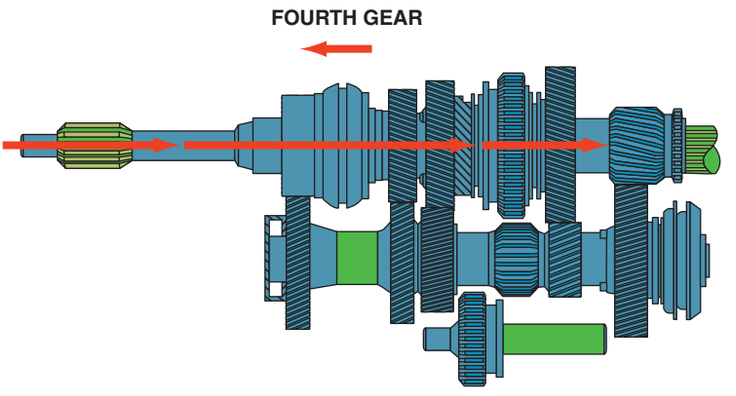

FIGURE 122–28 In fourth gear, the 3–4 synchronizer sleeve is moved forward, which locks the fourth speed gear to the output shaft.

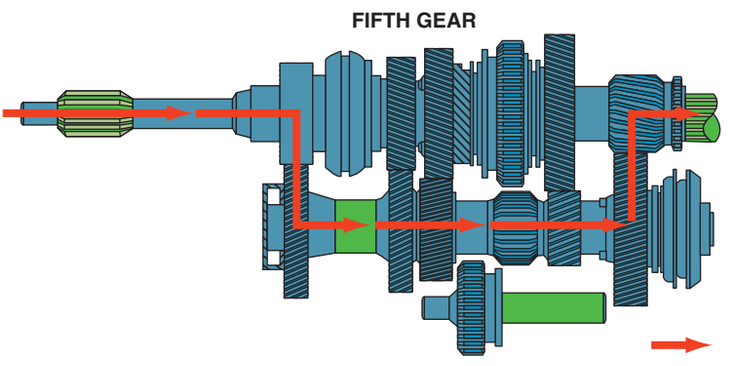

FIGURE 122–29 To achieve fifth gear, the shift linkage first centers the 3–4 synchronizer sleeve and then moves the fifth synchronizer sleeve toward the fifth speed gear, locking it to the output shaft.

SECOND GEAR. In **second gear,** the shift linkage slides the 1–2 synchronizer sleeve forward, away from the first speed gear and toward the second speed gear. ● **SEE FIGURE 122–26.** The synchronizer assembly releases first gear, then locks the second speed gear to the output shaft.

With the clutch engaged, the input shaft is driven at crankshaft speed and turns the countershaft. Engine torque transfers from the second counter gear to the second speed gear, which drives the output shaft through the 1–2 synchronizer hub splines. Torque flows through the transmission in gear reduction at the second gear ratio.

THIRD GEAR. In **third gear,** the shift linkage centers the 1–2 synchronizer sleeve and moves the 3–4 synchronizer sleeve back toward the third speed gear. ● **SEE FIGURE 122–27.** The synchronizer assembly locks the third speed gear to the output shaft.

With the clutch engaged and the input shaft driving the countershaft, the third counter gear transfers torque to the third speed gear. The speed gear drives the output shaft through the 3–4 synchronizer hub splines. Torque flows through the transmission in gear reduction at the third gear ratio.

FOURTH GEAR. In **fourth gear,** the shift linkage moves the 3–4 synchronizer sleeve forward, away from the third speed gear and toward the input shaft drive gear. ● **SEE FIGURE 122–28.** The synchronizer assembly locks the input shaft drive gear to the output shaft.

With the clutch engaged, the input shaft drives the output shaft through the 3–4 synchronizer hub splines and both shafts rotate at crankshaft speed. Torque flows straight through the transmission at a 1:1 ratio, delivering engine torque to the drive shaft. This is called direct drive because there is no gear reduction through the transmission. The counter gears also turn because they are in constant mesh, but they do not affect torque flow because all of the speed gears are freewheeling on the output shaft.

FIFTH GEAR. In **fifth gear,** the shift linkage centers the 3–4 synchronizer sleeve and moves the fifth synchronizer sleeve toward the fifth speed gear. ● **SEE FIGURE 122–29.** Note that on the T5 transmission

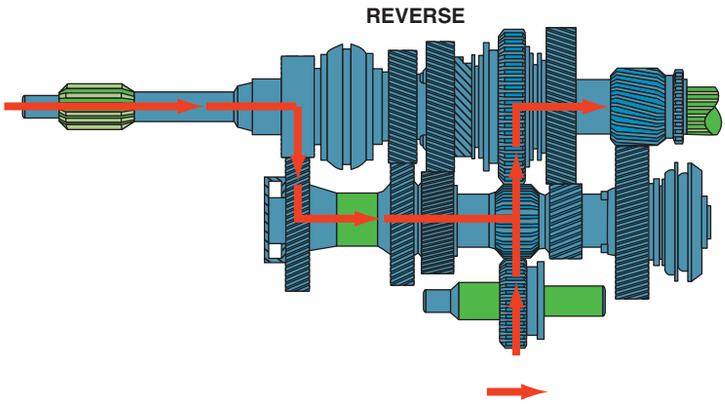

FIGURE 122–30 Torque flows through the transmission in reverse gear. Note that the idler gear drives the 1–2 synchronizer sleeve gear, which is splined to the output shaft.

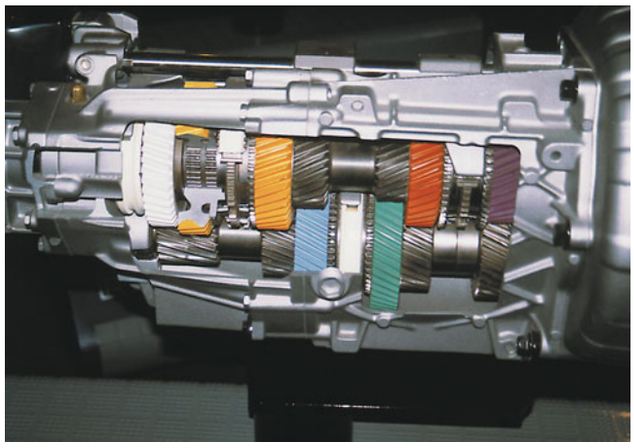

FIGURE 122–31 Cutaway of a T56 six-speed transmission showing all of its internal parts.

the synchronizer assembly locks the fifth speed gear to the countershaft. The speed gear drives a fixed gear on the output shaft.

With the clutch engaged, the input shaft drives the countershaft. The fifth synchronizer hub is splined to the countershaft, so it is driven and driving the fifth speed gear when fifth gear is engaged. This transfers engine torque to the output shaft through the fixed fifth gear. Note the countershaft gear is larger than the output shaft gear. Therefore, fifth gear is overdriven. Torque flows through the transmission at the fifth gear, or overdrive, ratio. Typical overdrive gear ratios are between 0.6:1 and 0.8:1. This lowers engine speed for economical highway cruising.

On some five-speed transmissions, the fifth speed gear is on the output shaft with the other speed gears. This type of arrangement is typically used with constant-mesh reverse gears. In these designs, fifth and reverse gears share a synchronizer assembly. The fixed countershaft gear drives the speed gear, which drives the output shaft through the hub splines when the sliding sleeve is engaged. Torque flow through the transmission is similar to any of the gear reduction forward speeds detailed above, but the fifth speed gear is generally overdriven.

REVERSE. There are two common **reverse** gear designs used on transmissions:

1. Sliding gear.
2. Constant-mesh gear.

With a **sliding reverse gear** design, such as on the Borg-Warner T5, the shift linkage slides the reverse idler gear on its shaft until it engages the reverse gears on the countershaft and output shaft gear. Both gears are fixed to their respective shafts. This design uses spur gears for reverse, not helical gears, because the gear teeth must move into and out of mesh. On some gearboxes, the sliding gear splines to the output shaft. The linkage moves the gear along the output shaft splines to engage the reverse idler gear.

An unusual feature of the Borg-Warner T5 is that it does not have a separate reverse output shaft gear. ● **SEE FIGURE 122–30.** Instead, spur teeth machined around the outside of the 1–2 synchronizer sleeve act as the reverse output gear. When the T5 is shifted into reverse, the linkage moves the reverse idler gear rearward so it simultaneously meshes with the countershaft reverse gear and the gear on the synchronizer sleeve.

When the clutch is engaged, the countershaft is driven and the reverse gear drives the idler gear, which rotates in the opposite direction of the countershaft. The idler gear drives the 1–2 synchronizer sleeve, so there is another directional change in rotation. Although the sleeve is not engaged to a speed gear, it remains splined to the output shaft, so the sleeve drives the output shaft when the idler gear is engaged. The output shaft rotates in the opposite direction of the input shaft because the idler gear is between them.

With **constant-mesh gears,** the shift linkage moves the 5-reverse synchronizer sleeve away from the fifth speed gear and toward the reverse speed gear when reverse is selected. Typically, no stop ring is used between the synchronizer sleeve and the reverse gear, so the output shaft must be stopped to engage reverse without grinding the sleeve splines against the coupling teeth of the reverse gear. The synchronizer assembly locks the reverse speed gear to the output shaft.

With the clutch engaged, the input shaft drives the countershaft. The reverse counter gear drives the reverse idler gear, which drives the reverse speed gear in the direction opposite normal rotation. The reverse speed gear drives the output shaft through the 5-reverse synchronizer hub splines. Torque flows through the transmission in gear reduction at the reverse gear ratio. The output shaft turns opposite its normal direction of rotation, so the vehicle moves to the rear. ● **SEE FIGURE 122–31.**

MANUAL TRANSAXLE CONSTRUCTION

A manually shifted transaxle includes an input shaft, an output shaft, and a differential assembly all in one case. The input shaft is attached to the clutch, which transfers engine torque from the engine flywheel to the input shaft when the clutch is engaged. Most transaxles use speed gears and synchronizers on both the input and output shafts, as shown in ● **FIGURE 122–32.** The differential assembly, also called a **final drive assembly,** attaches to the output shaft and splits the torque to both front drive axles. ● **SEE FIGURE 122–33.**

TRANSMISSION/ TRANSAXLE REMOVAL

Before removing the transmission/transaxle for service, double-check that the problem is not due to any malfunction of the clutch or shift linkage. To remove a transmission or transaxle, always follow

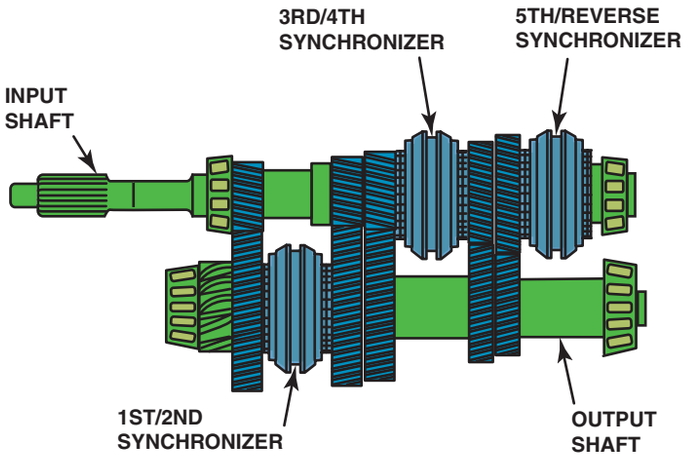

FIGURE 122–32 Notice that this five-speed transaxle from a Dodge/Plymouth Neon uses synchronizers on both the input and output shafts.

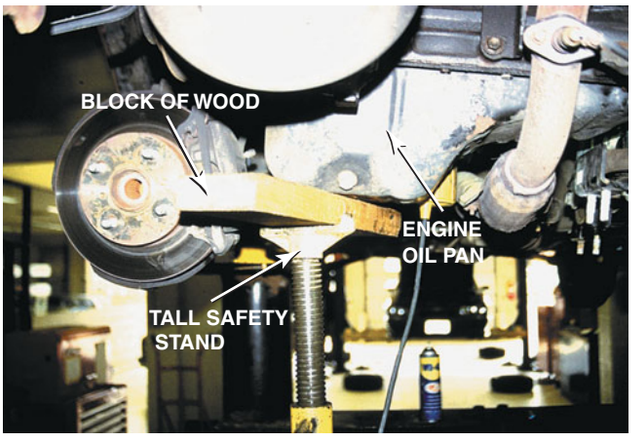

FIGURE 122–34 When the transmission/transaxle is removed from the vehicle, the engine must be supported. In this case, the engine oil pan is supported with a block of wood to spread the load across the entire oil pan to prevent damage. The block of wood is placed on top of a tall safety stand that allows room for the service technician to work while standing.

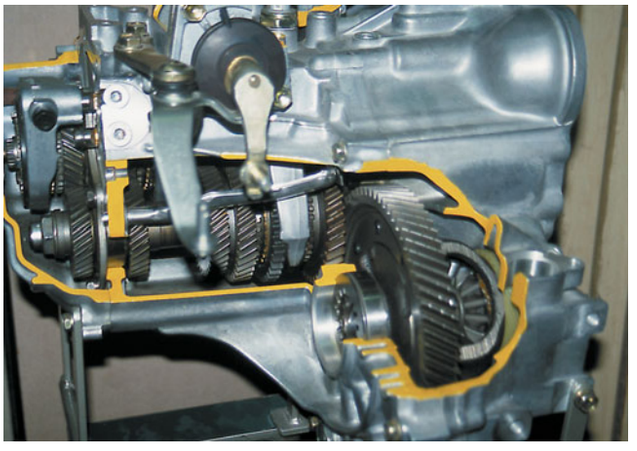

FIGURE 122–33 Cutaway of a typical manual transaxle showing all of its internal parts including the final drive assembly.

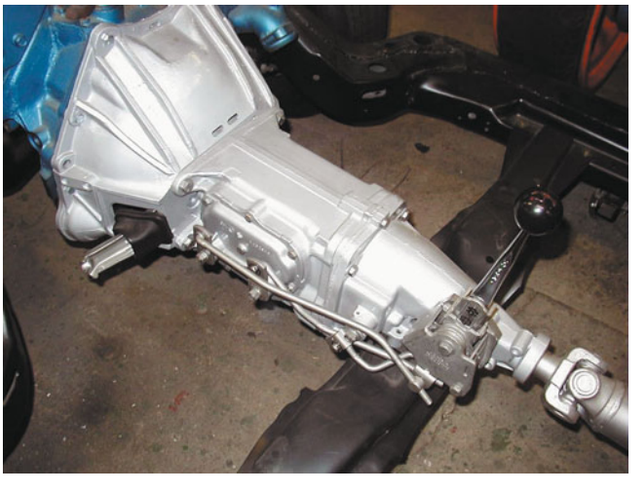

FIGURE 122–35 A transmission from a restored muscle car from the 1970s. Notice the use of external control rod shift linkage.

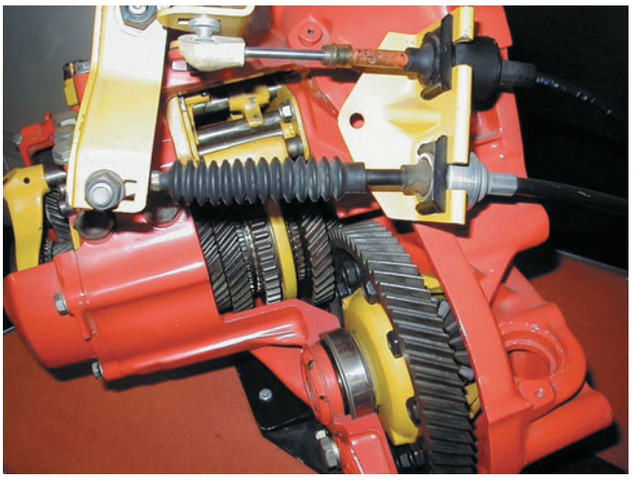
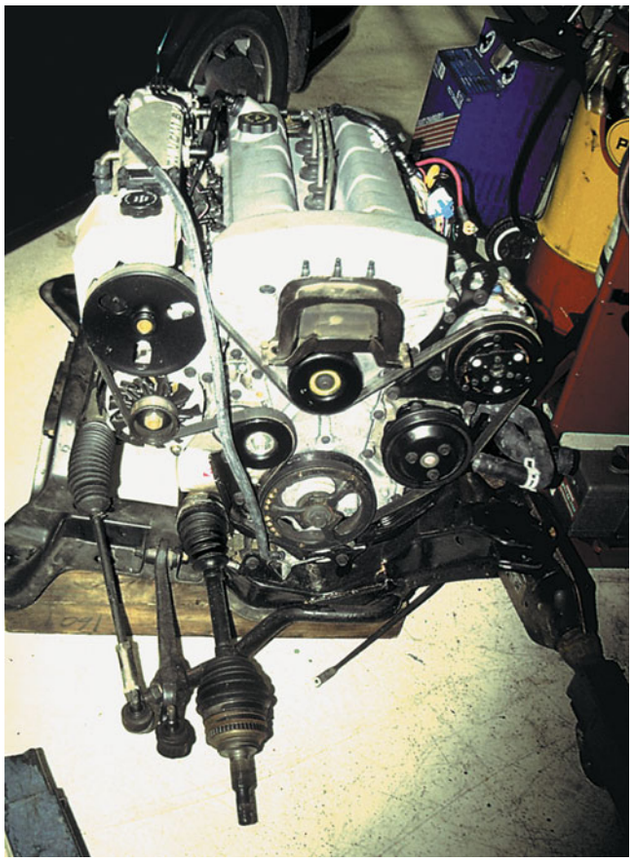
the procedure in the service manual to be assured of doing no harm to either the vehicle or to yourself. Steps typically involved in the removal and disassembly include

- Disconnecting the negative battery cable
- Safely hoisting and supporting the vehicle
- Supporting the engine with a holding fixture or other support (front-wheel-drive). ● **SEE FIGURE 122–34.**
- Removing the drive axle shafts or drive shaft (rear-wheel-drive)
- Removing the clutch linkage and shift linkage. ● **SEE FIGURES 122–35 AND 122–36.**
- Disconnecting the vehicle speed sensor and reverse (backup) light connectors
- Removing the attaching bolts/nuts from the engine and transmission/transaxle mounts and then removing the unit from the vehicle

Sometimes it is easier to remove the entire power train (engine and transaxle as an assembly) from the vehicle, as shown in ● **FIGURE 122–37.** When the entire assembly has been removed from the vehicle, often the transaxle can then be removed from the engine.





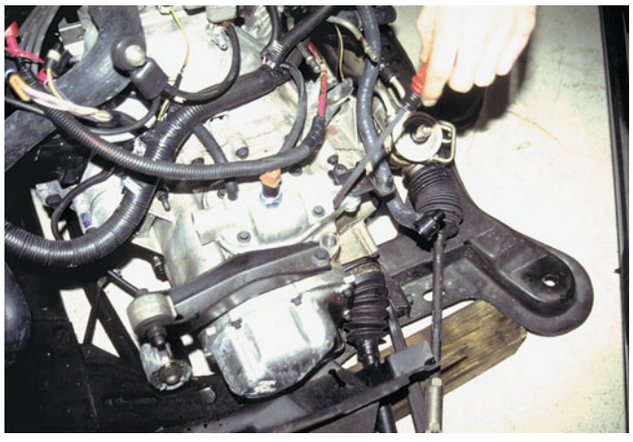


FIGURE 122–36 Typical cable-operated shift linkage used on a front-wheel-drive transaxle.

(a)

(b)

FIGURE 122–37 (a) Saturn drive train is removed as an assembly along with the cradle. (b) The transaxle can now be easily removed from the cradle and the engine.

TRANSMISSION/ TRANSAXLE DISASSEMBLY

Before disassembling the transmission/transaxle, drain any remaining gear lubricant from the unit and dispose of it properly.

CAUTION: Most extreme pressure (EP) lubricants contain sulfur compounds that can cause skin irritation. Either wear protective gloves or wash your hands thoroughly using soap and water after exposure to used gear lubricant.

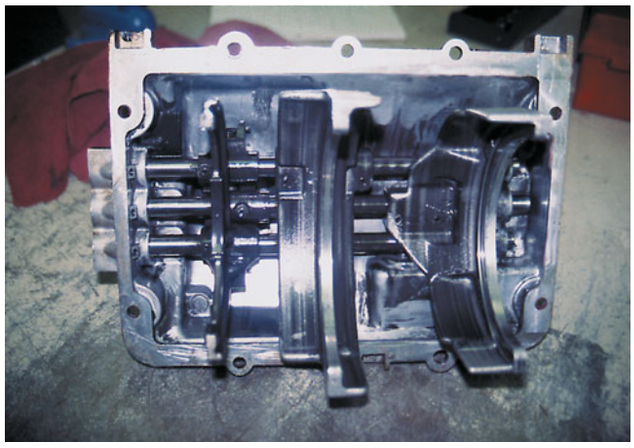

FIGURE 122–38 The shift forks should be inspected for wear.

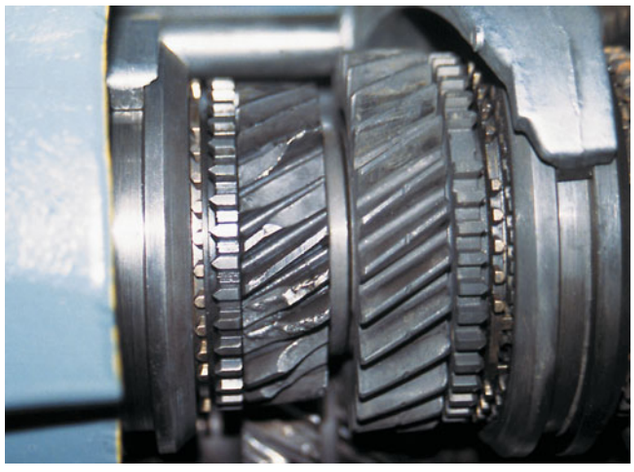

FIGURE 122–39 The cost to replace these gears may exceed the cost of a replacement transmission.

TECH TIP

Manual Transmission Service Tips

A wise technician once told a beginning technician to remember these items when working with transmissions:

- Always use a *brass* or *plastic* hammer when pounding on a steel or aluminum component.
- If using a steel hammer, always use a *brass* or *aluminum* punch or place wood between the steel components and the hammer.
- Many parts can be installed in either direction but usually only one way is correct.
- If you are exerting a lot of force, you are probably doing something wrong.
- Many drive train parts are pulled or pressed off and pressed or driven on.

Mount the transmission/transaxle on a holding fixture or place it on a large, clean work surface. Many vehicle manufacturers recommend removing the shift housing before further disassembly. The removal of the shifter housing allows the technician to see any obvious damage as well as providing the opportunity to check the shift forks, which are frequently worn in manually-shifted transmissions/transaxles. ● **SEE FIGURES 122–38 AND 122–39.**

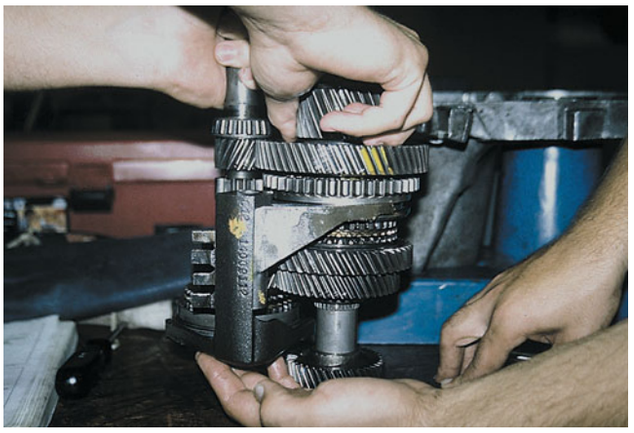

FIGURE 122–40 It often requires two people to assemble a transaxle because the shaft with the shifter forks needs to be placed into the case as an assembly, as on this unit.

The disassembly and reassembly of a manual transaxle is similar to that for a manual transmission except for the addition of the final drive unit. Some transaxles require two people for disassembly and reassembly because often the shift linkage has to be held in place while assembled components are placed into the case, as shown in ● **FIGURE 122–40.**

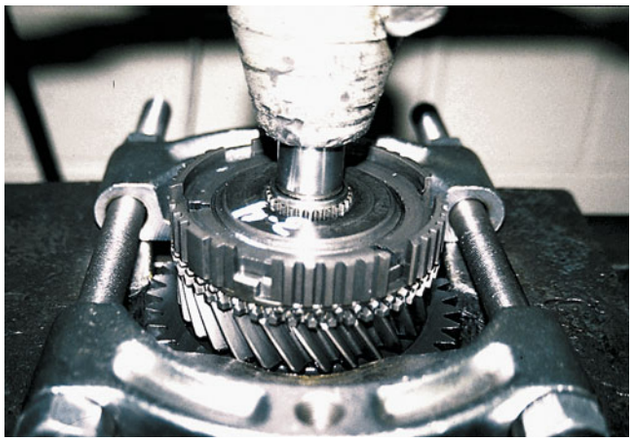
Check the service manual for the exact disassembly procedures to follow for the unit being serviced. Sometimes the main shaft is removed through the rear of the transmission and sometimes it is removed through the top of the case. Also look for hidden snap rings. ● **SEE FIGURES 122–41 AND 122–42.** Also see the Tech Tip titled "Manual Transmission Service Tips."

HARD-TO-SHIFT PROBLEM DIAGNOSIS

Several items that could be worn or defective can cause a manual transmission/transaxle to be difficult to shift, including

- **Clutch not fully disengaging.** If the clutch linkage is not properly adjusted or if there is a leak in the hydraulic clutch linkage, the clutch may not be fully disengaged. A shift is very difficult, if not impossible, if engine torque is being transferred through the transmission/transaxle as a shift is being attempted.
- **Worn synchronizer.** If the synchronizer rings are worn, the rings will be unable to properly match the speed gear speed, making the shift difficult and/or creating gear clash (noise) when shifting.
- **Worn, cracked, or loose shift forks.** If there is any problem with the shift forks, the synchronizer cannot be properly moved during a shift attempt, making shifting difficult, if not impossible. If only one fork is worn or defective, usually engaging two gears instead of one is likely.
- **Excessive input- or main-shaft end play.** Excessive end play in the input or main shaft will cause the gears to move away from the synchronizer assembly, resulting in grinding during shifts or shifts that are difficult or impossible to complete.

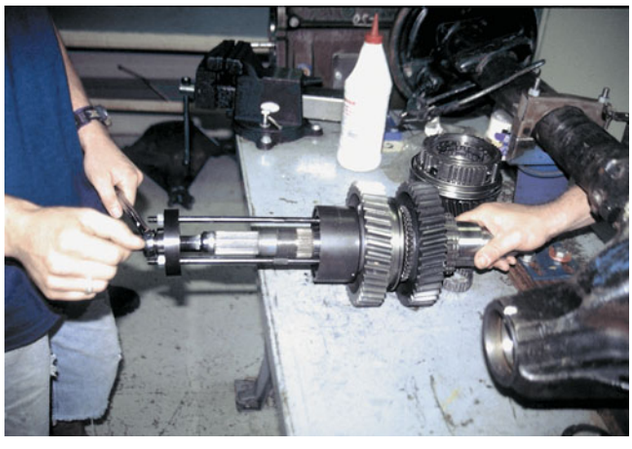
(a)



(b)

(c)

FIGURE 122–41 (a) During the disassembly of any manual transmission/transaxle, carefully check for the location of the snap rings. Often they are hidden. Consult the factory service manual or unit repair manual for information and procedures for the unit being serviced. (b) Using snap-ring pliers to remove a snap ring. Many snap rings have an "up" side. Be sure to reinstall any snap rings in the correct direction. (c) After the snap ring is removed, some components can be simply lifted off the main shaft, while other gears may require the use of a press.



- **Improper lubrication.** Many of today's manual transmissions use synchronizer rings (blocking rings) that are lined with compounds, paper, or other friction material. All of these transmissions/transaxles must be filled with the proper fluid formulated for proper shifting.

(a)

(b)

(c)

FIGURE 122–42 (a) Many gears require that a hydraulic press be used to separate the gear(s) from the shaft. After double-checking that all snap ring retainers have been removed and after checking in the service manual to see which gear needs to be pressed off, carefully position the "bearing splitter" as far inward as possible to avoid damaging the teeth during the pressing operation. (b) For safety, place an old brake drum over the gear(s) being pressed off. If the gear were to shatter, the parts will be trapped inside the brake drum. (c) Some transmission disassembly and reassembly procedures require the use of special pullers, such as this tool being used on a NV 4500 transmission.

REAL WORLD FIX

The Worn Shift Fork Mystery

A vehicle equipped with a manual transmission had to be repaired several times for worn shift forks. Even though the vehicle warranty paid for the repair, both the customer and the service department personnel were concerned about the repeated failures. All technical service bulletins (TSBs) were checked to see if there was an updated, improved shift fork. No luck. Even the manufacturer's technical assistance personnel were unable to determine why the shift forks were wearing out. After the third repair, the service technician rode with the customer to see if the cause could be determined. As the woman driver got into the driver's seat, she placed the handle of her purse over the shifter on the floor and allowed the purse to hang from the shifter. The technician asked the owner if she always placed her purse on the shifter and when she said yes, the technician knew immediately the cause of the worn shift forks. The purse exerted a force on the shifter all the time. This force pushed the shift forks against the synchronizer sleeve. Because the sleeve rotates all the time the vehicle is in motion, the shift forks were quickly worn. The service technician should have determined the root cause of the problem after the *first* repair. The customer agreed to find another location for her purse so that the transmission problem would not reoccur.

NOTE: A worn synchronizer sleeve and/or blocking ring can cause the transmission/transaxle to pop out of gear while accelerating or decelerating.

MANUAL TRANSMISSION INSTALLATION

When installing a repaired or replacement transmission/transaxle, the clutch should be carefully inspected and replaced as necessary. The clutch friction disc must be held in position using an alignment tool (sometimes called a *dummy shaft*) that is secured in the pilot bearing. This holds the disc in position while the pressure plate is being installed. Finally, the engine bell housing is put on the engine, if it was not installed before. The alignment of this type of bell housing is then checked.

CAUTION: Perfectly round cylinders can be distorted whenever another part of the engine is bolted and torqued to the engine block. For example, it has been determined that after the cylinders are machined, the rear cylinder bore can be distorted as much as 0.006 inch (0.15 millimeter) out-of-round after the bell housing is bolted onto the block! To help prevent this distortion, always apply the specified torque to all fasteners going into the engine block and tighten in the recommended sequence.

The clutch release yoke should be checked for free movement. Usually, the clutch release bearing is replaced, ensuring that the new bearing is securely attached to the clutch release yoke. The transmission can then be installed.

The transmission clutch shaft must be guided straight into the clutch disc and pilot bearing. See the Tech Tip "The Headless Bolt Trick." The transmission clutch shaft is rotated, as required, to engage in the splines of the clutch disc. The assembly bolts are secured when the transmission fully mates with the bell housing.

CAUTION: Always adjust the clutch free play *before* starting the engine to help prevent thrust bearing damage.

Complete the installation by attaching the transmission/transaxle mount, driveshaft (drive axle shafts), vehicle speed sensor, and reverse (backup) light switch.

GEAR LUBRICATION

After the installation of the transmission/transaxle, the unit should be filled with the correct lubricant. The various lubricants, their general use, and their American Petroleum Institute (API) rating include

GL-1 Straight mineral oil

GL-2 Worm-type gear lubricant

GL-3 Mild-type EP lubricant (will not protect hypoid gears)

GL-4 EP-type lubricant (okay for manual transmissions/transaxles)

GL-5 EP-type okay for hypoid gears and for Mil-L2150B (military)

FIGURE 122–43 Some manual transmissions/transaxles require synchromesh transmission fluid.

Manual transmissions/transaxles require one of the following lubricants:

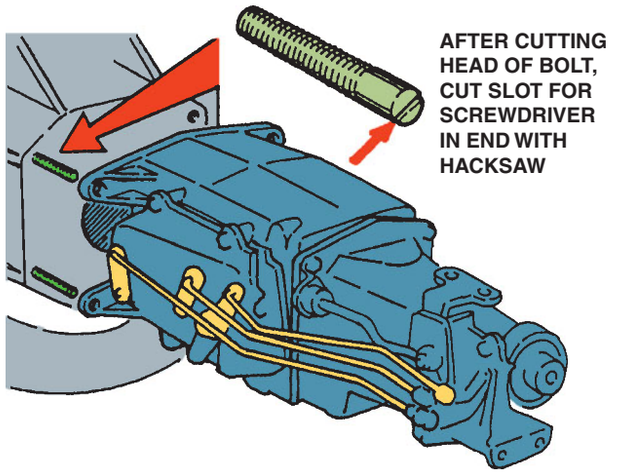
- SAE 80W-90 (GL-4) gear lube
- STF (synchromesh transmission fluid), but with friction characteristics designed for manual transmissions. ● **SEE FIGURE 122–43.**
- ATF (automatic transmission fluid)
- Engine oil (usually SAE 5W-30)

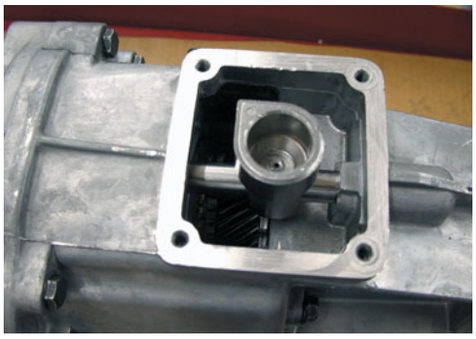
CAUTION: Failure to use the specified manual transmission/transaxle lubricant could cause hard shifting and possible severe transmission damage.

TECH TIP

The Headless Bolt Trick

Sometimes parts do not seem to line up correctly. Try this tip the next time. Cut the head off extra-long bolts that are of the same diameter and thread as those being used to retain the part, such as a transmission. ● **SEE FIGURE 122–44.** Use a hacksaw to cut a slot in the end of these guide bolts for a screwdriver slot. Install the guide bolts; then install the transmission. Use a straight-blade screwdriver to remove the guide bolts after securing the transmission with the retaining bolts.





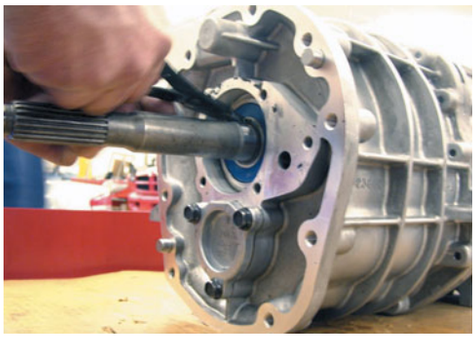


FIGURE 122–44 Headless, long bolts can be used to help install a transmission to the engine.

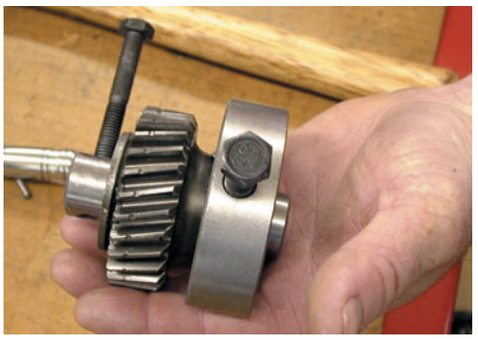
1 A NV-1500 five-speed manual transmission is used in two-wheel drive applications only.

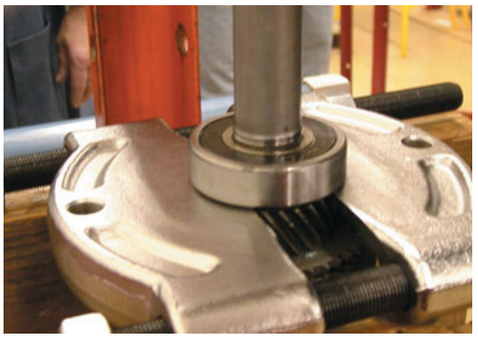
2 The shifter assembly has been removed. Note the roll pin in the center of the shift lever socket.

3 Snap-ring pliers are being used to remove the snap ring retaining the input shaft bearing.

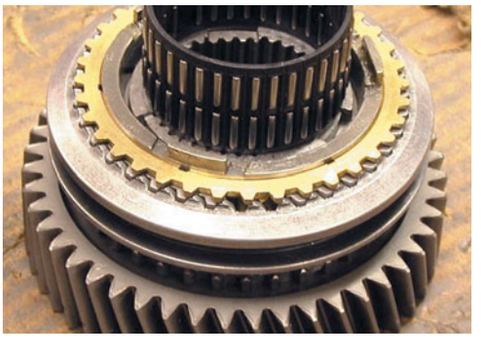


4 The upside down case is being separated showing the countershaft (top) and shift forks.

5 Before further disassembly can be accomplished, the shift lever socket roll pin must be driven out using a punch and a hammer.

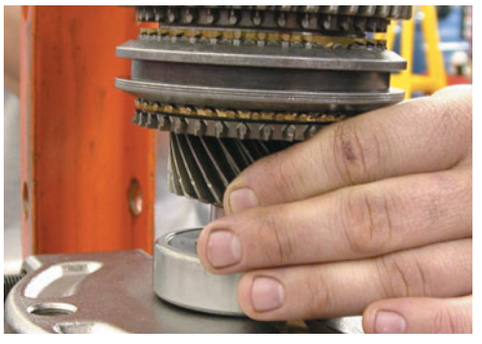


6 The shift shaft and forks can now be removed.



7 The reverse idle gear is unbolted from the case and removed.

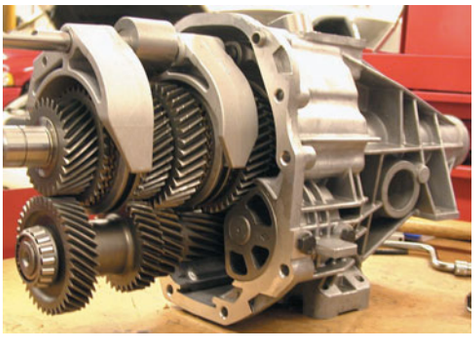
8 The output shaft assembly fifth gear (far left) and the synchronizer assemblies.



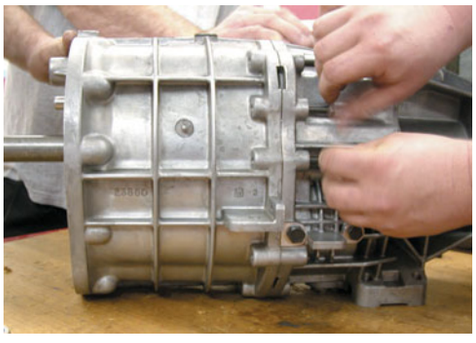
9 The bearing is being removed using a bearing splitter and a hydraulic press.

10 A speed gear (bottom) along with the double row needle bearing used between the shaft and the speed gear. The hub (center) is splined and rotates with the output shaft.

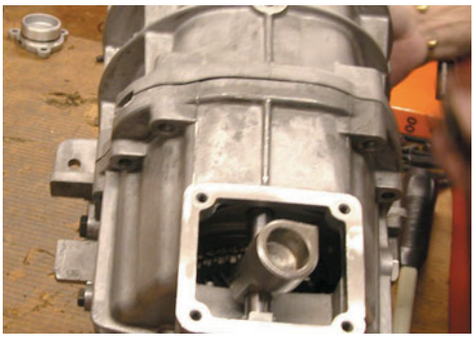
11 A synchronizer assembly being reassembled. It often takes several hands to hold the hub (center) and the sleeve (outer ring).



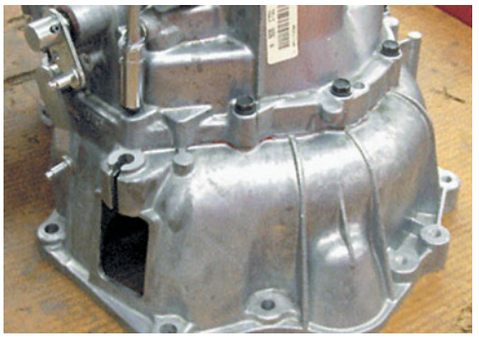
12 A hydraulic press is used to reassemble output shaft and bearing.



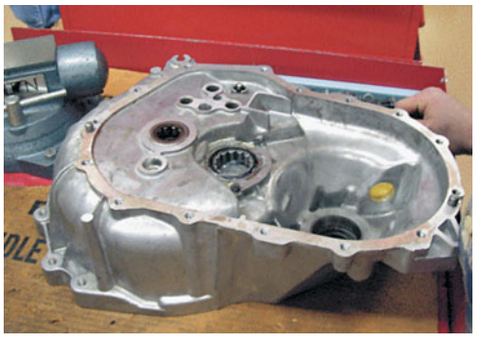
CONTINUED ▶



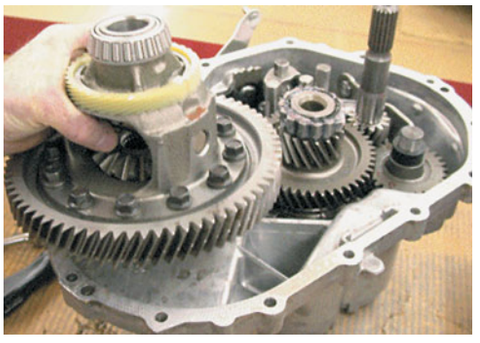
13 The assembled output shaft is held against the counter shaft to double check that all of the gears have been correctly assembled.



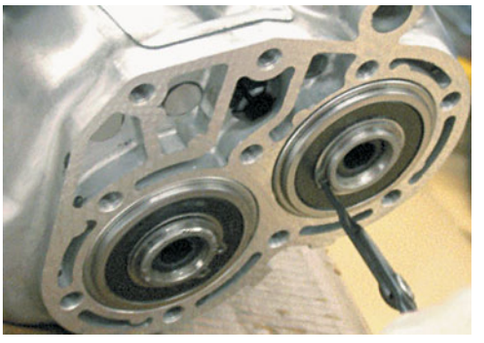
14 The assembled output shaft and counter shaft are being reinstalled in the transmission case.



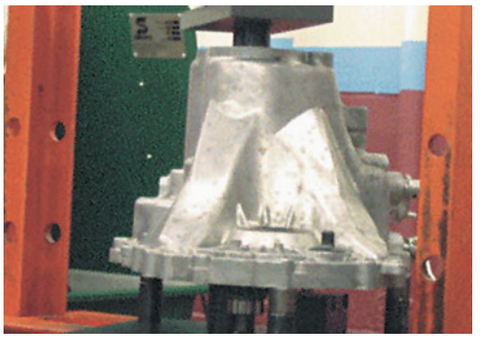
15 The case halves are bolted together.



16 The last step is to assembly the shift lever and check for proper operation in all gear positions.



1 After the transaxle has been removed from the vehicle and the fluid drained, place the transaxle on a work surface.



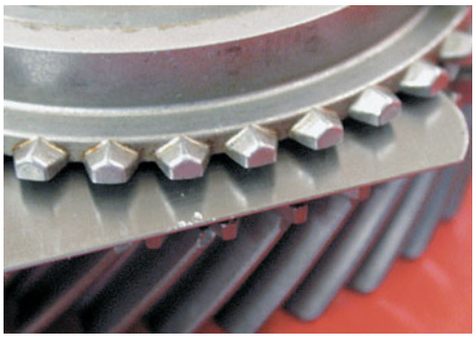
2 The bell housing case half containing the large output shaft front bearing (center) and the input shaft front bearing (smaller bearing on the left).

3 The differential assembly is simply lifted out of half of the case.

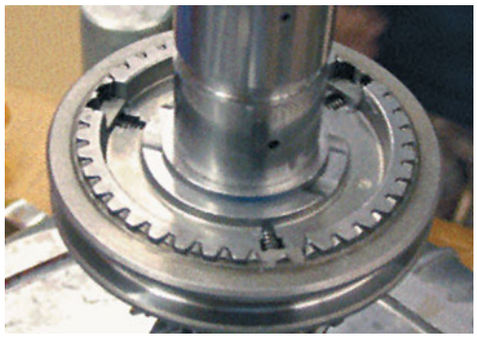
4 The input and output shafts are a press fit into the bearings and are also retained with a snap ring, which must be removed.

5 Using a special tool, the input and output shafts are pressed out of the housing using a hydraulic press.

6 The input shaft can be disassembled using a bearing splitter and a press, or two screwdrivers to pry the gears off the shaft.



CONTINUED ▶

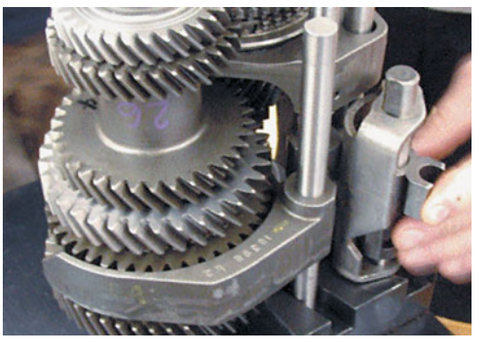


7 This transaxle uses both brass and powdered metal synchronizer rings with a fiber (paper) inner cone surface.

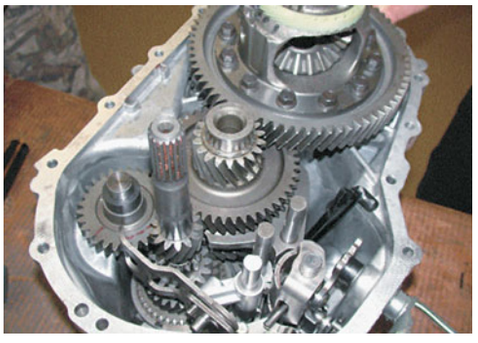
8 Synchronizer ring gaps are being measured using a feeler (thickness) gauge. The factory specifications are usually 0.040 in. to 0.069 in.

9 The gear clutch teeth should be inspected for wear.

10 An assembled synchronizer assembly containing a sleeve, keys, springs, and detent.

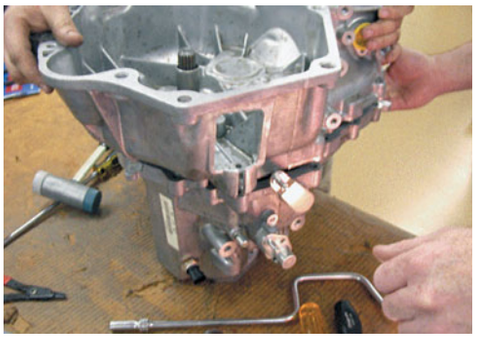


11 The input shaft (left) and the output shaft (right) are checked for proper assembly before being installed into the case.



12 The differential bearing preload is determined by measuring for zero end play; then adding the thickness shim under the bearing cup.

13 The bearing cup is being installed using an installation tool and a hammer.



14 All of the shift forks and shift arms must be aligned properly before installing the components into the case.

15 All of the components, including the differential (right), the output shaft (center), and the input shaft (left), plus the shift linkage are installed and checked for proper positioning.

16 The case halves being reinstalled. The bearings (top) must be pressed back onto the input and output shafts using a press.

17 The bell housing case being reattached.

18 The completed assembly. Notice the bearing cover (top) has already been installed.

REVIEW QUESTIONS

1. Calculate the gear ratio if the driven gear has 36 teeth and the driving gear has 12 teeth.
2. Explain what is meant by an overdrive ratio.
3. List the parts of a manual transmission.
4. Explain how a synchronizer assembly is able to allow a clash-free shift.
5. List four possible causes for a manual transmission/transaxle being difficult to shift.
6. List the possible lubricants that a manual transmission/ transaxle may require.

CHAPTER QUIZ

1. Technician A says that the torque available at the output shaft is greater in second gear than when the transmission/transaxle is in third gear at the same engine speed. Technician B says that the output shaft is rotating faster when the transmission/ transaxle is in second gear compared to third gear when the engine is at the same speed. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. The driving gear has 15 teeth and the driven gear has 29 teeth. Technician A says that the output gear will be going faster than the input gear. Technician B says the ratio is 3.86:1. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
3. Which part is splined to the clutch disc?
   a. Main shaft **c.** Cluster shaft
   b. Countershaft (lay shaft) **d.** Main gear
4. Two technicians are discussing how torque is increased inside a manual transmission/transaxle. Technician A says that the gear ratio in first gear between the main shaft and the countershaft should be *multiplied* by the ratio of the corresponding countershaft gear and output shaft gear. Technician B says that the two ratios should be added together. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
5. Which component cannot be removed before removing the transmission/ transaxle from the vehicle?
   a. Vehicle speed sensor
   b. Reverse (backup) light connector
   c. Front bearing retainer (quill)
   d. Drive axle shaft(s)
6. Technician A says that snap-rings are used to hold many components of a manual transmission/transaxle. Technician B says that snap rings have a "right side" that should always face up so that the snap-ring pliers can be applied. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
7. A customer complained of hard shifting particularly into first gear and reverse. Technician A says that the blocking ring may be worn. Technician B says that the clutch may be defective or out of adjustment. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
8. Which part of a synchronizer is splined to a shaft?
   a. Synchronizer sleeve
   b. Hub
   c. Synchronizer ring (blocking ring)
   d. Speed gear
9. A manual transmission is difficult to shift but only when the outside temperature is below freezing (32°F or 0°C). Technician A says that the brass blocking ring could be defective. Technician B says that incorrect gear lubricant could be the cause. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
10. Which type of lubricant is usually *not* used in a manual transmission/ transaxle?
    a. Automatic transmission fluid (ATF)
    b. High-temperature chassis grease
    c. SAE 80W-90 gear lube
    d. Engine oil

chapter 123

DRIVE AXLE SHAFTS AND CV JOINTS

OBJECTIVES: After studying Chapter 123, the reader will be able to: • Prepare for ASE Suspension and Steering (A4) certification test content area "C" (Related Suspension and Steering Service). • Name driveshaft and U-joint parts, and describe their function and operation. • Describe how CV joints work. • Explain how the working angles of the U-joints are determined. • List the various types of CV joints and their applications. • Discuss the proper grease to use in CV joints.

KEY TERMS: Cardan joints 1497 • Center support bearing 1495 • CV joint boot 1501 • CV joints 1498 • Double-Cardan joints 1498 • Drive axle shaft 1500 • Driveshaft 1495 • Fixed joint 1499 • Half shaft 1500 • Plunge joint 1500 • Propeller shaft 1495 • Rzeppa joint 1498 • Spider 1496 • Trunnions 1496 • Universal joints 1496

INTRODUCTION

A drive axle shaft transmits engine torque from the transmission or transaxle (if front wheel drive) to the rear axle assembly or drive wheels. ● **SEE FIGURES 123–1 AND 123–2.**

Driveshaft is the term used by the Society of Automotive Engineers (SAE) to describe the shaft between the transmission and the rear axle assembly on a rear-wheel-drive vehicle. General Motors and some other manufacturers use the term **propeller shaft** or *prop shaft* to describe this same part. The SAE term will be used throughout this textbook.

A typical driveshaft is a hollow steel tube. A splined end yoke is welded onto one end that slips over the splines of the output shaft of the transmission. ● **SEE FIGURE 123–3.** An end yoke is welded onto the other end of the driveshaft. Some driveshafts use a center support bearing.

DRIVESHAFT DESIGN

Most driveshafts are constructed of hollow steel tubing. *The forces are transmitted through the surface of the driveshaft tubing.* The surface is therefore in tension, and cracks can develop on the outside surface of the driveshaft due to metal fatigue. Driveshaft tubing can bend and, if dented, can collapse. A dented driveshaft should be replaced and no attempt should be made to repair the dent. ● **SEE FIGURE 123–4.**

Most rear-wheel-drive cars and light trucks use a one- or two-piece driveshaft. A steel tube driveshaft has a maximum *length of about 65 in. (165 cm).* Beyond this critical length, a **center support bearing** must be used, as shown in ● **FIGURE 123–5.** A center support bearing is also called a steady bearing or hanger bearing.

Some vehicle manufacturers use aluminum driveshafts; these can be as long as 90 in. (230 cm) with no problem. Many extended-cab pickup trucks and certain vans use aluminum driveshafts to eliminate the need (and expense) of a center support bearing. Composite-material driveshafts are also used in some vehicles. These carbon-fiber-plastic driveshafts are very strong yet lightweight, and can be made in extended lengths without the need for a center support bearing.

To dampen driveshaft noise, it is common to line the inside of the hollow driveshaft with cardboard or rubber. This helps eliminate the tinny sound whenever shifting between drive and reverse in a vehicle equipped with an automatic transmission. ● **SEE FIGURE 123–6.**

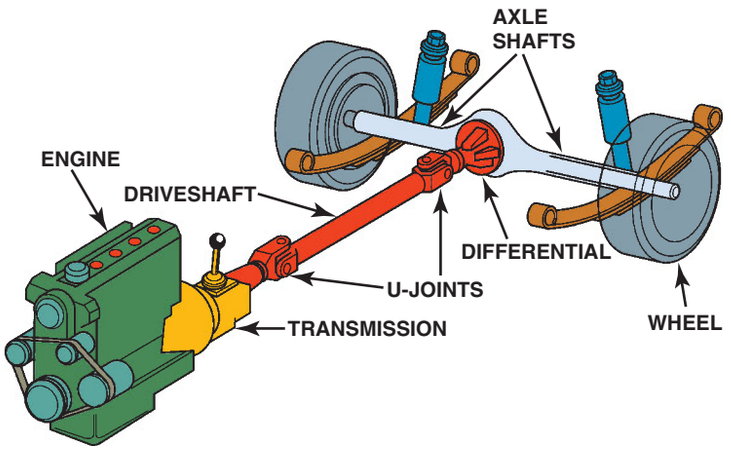


FIGURE 123–1 Typical rear-wheel-drive powertrain arrangement. The engine is mounted longitudinal (lengthwise).

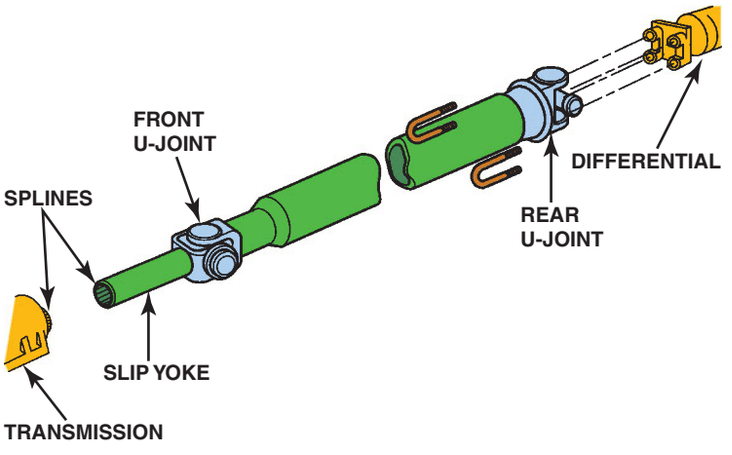

FIGURE 123–3 Typical driveshaft (also called a *propeller shaft*). The driveshaft transfers engine power from the transmission to the differential.

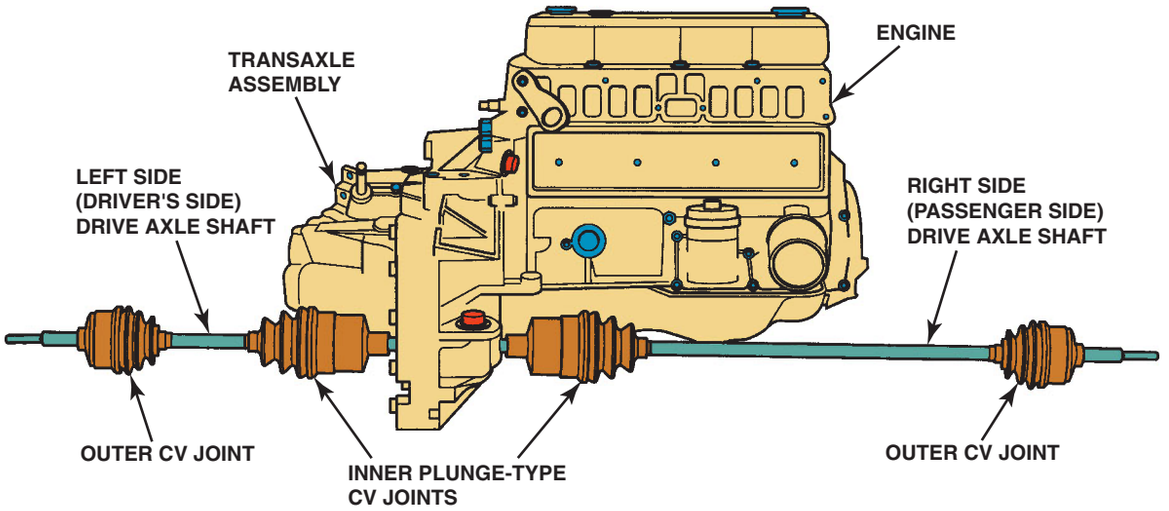

FIGURE 123–2 Typical front-wheel-drive powertrain arrangement. The engine is usually mounted transversely (sideways).

DRIVESHAFT BALANCE

All driveshafts are balanced. Generally, any driveshaft whose rotational speed is greater than 1,000 RPM must be balanced. Driveshaft balance should be within 0.5% of the driveshaft weight. (This is one of the biggest reasons why aluminum or composite driveshafts can be longer because of their light weight.)

Driveshafts are often not available by make, model, and year of the vehicle. There are too many variations at the factory, such as transmission type, differential, or U-joint type. To get a replacement driveshaft, it is usually necessary to know the series of U-joints (type or style of U-joint) and the center-to-center distance between the U-joints.

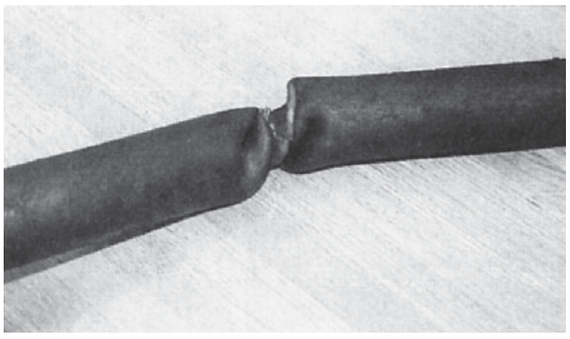

FIGURE 123–4 This driveshaft failed because it had a slight dent caused by a rock. When engine torque was applied, the driveshaft collapsed, twisted, and then broke.

U-JOINT DESIGN AND OPERATION

PARTS INVOLVED **Universal joints (U-joints)** are used at both ends of a driveshaft. U-joints allow the wheels and the rear axle to move up and down, remain flexible, and still transfer torque to the drive wheels. A simple universal joint can be made from two Y-shaped yokes connected by a crossmember called a cross or **spider.** The four arms of the cross are called **trunnions.** ● **SEE FIGURE 123–7** for a line drawing of a simple U-joint with all part names identified. A similar design is the common U-joint used with a socket wrench set.

FIGURE 123–6 Some driveshafts use rubber between an inner and outer housing to absorb vibrations and shocks to the driveline.

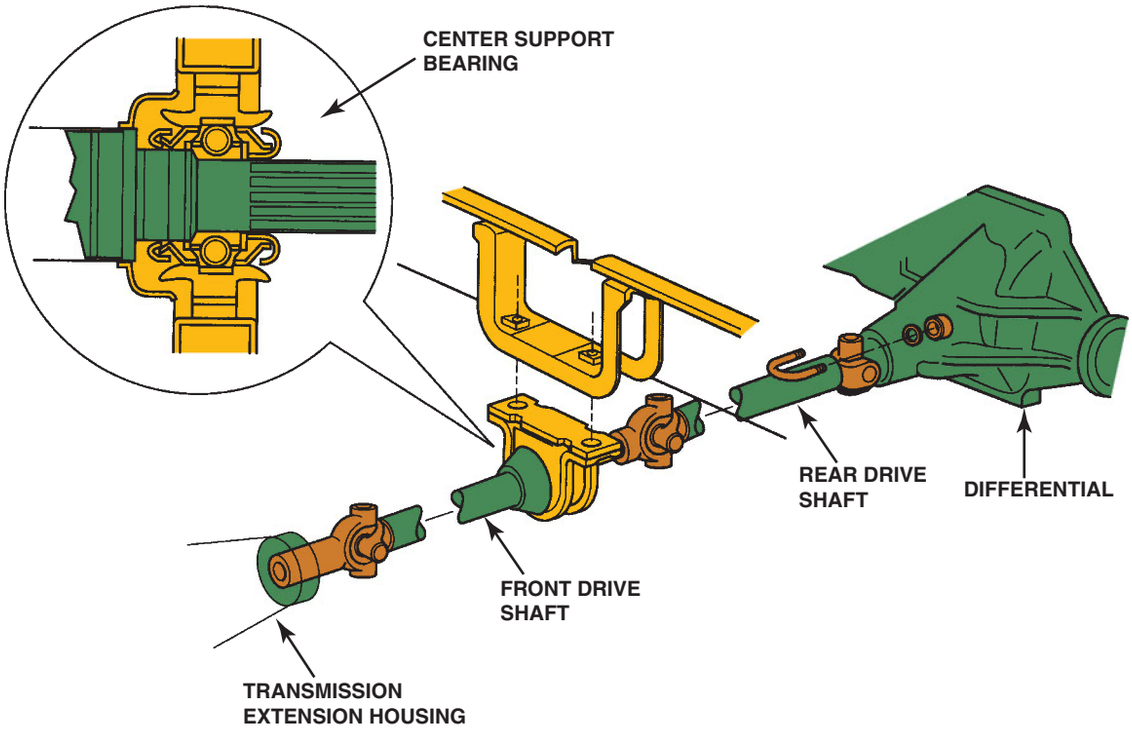

FIGURE 123–5 A center support bearing is used on many vehicles with long driveshafts such as long trucks.

Most U-joints are called cross-yoke joints or **Cardan joints.** *Cardan* is named for a sixteenth-century Italian mathematician who worked with objects that moved freely in any direction. Torque from the engine is transferred through the U-joint. The engine drives the U-joint at a constant speed, but the output speed of the U-joint changes because of the angle of the joint. The speed changes twice per revolution. *The greater the angle, the greater the change in speed (velocity).* ● **SEE FIGURE 123–8.**

U-JOINT OPERATION

If only one U-joint were used in a driveline, this change in speed of the driven side (output end) would generate vibrations in the driveline. To help reduce vibration, another U-joint is used at the other end of the driveshaft. If the angles of both joints are nearly equal, the acceleration and deceleration of one joint is offset by the alternate deceleration and acceleration of the second joint. *It is very important that both U-joints operate at about the same angle to prevent excessive driveline vibration.* ● **SEE FIGURE 123–9.**

ACCEPTABLE WORKING ANGLES

Universal joints used in a typical driveshaft should have a *working angle* of 1/2 to 3 degrees. ● **SEE FIGURE 123–10.** The working angle is the angle between the driving end and the driven end of the joint. If the driveshaft is perfectly straight (0-degree working angle), then the needle bearings inside the bearing cap are not revolving because there is no force (no difference in angles) to cause the rotation of the needle bearings.

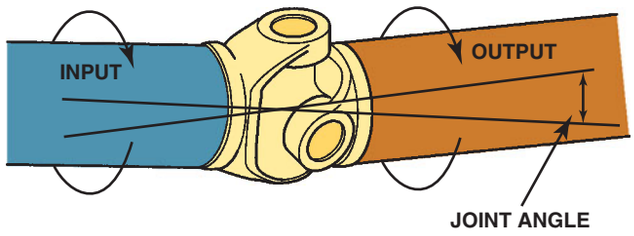

FIGURE 123–9 The joint angle is the difference between the angles of the joint. (*Courtesy of Dana Corporation*)

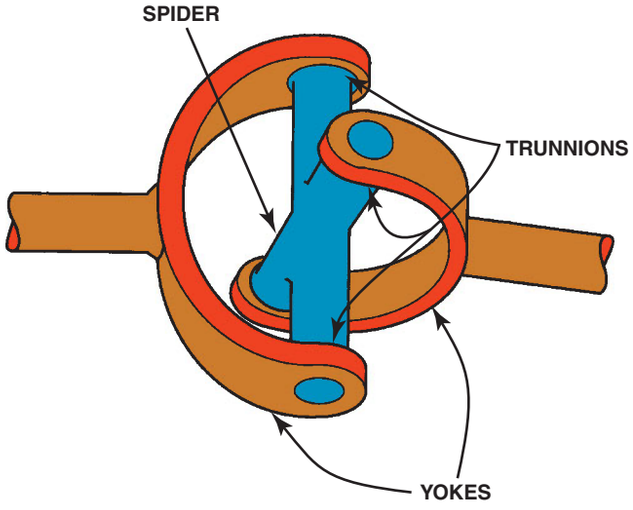

FIGURE 123–7 A simple universal joint (U-joint).

FIGURE 123–10 The angle of this rear Cardan U-joint is noticeable.

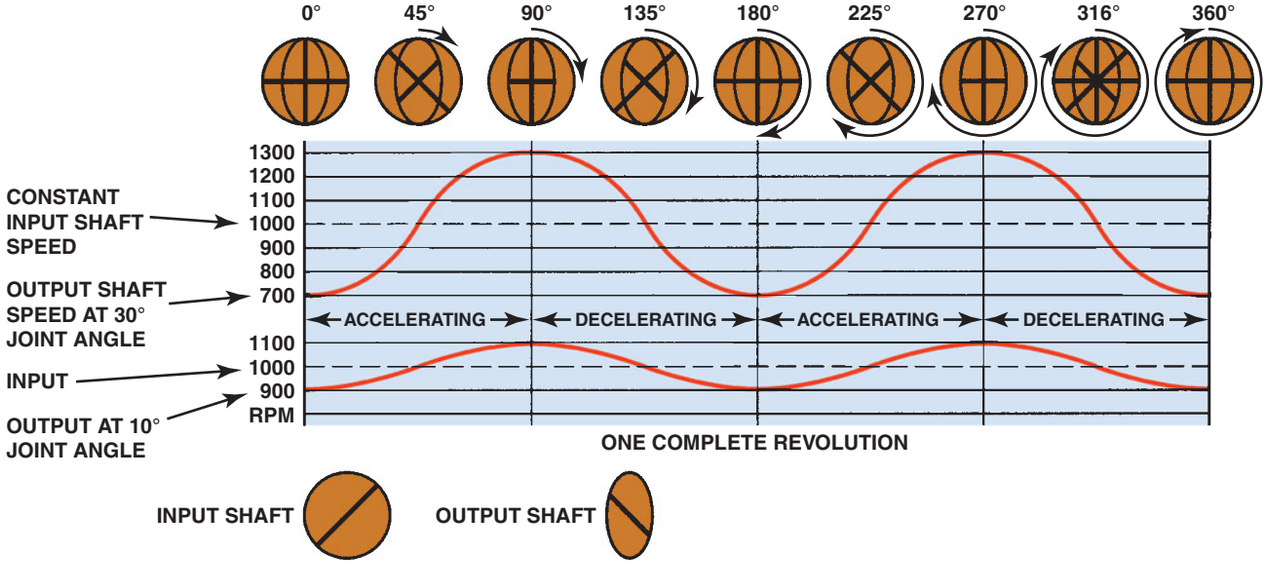

FIGURE 123–8 How the speed difference on the output of a typical U-joint varies with the speed and the angle of the U-joint. At the bottom of the chart, the input speed is a constant 1000 RPM, while the output speed varies from 900 RPM to 1100 RPM when the angle difference in the joint is only 10°. At the top part of the chart, the input speed is a constant 1000 RPM, yet the output speed varies from 700 to 1200 RPM when the angle difference in the joint is changed to 30°. (*Courtesy of Dana Corporation*)

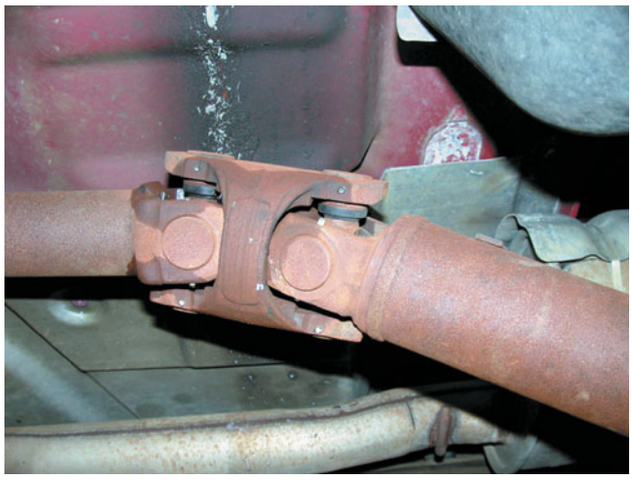

FIGURE 123–11 A double-Cardan U-joint.

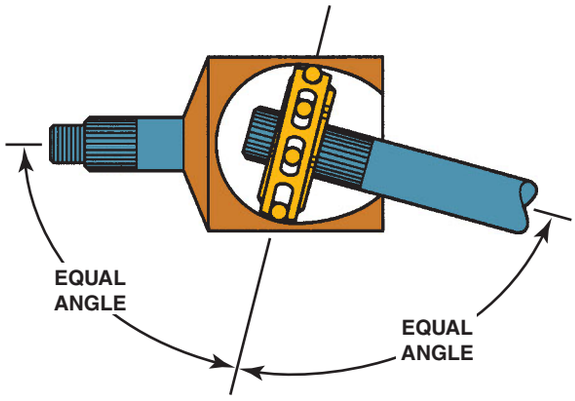

FIGURE 123–12 A constant velocity (CV) joint can operate at high angles without a change in velocity (speed) because the joint design results in equal angles between input and output.

If the needle bearings do not rotate, they can exert a constant pressure in one place and damage the bearing journal. If a two-piece driveshaft is used, one U-joint (usually the front) runs at a small working angle of about 1/2 degree, just enough to keep the needle bearings rotating. The other two U-joints (from the center support bearing and rear U-joint at the differential) operate at typical working angles of a single-piece driveshaft.

If the U-joint working angles differ by more than a 1/2 degree between the front and the rear joint, a vibration is usually produced that is *torque sensitive.* As the vehicle is first accelerated from a stop, engine torque can create unequal driveshaft angles by causing the differential to rotate on its suspension support arms. This vibration is most noticeable when the vehicle is heavily loaded and being accelerated at lower speeds. The vibration usually diminishes at higher speeds due to decrease in the torque being transmitted. If the driveshaft angles are excessive (over 3 degrees), a vibration is usually produced that increases as the speed of the vehicle (and driveshaft) increases.

FREQUENTLY ASKED QUESTION

What Is a 1350-Series U-Joint?

Most universal joints are available in sizes to best match the torque that they transmit. The larger the U-joint, the higher the amount of torque. Most U-joints are sized and rated by series numbers. See the accompanying chart for series numbers and sizes.

Series Number	Cap Diameter (inches)	Overall Length (inches)	Trunnion Diameter (inches)
1000	15/16	2 5/64	1/2
1100	15/16	2 13/64	1/2
1260/1270	1 1/16	2 31/32	19/32
1280	1 1/16	2 31/32	39/64
1310	1 1/16	2 31/32	21/32
1330	1 1/16	3 3/8	21/32
1350	1 3/16	3 3/8	49/64
1410	1 3/16	3 15/16	49/64
1480	1 3/8	3 7/8	57/64

CONSTANT VELOCITY JOINTS

PURPOSE AND FUNCTION Constant velocity joints, commonly called **CV joints,** are designed to rotate without changing speed. Regular U-joints are usually designed to work up to 12 degrees of angularity. If two Cardan-style U-joints are joined together, the angle at which this **double-Cardan joint** can function is about 18 to 20 degrees. ● **SEE FIGURE 123–11.**

Double-Cardan U-joints were first used on large rear-wheel-drive vehicles to help reduce drive-line-induced vibrations, especially when the rear of the vehicle was fully loaded and driveshaft angles were at their greatest. As long as a U-joint (either single or double Cardan) operates in a straight line, the driven shaft will rotate at the same constant speed (velocity) as the driving shaft. As the angle increases, the driven shaft speed or velocity varies during each revolution. This produces pulsations and a noticeable vibration or surge. The higher the shaft speed and the greater the angle of the joint, the greater the pulsations.

NOTE: Many four-wheel-drive light trucks use standard Cardan-style U-joints in the front drive axles. If the front wheels are turned sharply and then accelerated, the entire truck often shakes due to the pulsations created by the speed variations through the U-joints. This vibration is normal and cannot be corrected. It is characteristic of this type of design and is usually not noticeable in normal driving.

The first constant velocity joint was designed by Alfred H. Rzeppa (pronounced shep'pa) in the mid-1920s. The **Rzeppa joint** transfers torque through six round balls that are held in position midway between the two shafts. This design causes the angle between the shafts to be equally split regardless of the angle. ● **SEE FIGURE 123–12.** Because the angle is always split equally, torque is transferred equally without the change in speed (velocity) that occurs in Cardan-style U-joints. This style of joint results in a constant velocity between driving and driven shafts. It can also function at angles greater than simple U-joints can, up to 40 degrees.

NOTE: CV joints are also called LOBRö joints, the brand name of an original equipment manufacturer.

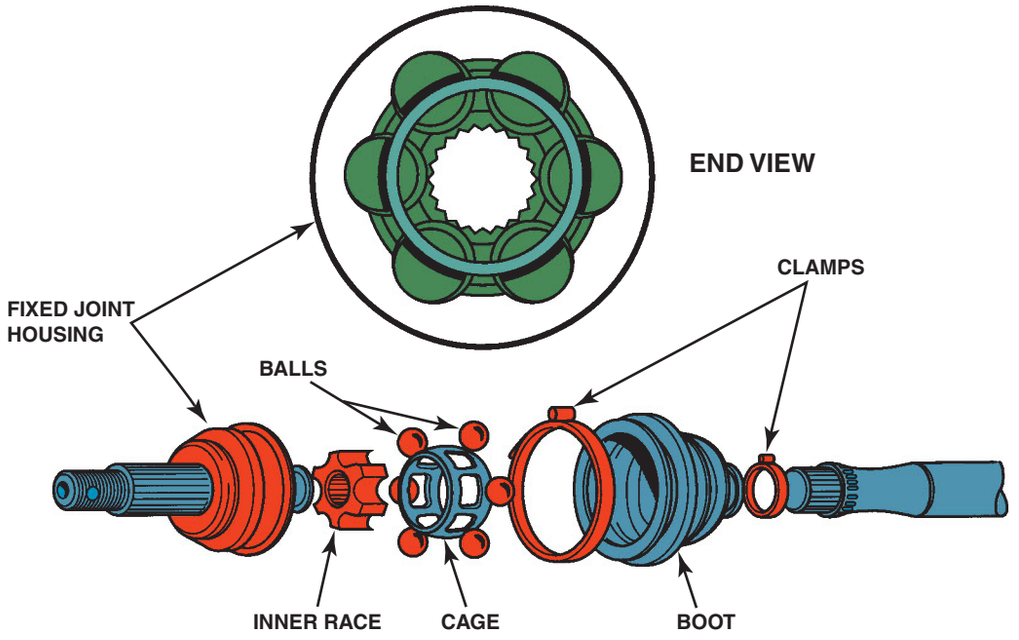

FIGURE 123–13 A Rzeppa fixed joint on a front-wheel-drive vehicle. This type of CV joint is commonly used at the wheel side of the drive axle shaft on a front-wheel-drive vehicle. This joint can operate at high angles to compensate for suspension travel and steering angle changes. (*Courtesy of Dana Corporation*)

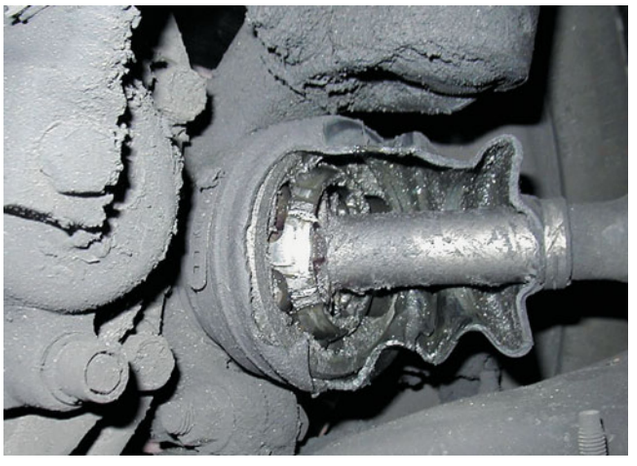

FIGURE 123–14 The protective CV joint boot has been torn away on this vehicle and all of the grease has been thrown outward onto the brake and suspension parts. The driver of this vehicle noticed a "clicking" noise, especially when turning.

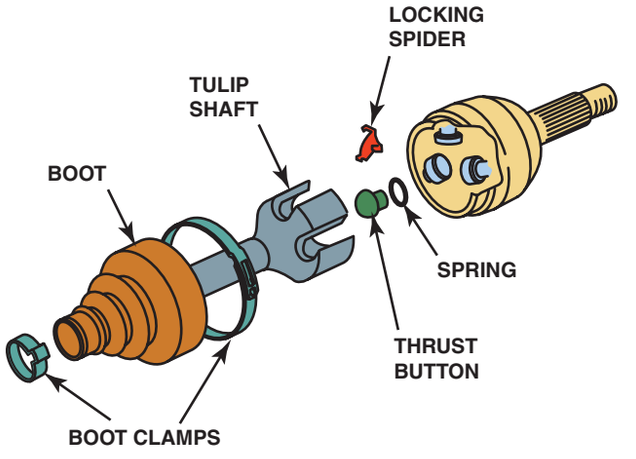

FIGURE 123–15 A tripod fixed joint. This type of joint is found on some Japanese vehicles. If the joint wears out, it is to be replaced with an entire drive axle shaft assembly.

While commonly used today in all front-wheel-drive vehicles and many four-wheel-drive vehicles, its first use was on the front-wheel-drive 1929 Cord. Built in Auburn, Indiana, the Cord was the first front-wheel-drive car to use a CV-type drive axle joint.

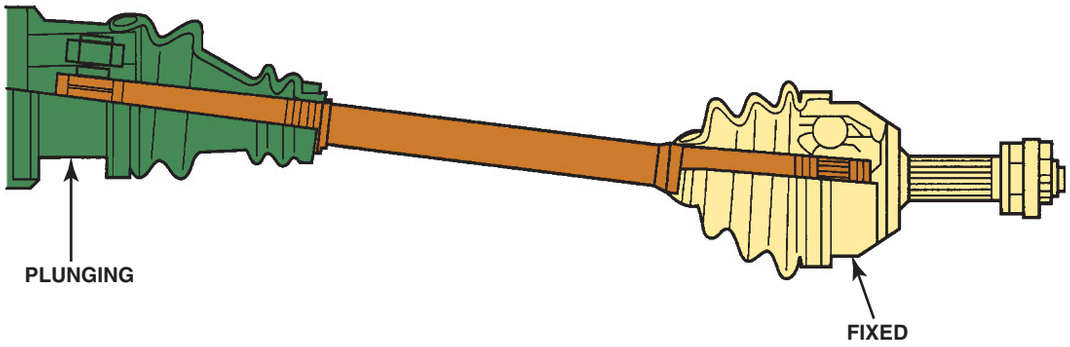
OUTER CV JOINTS The Rzeppa-type CV joint is most commonly used as an outer joint on most front-wheel-drive vehicles. ● **SEE FIGURE 123–13.** The outer joint must do the following:

1. Allow up to 40 degrees or more of movement to allow the front wheels to turn
2. Allow the front wheels to move up and down through normal suspension travel in order to provide a smooth ride over rough surfaces
3. Be able to transmit engine torque to drive the front wheels

Outer CV joints are called **fixed joints.** The outer joints are also attached to the front wheels. They are more likely to suffer from road hazards that often can cut through the protective outer flexible boot. ● **SEE FIGURE 123–14.** Once this boot has been split open, the special high-quality grease is thrown out and contaminants such as dirt and water can enter. Some joints cannot be replaced individually if worn. ● **SEE FIGURE 123–15.**

NOTE: Research has shown that in as few as eight hours of driving time, a CV joint can be destroyed by dirt, moisture, and a lack of lubrication if the boot is torn. The technician should warn the owner as to the possible cost involved in replacing the CV joint itself whenever a torn CV boot is found.

INNER CV JOINTS Inner CV joints attach the output of the transaxle to the drive axle shaft. Inner CV joints are



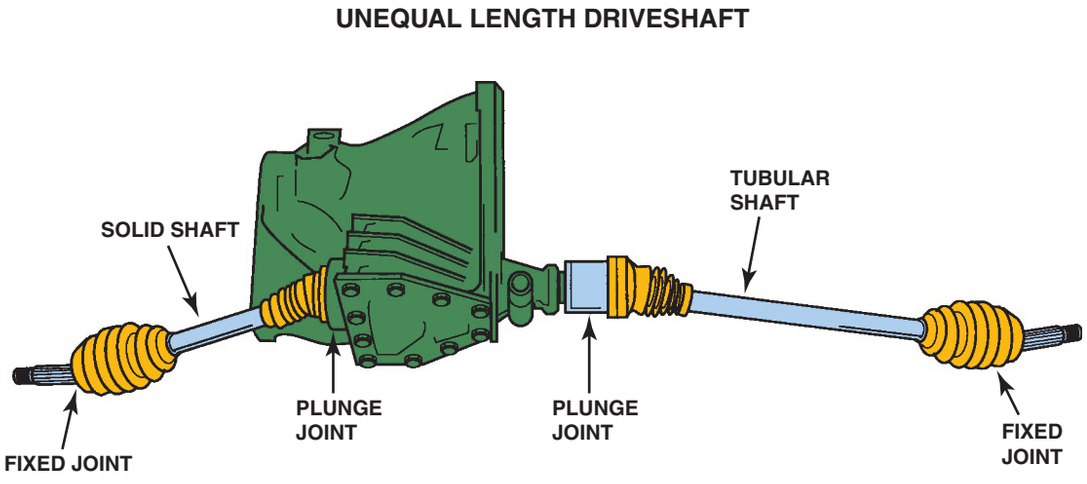


FIGURE 123–16 The fixed outer joint is required to move in all directions because the wheels must turn for steering as well as move up and down during suspension movement. The inner joint has to be able to not only move up and down but also plunge in and out as the suspension moves up and down. (*Courtesy of Dana Corporation*)

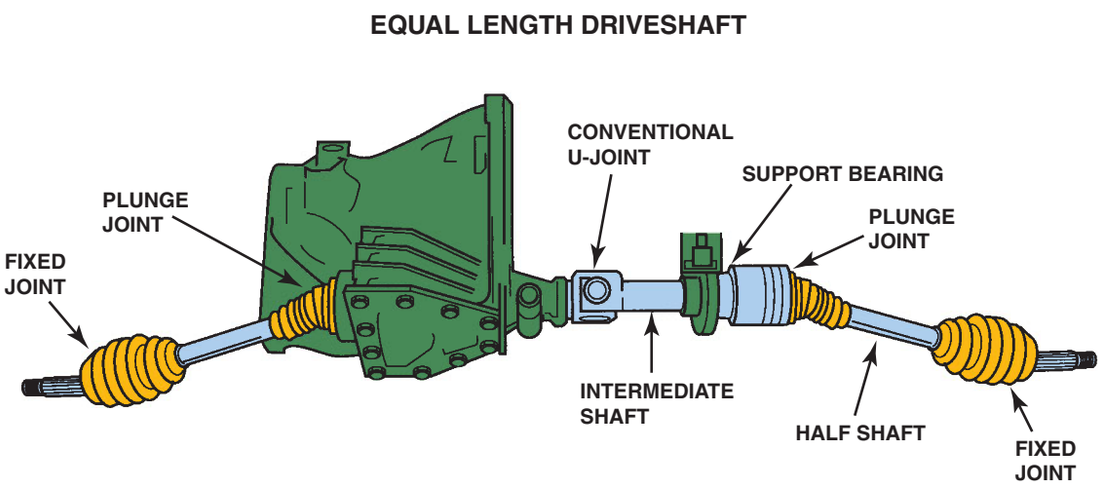

FIGURE 123–17 Unequal-length driveshafts result in unequal drive axle shaft angles to the front drive wheels. This unequal angle side-to-side often results in a steering of the vehicle during acceleration called torque steer. By using an intermediate shaft, both drive axles are the same angle and the torque steer effect is reduced. (*Courtesy of Dana Corporation*)

therefore inboard, or toward the center of the vehicle. ● **SEE FIGURE 123–16.**

Inner CV joints have to be able to perform two very important movements:

1. Allow the drive axle shaft to move up and down as the wheels travel over bumps.
2. Allow the drive axle shaft to change length as required during vehicle suspension travel movements (lengthening and shortening as the vehicle moves up and down; same as the slip yoke on a conventional RWD driveshaft). CV joints are also called **plunge joints.**

DRIVE AXLE SHAFTS Unequal-length **drive axle shafts** (also called **half shafts**) result in unequal drive axle shaft angles to the front drive wheels. ● **SEE FIGURE 123–17.** This unequal angle often results in a pull on the steering wheel during acceleration. This

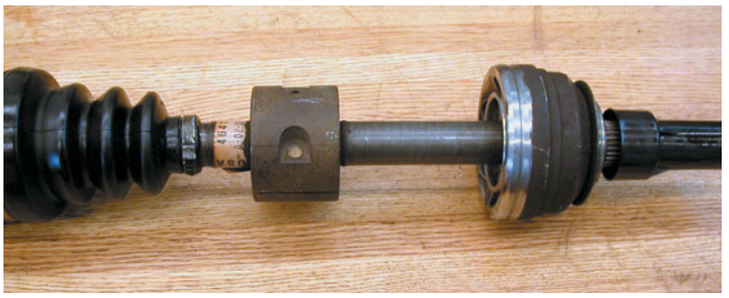

FIGURE 123–18 A typical drive axle shaft with dampener weight.

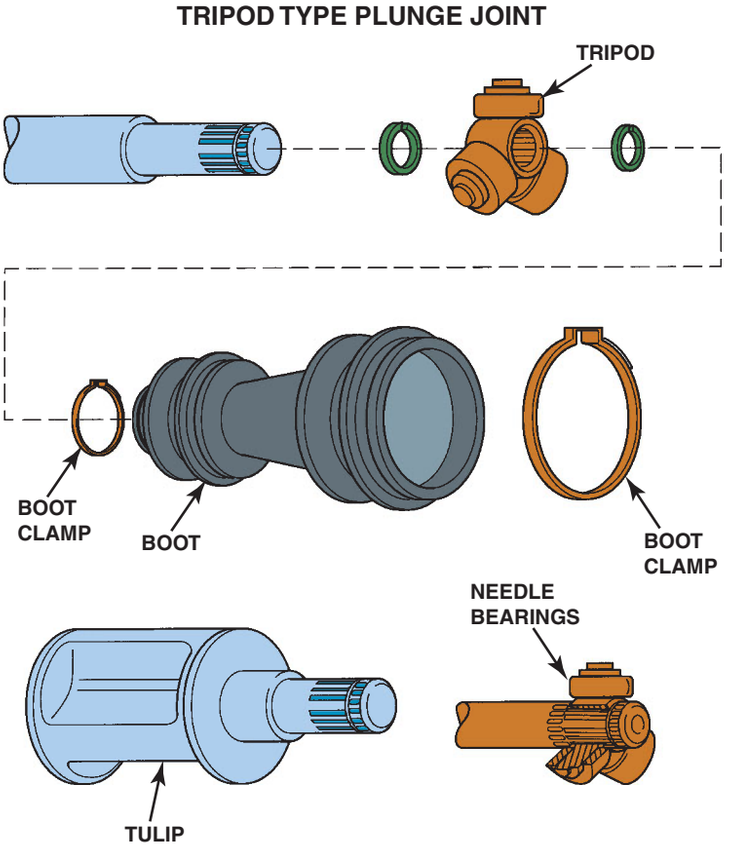

FIGURE 123–19 A tripod joint is also called a tripot, tripode, or tulip design. (*Courtesy of Dana Corporation*)

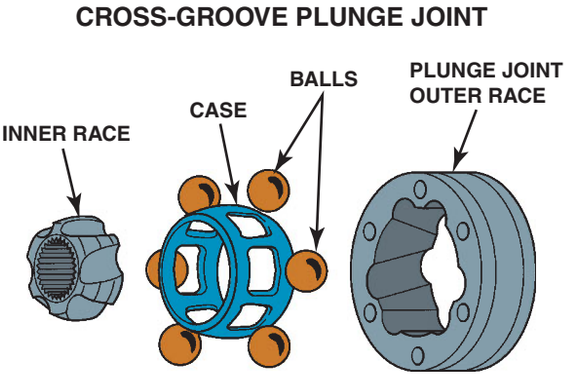

FIGURE 123–20 A cross-groove plunge joint is used on many German front-wheel-drive vehicles and as both inner and outer joints on the rear of vehicles that use an independent-type rear suspension. (*Courtesy of Dana Corporation*)

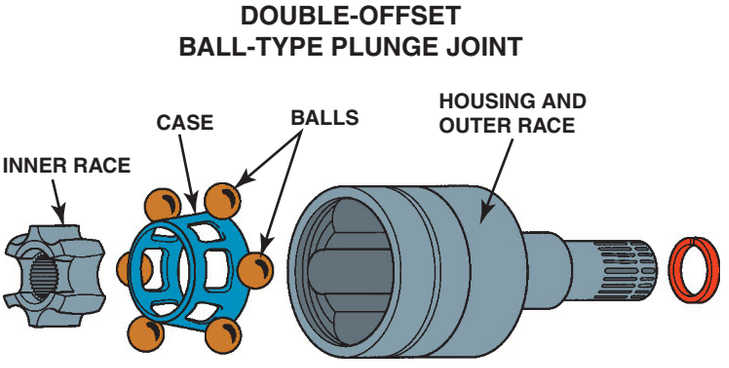

FIGURE 123–21 Double-offset ball-type plunge joint. (*Courtesy of Dana Corporation*)

pulling to one side during acceleration due to unequal engine torque being applied to the front drive wheels is called torque steer. To help reduce the effect of torque steer, some vehicles are manufactured with an intermediate shaft that results in equal drive axle shaft angles. Both designs use fixed outer CV joints with plunge-type inner joints.

Typical types of inner CV joints that are designed to move axially, or *plunge,* include the following:

1. Tripod. ● **SEE FIGURE 123–19.**
2. Cross groove. ● **SEE FIGURE 123–20.**
3. Double offset. ● **SEE FIGURE 123–21.**

CV joints are also used in rear-wheel-drive vehicles and in many four-wheel-drive vehicles.

CV JOINT BOOT MATERIALS The pliable boot surrounding the CV joint, or **CV joint boot,** must be able to remain flexible under all weather conditions and still be strong enough to avoid being punctured by road debris. There are four basic types of boot materials used over CV joints:

1. *Natural rubber* (black) uses a bridge-type stainless steel clamp to retain.
2. *Silicone rubber* (gray) is a high-temperature-resistant material that is usually only used in places that need heat protection, such as the inner CV joint of a front-wheel-drive vehicle.

? FREQUENTLY ASKED QUESTION

What Is That Weight for on the Drive Axle Shaft?

Some drive axle shafts are equipped with what looks like a balance weight. ● **SEE FIGURE 123–18.** It is actually a dampener weight used to dampen out certain drive line vibrations. The weight is not used on all vehicles and may or may not appear on the same vehicle depending on engine, transmission, and other options. The service technician should always try to replace a defective or worn drive axle shaft with the exact replacement. When replacing an entire drive axle shaft, the technician should always follow the manufacturer's instructions regarding either transferring or not transferring the weight to the new shaft.

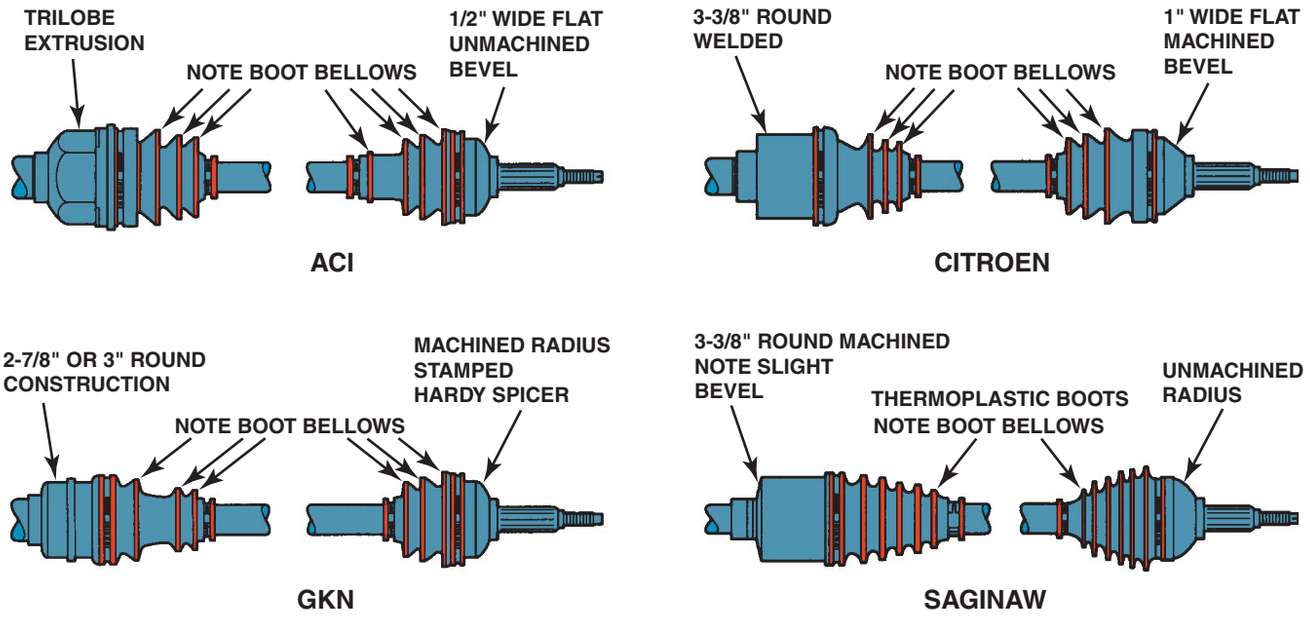

FIGURE 123–22 Getting the correct boot kit or parts from the parts store is more difficult on many Chrysler front-wheel-drive vehicles because Chrysler has used four different manufacturers for its axle shaft assemblies. (*Courtesy of Dana Corporation*)

3. *Hard thermoplastic* (black) is a hard plastic material requiring heavy-duty clamps and a lot of torque to tighten (about 100 lb-ft!).
4. *Urethane* (usually blue) is a type of boot material usually found in an aftermarket part. ● **SEE FIGURE 123–22** for examples of various types of CV joint boots depending on the manufacturer of the CV joints and shafts.

NOTE: Some aftermarket companies offer a split-style replacement CV joint boot. Being split means that the boot can be replaced without having to remove the drive axle shaft. Vehicle manufacturers usually do *not* recommend this type of replacement boot because the joint cannot be disassembled and properly cleaned with the drive axle still in the vehicle. The split boots must also be kept perfectly clean (a hard job to do with all the grease in the joint) in order to properly seal the seam on the split boot.

It is important that boot seals be inspected regularly and replaced if damaged. The inboard (plunging joint) can often pump water into the joint around the seals or through small holes in the boot material itself because the joint moves in and out. Seal retainers are used to provide a leakproof connection between the boot seal and the housing or axle shaft.

CV JOINT GREASE CV joints require special greases. Grease is an oil with thickening agents. Greases are named for the thickening agents used.

Most CV joint grease is molybdenum-disulfide-type grease, commonly referred to as *moly* grease. The exact composition of grease can vary depending on the CV joint manufacturer. *The grease supplied with a replacement CV joint or boot kit should be the only grease used.*

The exact mix of chemicals, viscosity (thickness), wear, and corrosion-resistant properties varies from one CV joint application to another. Some technicians mistakenly think that the *color* of the grease determines in which CV joint it is used. The color—such as black, blue, red, or tan—is used to identify the grease during manufacturing and packaging as well as to give the grease a consistent, even color (due to blending of various ingredients in the grease).

The exact grease to use depends on many factors, including the following:

1. The type (style) of CV joint. For example, outer (fixed) and inner (plunging) joints have different lubricating needs.
2. The location of the joint on the vehicle. For example, inner CV joints are usually exposed to the greatest amount of heat.
3. The type of boot. The grease has to be compatible with the boot material.

REVIEW QUESTIONS

1. Explain why Cardan-type U-joints on a driveshaft must be within 1/2-degree working angles.
2. What makes a constant velocity joint able to transmit engine torque through an angle at a constant velocity?
3. What type of grease must be used in CV joints?

CHAPTER QUIZ

1. The name most often used to describe the universal joints on a conventional rear-wheel-drive vehicle driveshaft is _____.
   a. Trunnion **c.** CV
   b. Cardan **d.** Spider
2. A rear-wheel-drive vehicle shudders or vibrates when first accelerating from a stop. The vibration is less noticeable at higher speeds. The most likely cause is _____.
   a. Driveshaft unbalance
   b. Excessive U-joint working angles
   c. Unequal U-joint working angles
   d. Brinelling of the U-joint
3. All driveshafts are balanced.
   a. True **b.** False
4. The maximum difference between the front and rear working angle of a driveshaft is _____.
   a. 1/4 degree **c.** 1 degree
   b. 1/2 degree **d.** 3 degrees
5. Which series U-joint has the greatest torque capacity?
   a. 1260 **c.** 1350
   b. 1310 **d.** 1480
6. Two technicians are discussing torque steer on a front-wheel-drive vehicle. Technician A says that equal length drive axle shafts help reduce torque steer. Technician B says that equal drive axle shaft angles help reduce torque steer. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. The outer CV joints used on front-wheel-drive vehicles are _____.
   a. Fixed type
   b. Plunge type
8. The proper grease to use with a CV joint is _____.
   a. Black chassis grease
   b. Dark blue EP grease
   c. Red moly grease
   d. The grease that is supplied with the boot kit
9. Drive axle shafts are also called _____.
   a. Double-Cardan shafts **c.** Driveshafts
   b. Half shafts **d.** Propeller shafts
10. Two technicians are discussing a dented driveshaft. Technician A says that it should be repaired. Technician B says it should be replaced. Which technician is correct?
    a. Technician A only **c.** Both Technicians A and B
    b. Technician B only **d.** Neither Technician A nor B

chapter 124 DRIVE AXLE SHAFT AND CV JOINT SERVICE

OBJECTIVES: **After studying Chapter 124, the reader will be able to:** • Prepare for ASE Suspension and Steering (A4) certification test content area "C" (Related Suspension and Steering Service). • Explain how to perform a U-joint inspection. • List the steps necessary to replace a U-joint. • Explain how to perform a measurement of the working angles of a U-joint. • Describe the service procedures for replacing CV joints and boots. • Describe the routine maintenance service procedures required for drive axle shafts and universal CV joints. • How to properly grease a u-joint • Describe the symptoms of a defective universal joint

KEY TERMS: Inclinometer 1508 • Pinch bolt 1510 • Plastic (Nylon) retainers 1507 • Spline bind 1506 • Torque prevailing nut 1510 • U-joints 1504

U-JOINT FAULT SYMPTOMS

The driveshaft of a typical rear-wheel-drive (RWD) vehicle rotates about three times faster than the wheels. This is due to the gear reduction that occurs in the differential. The differential not only provides gear reduction but also allows for a difference in the speed of the rear wheels that is necessary whenever turning a corner.

The driveshaft rotates at the same speed as the engine if the transmission ratio is 1 to 1 (1:1). The engine speed, in revolutions per minute (RPM), is transmitted through the transmission at the same speed. In lower gears, the engine speed is many times faster than the output of the transmission. Most transmissions today, both manual and automatic, have an overdrive gear. This means that at highway speeds, the driveshaft is rotating faster than the engine (the engine speed is decreased or overdriven to help reduce engine speed and improve fuel economy).

FIGURE 124–1 Notice how the needle bearings have worn grooves into the bearing surface of the U-joint.

REAL WORLD FIX

The Squeaking Pickup Truck

The owner of a pickup truck complained that a squeaking noise occurred while driving in reverse. The "eeeee-eeeee-eeee" sound increased in frequency as the truck increased in speed, yet the noise did not occur when driving forward.

Because there was no apparent looseness in the U-joints, the service technician at first thought that the problem was inside either the transmission or the rear end. When the driveshaft was removed to further investigate the problem, it became obvious where the noise was coming from. The U-joint needle bearing had worn the cross-shaft bearing surface of the U-joint. ● **SEE FIGURE 124–1.** The noise occurred only in reverse because the wear had occurred in the forward direction, and therefore only when the torque was applied in the opposite direction did the needle bearing become bound up and start to make noise. A replacement U-joint solved the squeaking noise in reverse.

The driveshaft must travel up and down as the vehicle moves over bumps and dips in the road while rotating and transmitting engine power to the drive wheels. The driveshaft and universal joints should be carefully inspected whenever any of the following problems or symptoms occur:

1. Vibration or harshness at highway speed
2. A clicking sound whenever the vehicle is moving either forward or in reverse
3. A clunking sound whenever changing gears, such as moving from Drive to Reverse

NOTE: A click-click-click sound while moving in reverse is usually the first indication of a defective U-joint. This clicking occurs in reverse because the needle bearings are being forced to rotate in a direction opposite the usual.

DRIVESHAFT AND U-JOINT INSPECTION

VISUAL INSPECTION

The driveshaft should be inspected for the following:

1. Any dents or creases caused by incorrect hoisting of the vehicle or by road debris.

   CAUTION: A dented or creased driveshaft can collapse, especially when the vehicle is under load. This collapse of the driveshaft can cause severe damage to the vehicle and may cause an accident.

2. Undercoating, grease, or dirt buildup on the driveshaft can cause a vibration.
3. Undercoating should be removed using a suitable solvent and a rag. Always dispose of used rags properly.

LUBRICATION

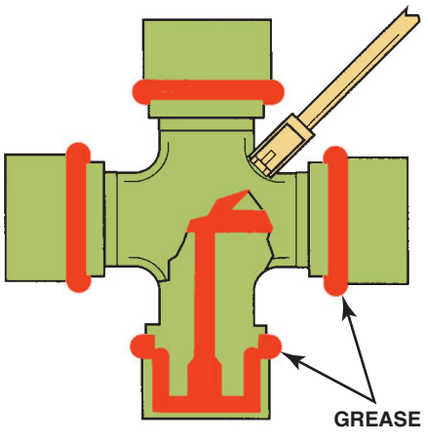
The **U-joints** should be inspected every time the vehicle chassis is lubricated, or four times a year. Original equipment (OE) U-joints are permanently lubricated and have no provision for greasing. If there is a grease fitting, the U-joint should be lubricated by applying grease with a grease gun. ● **SEE FIGURES 124–2 AND 124–3.**

In addition to periodic lubrication, the driveshaft should be grabbed and moved to see if there is any movement of the U-joints. If *any* movement is noticed when the driveshaft is moved, the U-joint is worn and must be replaced.

NOTE: U-joints are not serviceable items and cannot be repaired. If worn or defective, they must be replaced.

PREPARATION FOR REMOVAL

U-joints can be defective and still not show noticeable free movement. *A proper U-joint inspection can be performed only by removing the driveshaft from the vehicle.*



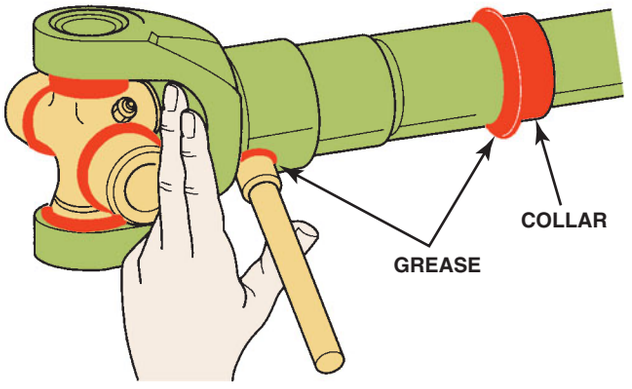
Before removing the driveshaft, always mark the position of all mating parts to ensure proper reassembly. White correction fluid, also known as "White Out" or "Liquid Paper," is an easy and fast-drying marking material. ● **SEE FIGURE 124–4.**

To remove the driveshaft from a rear-wheel-drive vehicle, remove the four fasteners at the rear U-joint at the differential. ● **SEE FIGURE 124–5.**

Push the driveshaft forward toward the transmission and then down and toward the rear of the vehicle. The driveshaft should slip out of the transmission spline and can be removed from underneath the vehicle.

NOTE: With the driveshaft removed, transmission lubricant can leak out of the rear extension housing. To prevent a mess, use an old spline the same size as the one being removed or place a plastic bag over the extension housing to hold any escaping lubricant. A rubber band can be used to hold the bag onto the extension housing.

To inspect U-joints, move each joint through its full travel, making sure it can move (articulate) freely and equally in all directions. ● **SEE FIGURE 124–6.**



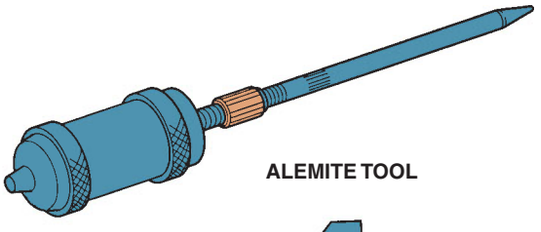


FIGURE 124–2 All U-joints and spline collars equipped with a grease fitting should be greased four times a year as part of a regular lubrication service. (*Courtesy of Dana Corporation*)

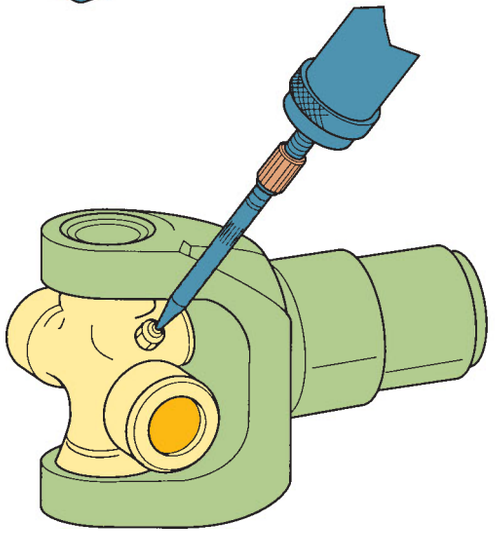

FIGURE 124–3 Many U-joints require a special grease gun tool to reach the grease fittings. Alemite is a manufacturer of lubrication equipment so many parts and tools use the Alemite name. (*Courtesy of Dana Corporation*)

FIGURE 124–4 Always mark the original location of U-joints before disassembly.

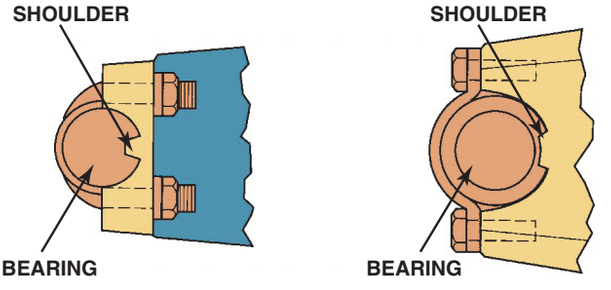

FIGURE 124–5 Two types of retaining methods that are commonly used at the rear U-joint at the differential. (*Courtesy of Dana Corporation*)

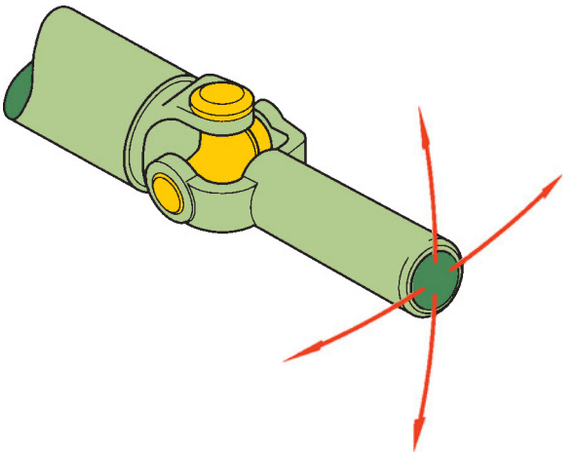

FIGURE 124–6 The best way to check any U-joint is to remove the driveshaft from the vehicle and move each joint in all directions. A good U-joint should be free to move without binding. (*Courtesy of Dana Corporation*)

U-JOINT REPLACEMENT

REMOVAL All movement in a U-joint should occur between the trunnions and the needle bearings in the end caps. The end caps are press-fit to the yokes, which are welded to the driveshaft. Three types of retainers are used to keep the bearing caps on the U-joints: the outside snap ring (● **SEE FIGURE 124–7**), the inside retaining ring, and injected synthetic (usually nylon).

DISASSEMBLY After removing the retainer, (● **SEE FIGURE 124–8**) use a press or a vise to separate the U-joint from the yoke. ● **SEE FIGURE 124–9.**

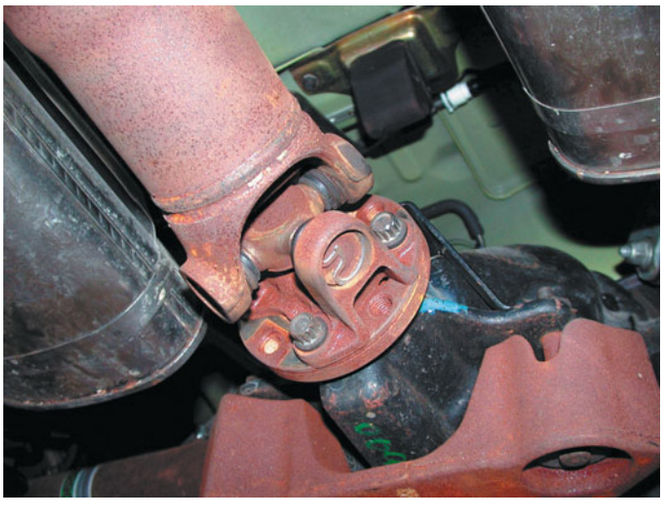

FIGURE 124–7 Typical U-joint that uses an outside snap ring. This style of joint bolts directly to the companion flange that is attached to the pinion gear in the differential.

FIGURE 124–8 A U-joint that is held together by nylon and usually requires that heat be applied to remove from the yoke.

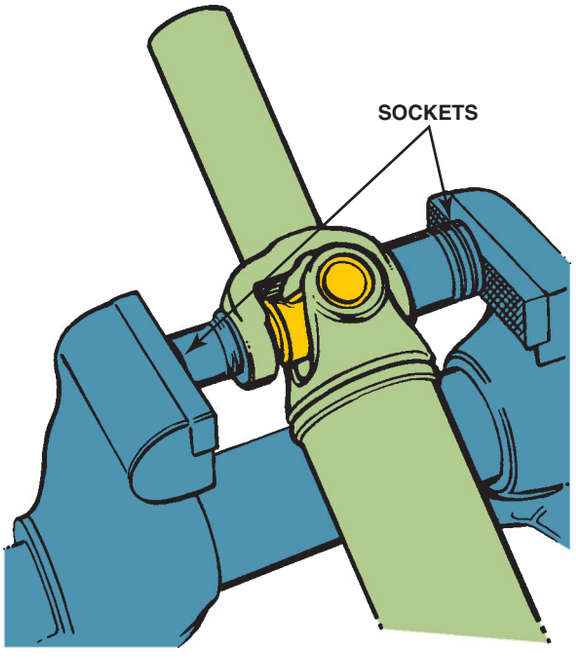

FIGURE 124–9 Use a vise and two sockets to replace a U-joint. One socket fits over the bearing cup and one fits on the bearing to press fit the cups from the crosspiece.

TECH TIP

Spline Bind Cure

Driveline "clunk" often occurs in rear-wheel-drive vehicles when shifting between drive and reverse or when accelerating from a stop. Often the cause of this noise is excessive clearance between the teeth of the ring and pinion in the differential. Another cause is called **spline bind,** where the changing rear pinion angle creates a binding in the spline when the rear springs change in height. For example, when a pickup truck stops, the weight transfers toward the front and unloads the rear springs. The front of the differential noses downward and forward as the rear springs unload. When the driver accelerates forward, the rear of the truck squats downward, causing the drive shaft to be pulled rearward when the front of the differential rotates upward. This upward movement on the spline often causes the spline to bind and make a loud clunk when the bind is finally released.

The method recommended by vehicle manufacturers to eliminate this noise is to follow these steps:

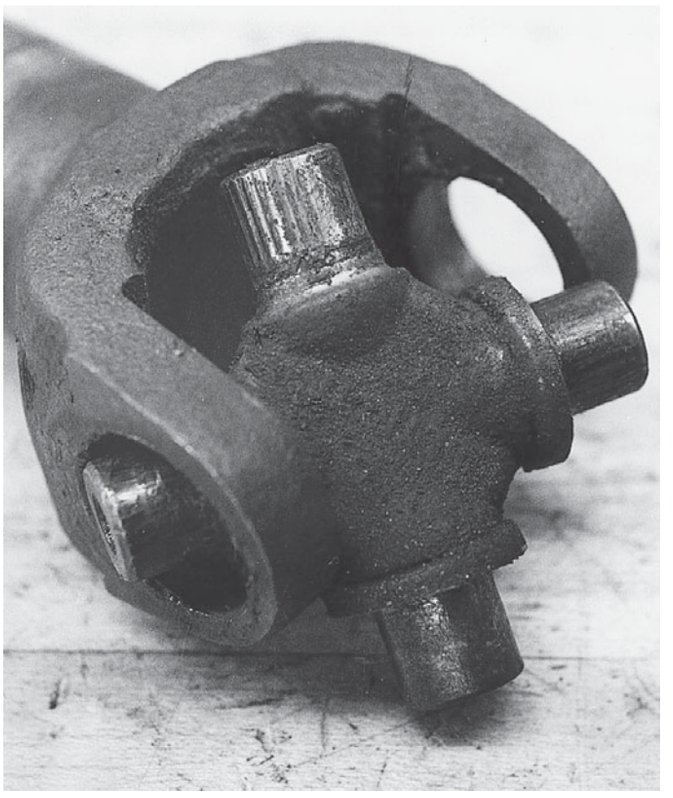
1. Remove the driveshaft.
2. Clean the splines on both the driveshaft yoke and the transmission output shaft.
3. Remove any burrs on the splines with a small metal file (remove all filings).
4. Apply a high-temperature grease to the spline teeth of the yoke. Apply grease to each spline, but do not fill the splines. Synthetic chassis grease is preferred because of its high temperature resistance.
5. Reinstall the driveshaft.

TECH TIP

Use Tape to Be Safe

When removing a driveshaft, use tape to prevent the rear U-joint caps from falling off. If the caps fall off the U-joint, all of the needle bearings will fall out and scatter over the floor. ● **SEE FIGURE 124–10.**

FIGURE 124–10 Taping the U-joint to prevent the caps from coming off.



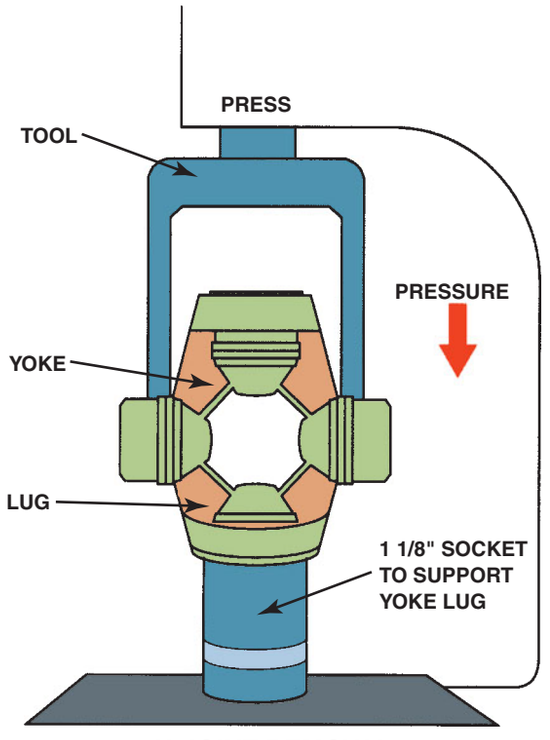


FIGURE 124–12 Removing the worn cross from the yoke.

U-JOINT REMOVAL
PLASTIC (NYLON) RETAINERS

FIGURE 124–11 A special tool being used to press apart a U-joint that is retained by injected plastic. Heat from a propane torch may be necessary to soften the plastic to avoid exerting too much force on the U-joint.

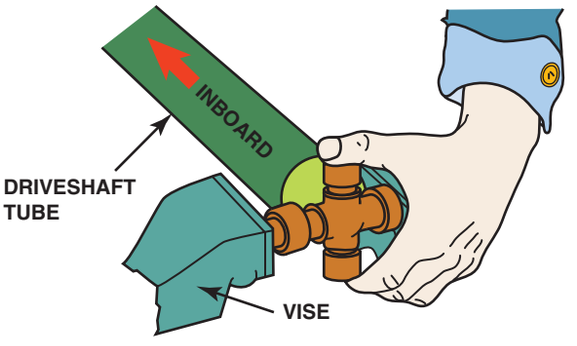

FIGURE 124–13 When installing a new U-joint, position the grease fitting on the inboard side (toward the driveshaft tube) and in alignment with the grease fitting of the U-joint at the other end.

U-joints that use **Plastic (Nylon) retainers** must be separated using a press and a special tool to press onto both sides of the joint in order to shear the plastic retainer, as shown in ● **FIGURE 124–11.**

REPLACEMENT Replacement U-joints use spring clips instead of injected plastic. Remove the old U-joint from the yoke, as shown in ● **FIGURE 124–12,** and replace with a new U-joint. Replacement U-joints should be *forged* (never cast) and use up to 32 needle bearings (also called *pin bushings*) instead of just 24 needle bearings, as used in lower-quality U-joints. Replacement U-joints usually have a grease fitting so that the new replacement U-joint can be properly lubricated. ● **SEE FIGURE 124–13.**

After removing any dirt or burrs from the yoke, press in a new U-joint. Rotate the new joint after installation to make sure it moves freely, without binding or stiffness. If a U-joint is stiff, it can cause a vibration.

NOTE: If a U-joint is slightly stiff after being installed, strike the U-joint using a brass punch and a light hammer. This often frees a stiff joint and is often called "relieving the joint." The shock aligns the needle bearings in the end caps.

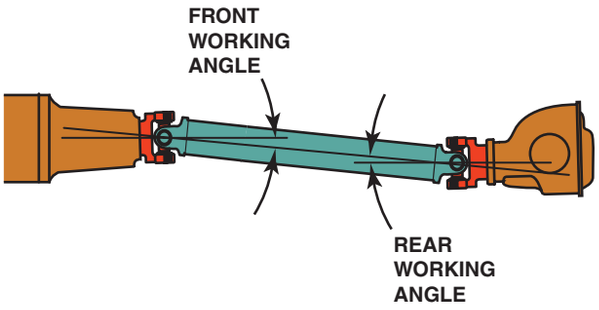

FIGURE 124–14 The working angle of most U-joints should be at least 1/2 degree (to permit the needle bearing to rotate in the U-joints) and should not exceed 3 degrees or a vibration can occur in the driveshaft, especially at higher speeds. The difference between the front and rear working angles should be within 1/2 degree of each other.

FIGURE 124–15 An inclinometer with a magnetic base is being used to measure the angle of the driveshaft at the rear U-joint.

U-JOINT WORKING ANGLES

POSSIBLE CAUSES OF INCORRECT U-JOINT ANGLES

Unequal or incorrect U-joint working angles can cause severe vibrations. Driveshaft and U-joint angles may change from the original factory setting due to one or more of the following:

1. Defective or collapsed engine or transmission mounts
2. Defective or sagging springs, especially the rear springs due to overloading or other causes
3. Accident damage or other changes to the chassis of the vehicle
4. Vehicle modification that raises or lowers the ride height

Replace any engine or transmission mount that is cracked or collapsed. When a mount collapses, the engine drops from its original location. The collapsed mount causes a change in the driveshaft angles are changed and a vibration may be felt.

Rear springs often sag after many years of service or after being overloaded. This is especially true of pickup trucks. Many people carry as much as the cargo bed can hold, often exceeding the factory-recommended carry capacity or gross vehicle weight (GVW) of the vehicle.

To measure U-joint and driveshaft angles, the vehicle must be hoisted using an axle contact or drive-on-type lift so as to maintain the same driveshaft angles as the vehicle has while being driven.

MEASURING THE WORKING ANGLES

The working angles of the two U-joints on a driveshaft should be within 1/2 degree of each other in order to cancel out speed changes. ● **SEE FIGURE 124–14.**

To measure the working angle of a U-joint, follow these steps:

STEP 1 Place an **inclinometer** (a tool used to measure angles) on the rear U-joint bearing cap. Level the bubble and read the angle. ● **SEE FIGURE 124–15**; the pictured reading is 19.5 degrees.

STEP 2 Rotate the driveshaft 90 degrees and read the angle of the rear yoke. For example, this reading is 17 degrees.

STEP 3 Subtract the smaller reading from the larger reading to obtain the working angle of the joint. In this example, it is 2.5 degrees (19.5 degrees − 17 degrees = 2.5 degrees).

Repeat the same procedure for the front U-joint. The front and rear working angles should be within 0.5 degrees. If the two working angles are not within 0.5 degrees, shims can be added to bring the two angles closer together. The angle of the rear joint is changed by installing a tapered shim between the leaf spring and the axle, as shown in ● **FIGURE 124–16.**

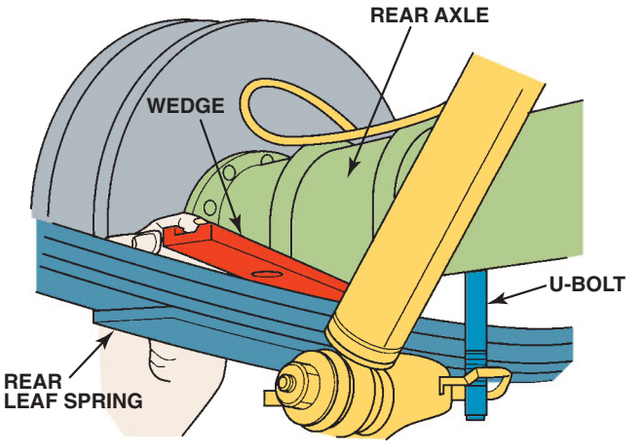

FIGURE 124–16 Placing a tapered metal wedge between the rear leaf spring and the rear axle pedestal to correct rear U-joint working angles.

CAUTION: Use caution whenever using wedges between the differential and the rear leaf spring to restore the correct U-joint working angle. Even though wedges are made to raise the front of the differential, the tilt often prevents rear-end lubricant from reaching the pinion bearing, resulting in pinion bearing noise and eventual failure.

The angle of the front joint is changed by adding or removing shims from the mount under the transmission. ● **SEE FIGURE 124–17.**

CV JOINT DIAGNOSIS

When a CV joint wears or fails, the most common symptom is noise while driving. An outer fixed CV joint will most likely be heard when turning sharply and accelerating at the same time. This noise is usually a clicking sound. While inner joint failure is less common, a defective inner CV joint often creates a loud clunk while accelerating from rest. To help verify a defective joint, drive the vehicle in reverse while turning and accelerating. This almost always will reveal a defective outer joint.

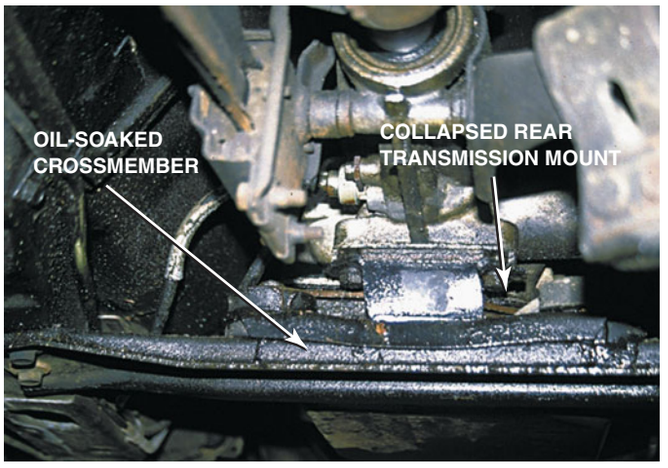

FIGURE 124–17 A transmission oil pan gasket leak allowed automatic transmission fluid (ATF) to saturate the rear transmission mount rubber, causing it to collapse. After replacing the defective mount, proper driveshaft angles were restored and the driveline vibration was corrected.

TECH TIP

Quick and Easy Backlash Test

Whenever a driveline clunk is being diagnosed, one possible cause is excessive backlash (clearance) between the ring gear teeth and differential pinion teeth in the differential. Another common cause of excessive differential backlash is too much clearance between differential carrier pinion teeth and side gear teeth. A quick test to check backlash involves three easy steps:

STEP 1 Hoist the vehicle on a frame contact lift, allowing the drive wheels to be rotated.

STEP 2 Have an assistant hold one drive wheel and the driveshaft to keep them from turning.

STEP 3 Move the other drive wheel, observing how far the tire can rotate. This is the amount of backlash in the differential; it should be less than 1 in. (25 mm) of movement measured *at the tire.*

If the tire can move more than 1 in. (25 mm), then the differential should be inspected for wear and parts should be replaced as necessary. If the tire moves *less* than 1 in. (25 mm), then the backlash between the ring gear and pinion is probably *not* the cause of the noise.

REPLACEMENT SHAFT ASSEMBLIES

Front-wheel-drive vehicles were widely used in Europe and Japan long before they became popular in North America. The standard repair procedure used in these countries is the replacement of the entire drive assembly if there is a CV joint failure. Replacement boot kits are rarely seen in Europe because it is felt that even a slight amount of dirt or water inside a CV joint is unacceptable. Vehicle owners simply wait until the joint wear causes severe noise, and then the entire assembly is replaced.

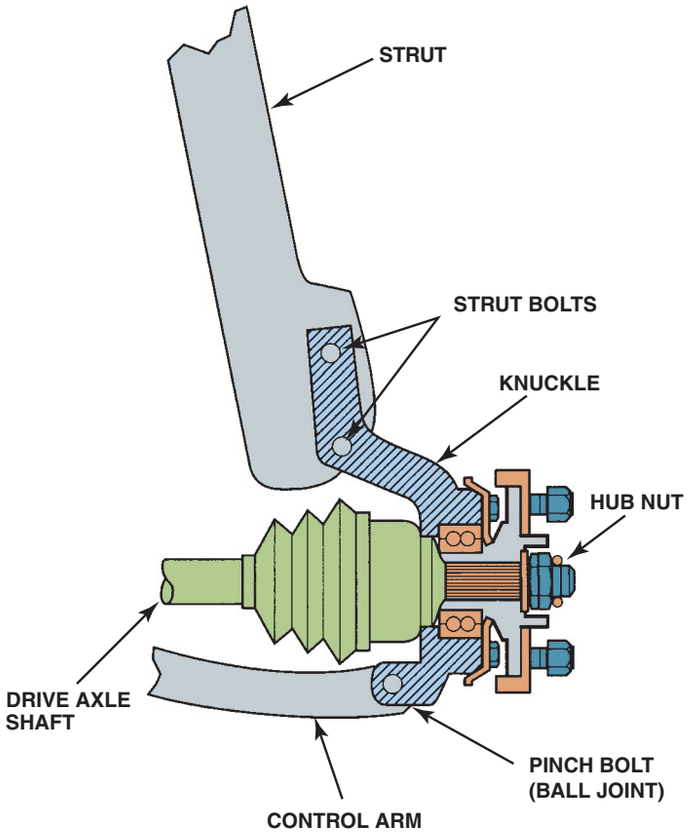

FIGURE 124–18 The hub nut must be removed before the hub bearing assembly or drive axle shaft can be removed from the vehicle.

The entire drive axle shaft assembly can easily be replaced and the defective unit can be sent to a company for remanufacturing. Even though cost to the customer is higher, the parts and repair shop does not have to inventory every type, size, and style of boot kit and CV joint. Service procedures and practices therefore vary according to location and the availability of parts. For example, some service technicians use replacement drive axle assemblies from salvage yards with good success.

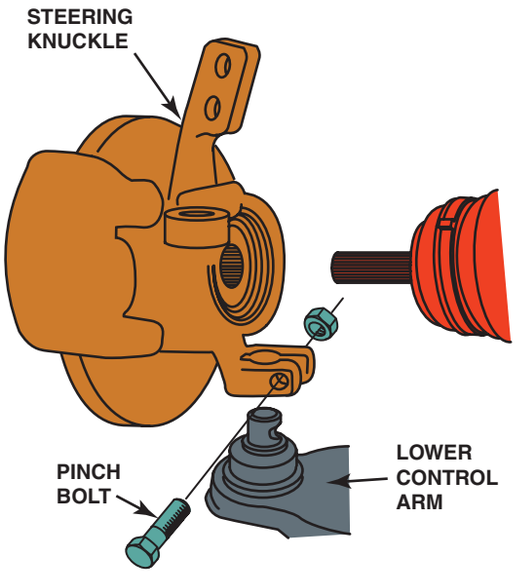
NOTE: Some drive axle shafts have a weight attached between the inner and outer CV joints. This is a dampener weight. It is not a balance weight, and it need not be transferred to the replacement drive axle shaft (half shaft) unless instructed to do so in the directions that accompany the replacement shaft assembly.

CV JOINT SERVICE

The hub nut must be removed whenever servicing a CV joint or shaft assembly on a front-wheel-drive vehicle. Since these nuts are usually torqued to almost 200 lb-ft (260 N-m), keep the vehicle on the ground until the hub nut is loosened and then follow these steps (● **SEE FIGURE 124–18**):

STEP 1 Remove the front wheel and hub nut.

NOTE: Most manufacturers warn against using an air impact wrench to remove the hub nut. The impacting force can damage the hub bearing.



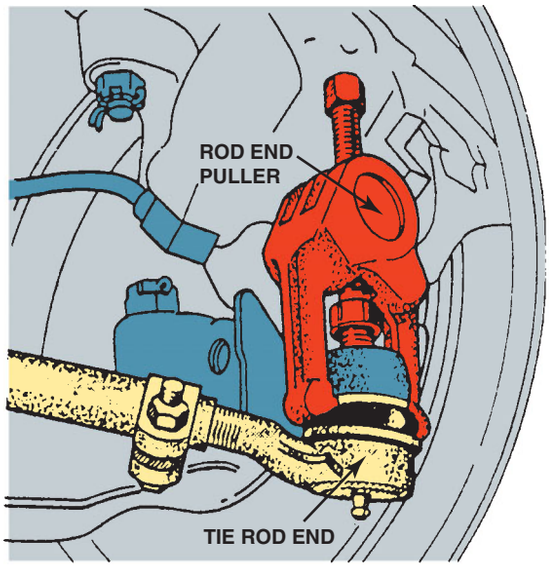


FIGURE 124–19 Many knuckles are attached to the ball joint on the lower control arm by a pinch bolt.

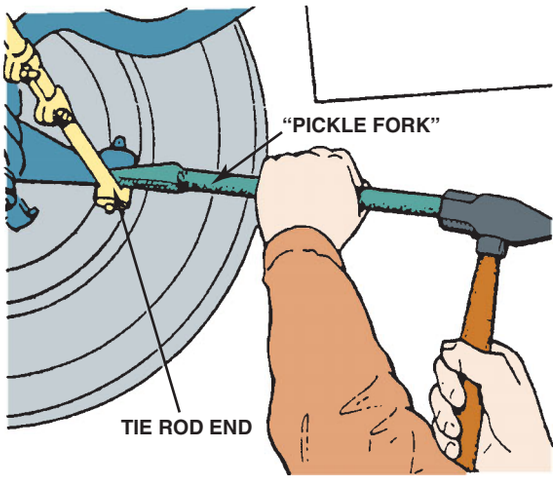

FIGURE 124–20 The preferred method for separating the tie rod end from the steering knuckle is to use a puller such as the one shown. A "pickle-fork"-type tool should be used only if the tie rod is going to be replaced. A pickle-fork-type tool can damage or tear the rubber grease boot. Striking the tie rod end with a hammer while holding another hammer behind the joint to shock and break the taper from the steering knuckle can also be used.

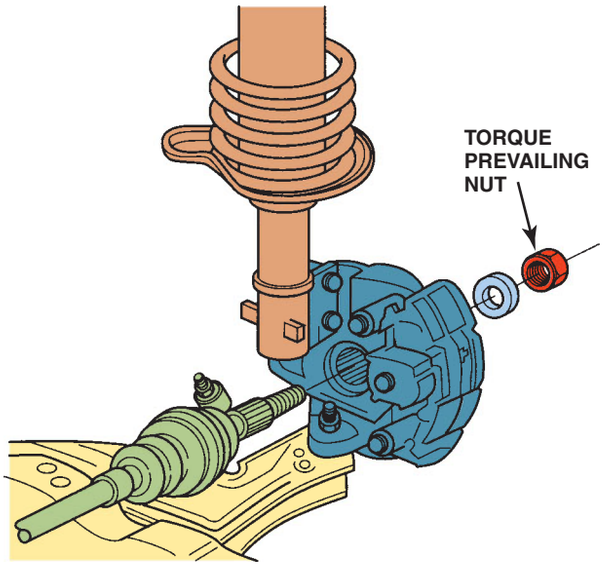

FIGURE 124–21 Many drive axles are retained by **torque prevailing nuts** that must not be reused. Torque prevailing nuts are slightly deformed or contain a plastic insert that holds the nut tight (retains the torque) to the shaft without loosening.

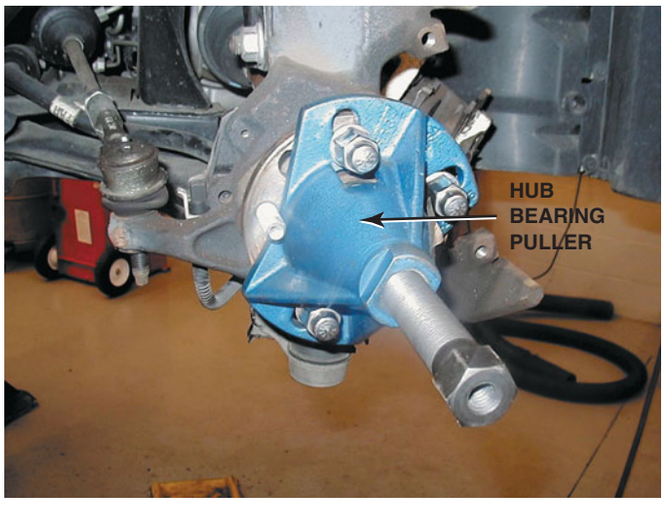

FIGURE 124–22 A special General Motors tool is being used to separate the drive axle shaft from the wheel hub bearing.

STEP 2 To allow the knuckle room to move outward enough to remove the drive axle shaft, some or all of the following will have to be disconnected:

- **a.** Lower ball joint or **pinch bolt** (● **SEE FIGURE 124–19**).
- **b.** Tie rod end (● **SEE FIGURE 124–20**).
- **c.** Stabilizer bar link.
- **d.** Front disc brake caliper.

STEP 3 Remove the splined end of the axle from the hub bearing. Sometimes a special puller may be necessary, but in most cases the shaft can be tapped inward through the hub bearing with a light hammer and a brass punch can be used. To protect the threads of the drive axle shaft, install the hub nut temporarily. ● **SEE FIGURES 124–21 AND 124–22**.

STEP 4 Use a prybar or special tool with a slide hammer, as shown in ● **FIGURE 124–23**, and remove the inner joint from the transaxle.

STEP 5 Disassemble, clean, and inspect all components. ● **SEE FIGURES 124–24 THROUGH 124–30**.

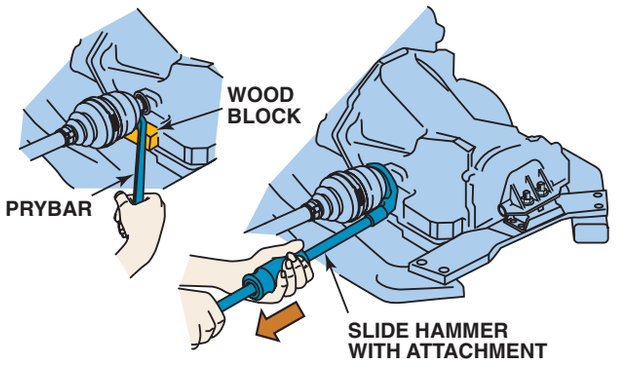

FIGURE 124–23 Most inner CV joints can be separated from the transaxle with a prybar.

FIGURE 124–24 When removing a drive axle shaft assembly, use care to avoid pulling the plunge joint apart.

FIGURE 124–25 If other service work requires that just one end of the drive axle shaft be disconnected from the vehicle, be sure that the free end is supported to prevent damage to the protective boots or allowing the joint to separate.

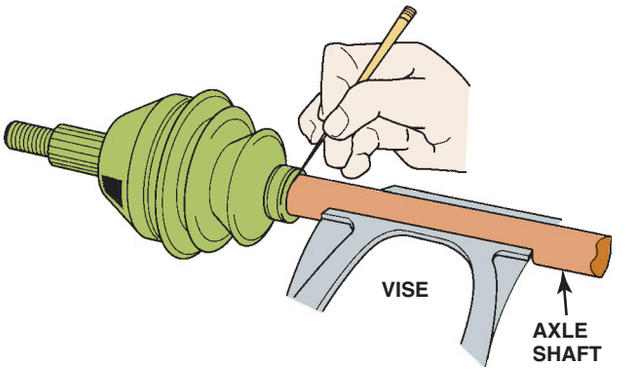

FIGURE 124–26 With a scribe, mark the location of the boots before removal. The replacement boots must be in the same location.

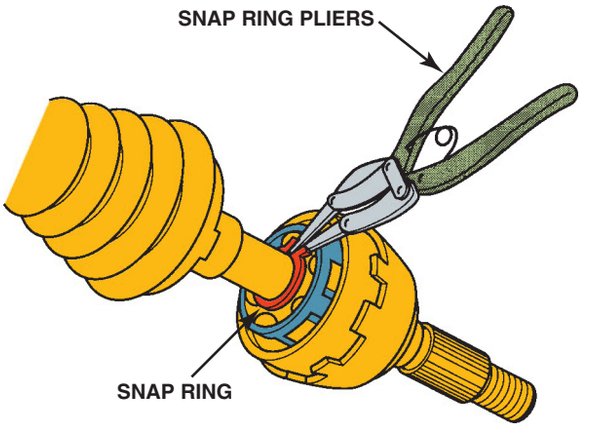

FIGURE 124–27 Most CV joints use a snap ring to retain the joint on the drive axle shaft.

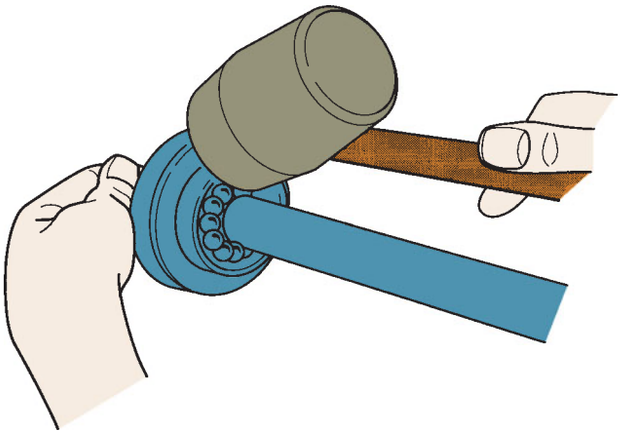

FIGURE 124–28 After releasing the snap ring, most CV joints can be tapped off the shaft using a brass or shot-filled plastic (dead-blow) hammer.

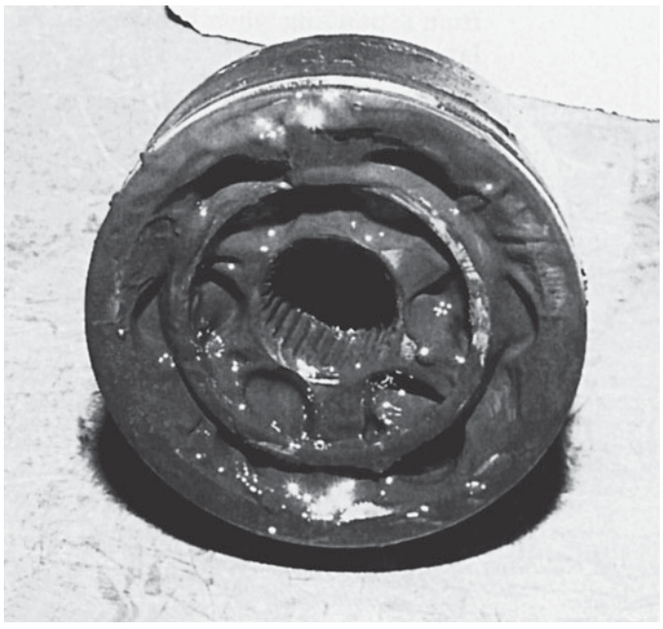

FIGURE 124–29 Typical outer CV joint after removing the boot and the joint from the drive axle shaft. This joint was removed from the vehicle because a torn boot was found. After disassembly and cleaning, this joint was found to be OK and was put back into service. Even though the grease looks terrible, there was enough grease in the joint to provide enough lubrication to prevent any wear from occurring.

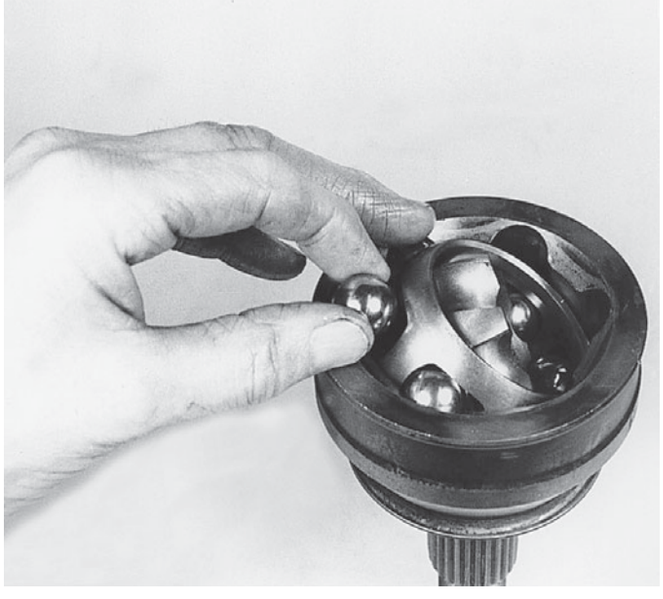

FIGURE 124–30 The cage of this Rzeppa-type CV joint is rotated so that one ball at a time can be removed. Some joints require that the technician use a brass punch and a hammer to move the cage.

STEP 6 Replace the entire joint if there are *any* worn parts. Pack *all* the grease that is supplied into the assembly or joint. ● **SEE FIGURE 124–31**. Assemble the joint and position the boot in the same location as marked. Before clamping the last seal on the boot, be sure to release trapped air to prevent the boot from expanding when heated and collapsing when cold. This is sometimes called *burping the boot.* Clamp the boot according to the manufacturer's specifications.

STEP 7 Reinstall the drive axle shaft in the reverse order of removal, and torque the drive axle nut to factory specifications. ● **SEE FIGURE 124–32**.

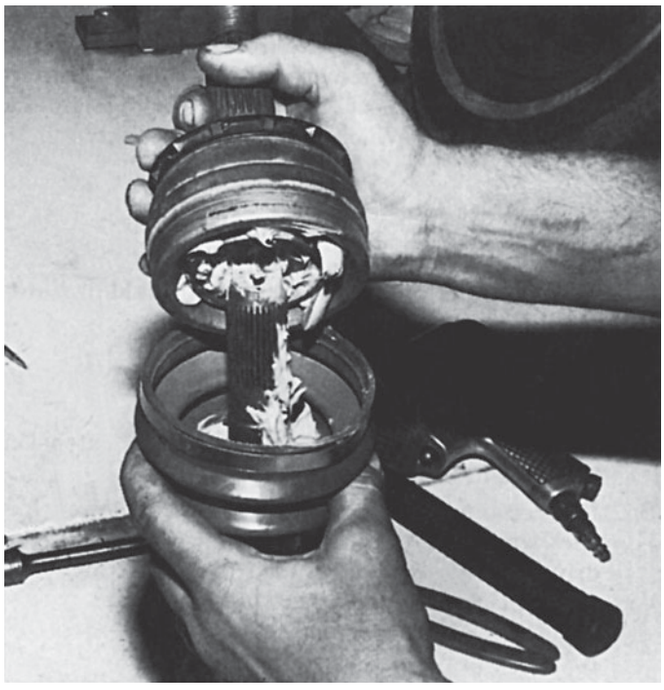

FIGURE 124–31 Be sure to use *all* of the grease supplied with the replacement joint or boot kit. Use only the grease supplied and do not use substitute grease.

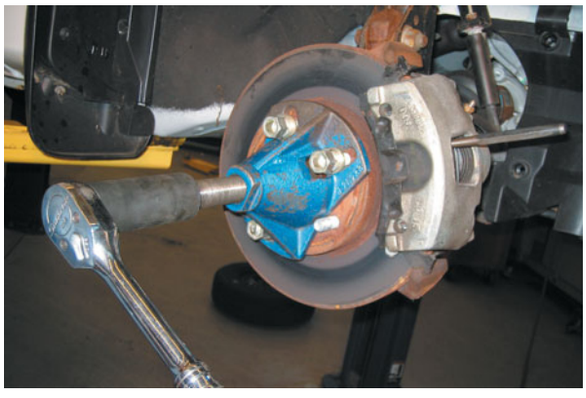
FIGURE 124–32 A screwdriver is shown, but a punch would be better, to keep the rotor from rotating while removing or installing the drive axle shaft spindle nut.

FIGURE 124–33 The engine had to be raised higher to get the new (noncollapsed) engine mount installed.

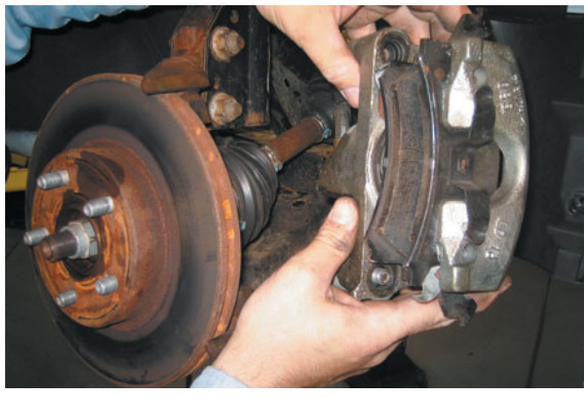
REAL WORLD FIX

The Vibrating Buick

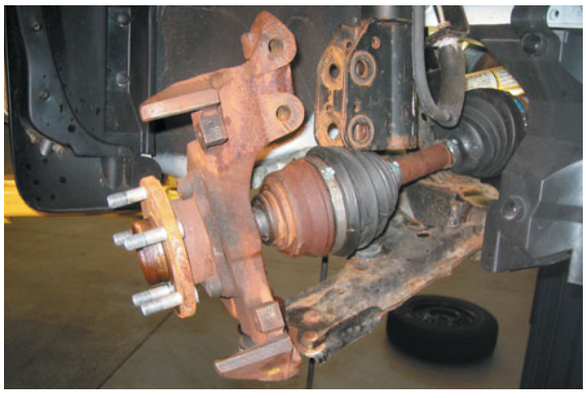
The owner of a front-wheel-drive Buick complained that it vibrated during acceleration only. The vehicle would also pull toward one side during acceleration. An inspection discovered a worn (cracked) engine mount. After replacing the mount, the CV joint angles were restored and both the vibration and the pulling to one side during acceleration were solved. ● **SEE FIGURE 124–33.**



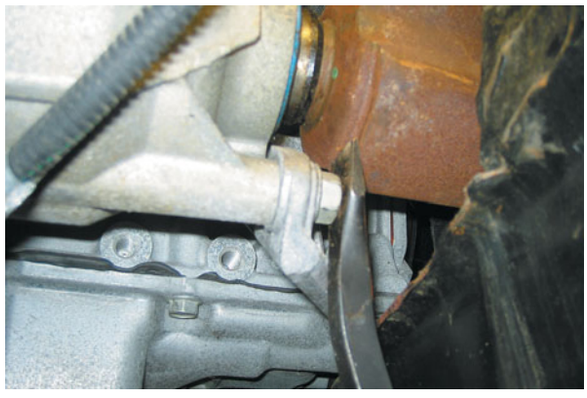
DRIVE AXLE SHAFT REPLACEMENT



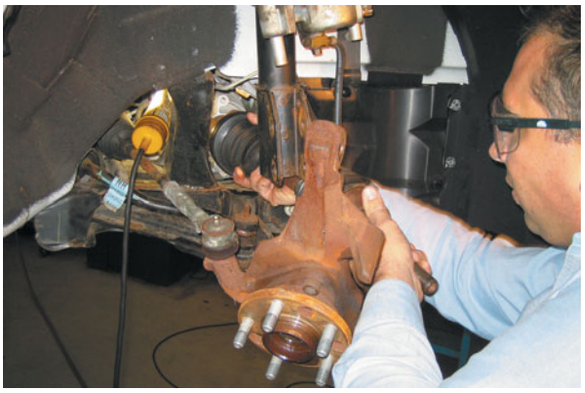
1 Tools needed to replace a drive axle shaft on a General Motors vehicle include a punch, sockets, plus a prybar bearing/axle shaft special tool.



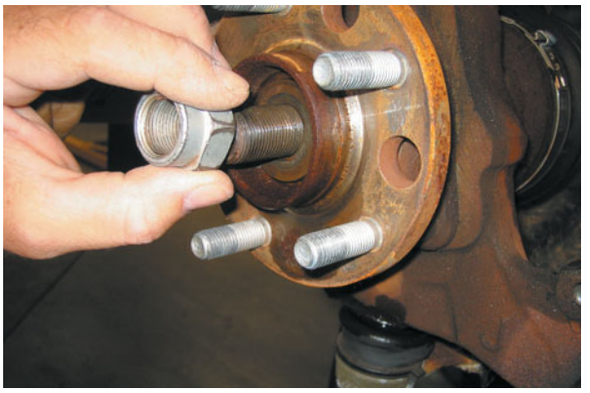
2 The drive axle shaft retaining nut can be loosened with the tire on the ground, or use a drift inserted into the rotor cooling fins before removing the nut.



3 Using a special tool to push the drive axle splines from the bearing assembly.



4 Remove the disc brake caliper and support it out of the way. Then, remove the disc brake rotor.



5 To allow for the removal of the drive axle shaft, the strut is removed from the steering knuckle assembly.

6 A prybar is used to separate the inner drive axle shaft joint from the transaxle.

7 After the inner joint splines have been released from the transaxle, carefully remove the drive axle shaft assembly from the vehicle.

8 To install, reverse the disassembly procedure and be sure to install the washer under the retainer-nut, and always use a new prevailing torque nut.

9 Reinstall the disc brake rotor and caliper and then torque the drive axle shaft retaining nut to factory specifications.

REVIEW QUESTIONS

1. List two items that should be checked when inspecting a driveshaft.
2. List the steps necessary to measure driveshaft U-joint working angles.
3. Describe how to replace a Cardan-type U-joint.
4. Explain the proper steps to perform when replacing a CV joint.

CHAPTER QUIZ

1. Two technicians are discussing U-joints. Technician A says that a defective U-joint could cause a loud clunk when the transmission is shifted between Drive and Reverse. Technician B says a worn U-joint can cause a clicking sound often when driving the vehicle in reverse. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. Incorrect or unequal U-joint working angles are most likely to be caused by _____.
   a. A bent driveshaft
   b. A collapsed engine or transmission mount
   c. A dry output shaft spline
   d. Defective or damaged U-joints
3. A defective outer CV joint will usually make a _____.
   a. Rumbling noise
   b. Growling noise
   c. Clicking noise
   d. Clunking noise
4. The last step after installing a replacement CV boot is to _____.
   a. "Burp the boot"
   b. Lubricate the CV joint with chassis grease
   c. Mark the location of the boot on the drive axle shaft
   d. Separate the CV joint before installation
5. A Cardan-type U-joint may require what tool(s) to replace? _____
   a. A special tool
   b. A torch
   c. A press or a vise
   d. May require any of the above
6. What needs to be removed to replace a drive axle shaft from a front-wheel-drive vehicle?
   a. Tie rod end
   b. Lower control arm or ball joint
   c. Hub nut
   d. All of the above
7. The splines of the driveshaft yoke should be lubricated to prevent _____.
   a. A vibration
   b. Spline bind
   c. Rust
   d. Transmission fluid leaking from the extension housing
8. It is recommended by many experts that an air impact wrench *not* be used to remove or install the drive axle shaft nut because the impacting force can damage the hub bearing.
   a. True
   b. False
9. Front and rear driveshaft U-joint working angles should be within _____ degrees of each other.
   a. 0.5
   b. 1.0
   c. 3.0
   d. 4.0
10. A defective (collapsed) engine mount on a front-wheel-drive vehicle can cause a vibration.
    a. True
    b. False

chapter 125 DIFFERENTIALS

OBJECTIVES: **After studying Chapter 125, the reader will be able to:** • Prepare for ASE Manual Drive Train and Axles (A3) certification test content area "E" (Rear Axle Diagnosis and Repair). • Describe how the differential allows engine torque to be applied to both drive wheels and still allow a difference in the speed of the drive wheels during cornering. • Discuss differential seals and bearings. • Explain how a limited slip-type differential works. • Determine the rear axle ratio. • Perform a tooth contact pattern check and determine corrective action. • Describe how to determine proper drive pinion gear depth. • Explain how to achieve proper drive pinion bearing preload. • Describe how to adjust the ring gear position to provide the proper backlash.

KEY TERMS: Axle ratio 1519 • Coast (or concave) side 1518 • Companion flange 1521 • Crown 1518 • Diff 1517 • Differential case 1517 • Drive (or convex) side 1518 • Drive pinion gear 1517 • Floating position 1518 • Heel 1518 • Hunting gear sets 1519 • Hypoid gear set 1517 • Lap 1519 • Nonhunting gear sets 1519 • Partially nonhunting gear sets 1519 • Pinion gear 1517 • Pinion shaft 1517 • Preloaded clutch 1520 • Rear end 1517 • Ring gear 1517 • Ring gear runout 1525 • Root 1518 • Side gears 1517 • Spider gears 1517 • Straddle-mounted pinion 1522 • Toe 1518 • Turning torque 1529 • Viscous coupling 1521

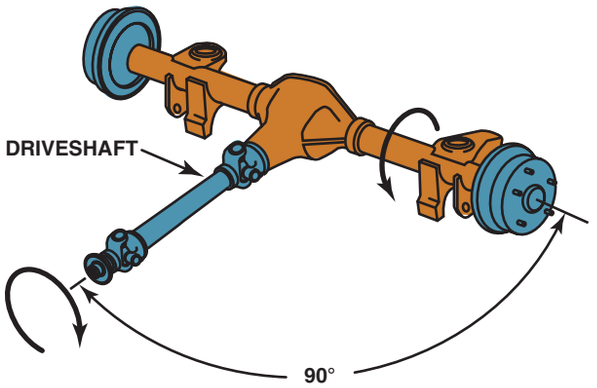


FIGURE 125–1 The differential assembly changes the direction of engine torque and increases the torque to the drive wheels.

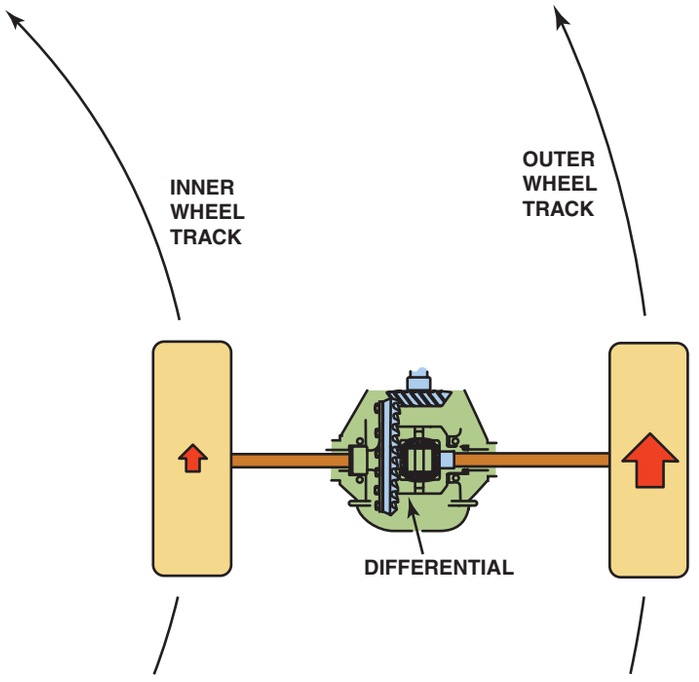

FIGURE 125–2 The difference between the travel distance of the drive wheels is controlled by the differential.

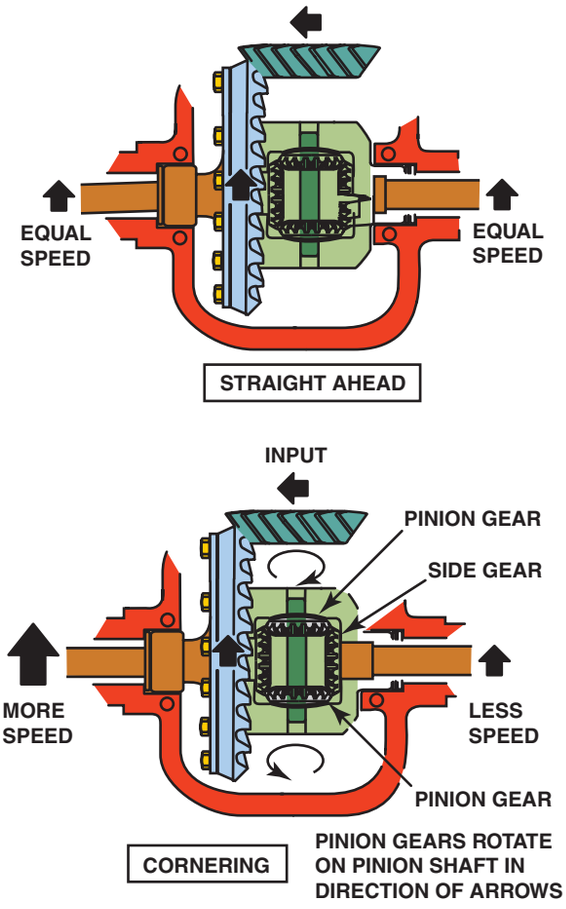

FIGURE 125–3 When the vehicle turns a corner, the inner wheel slows and the outer wheel increases in speed to compensate. This difference in rotational speed causes the pinion gears to "walk" around the slower side gear.

NOTE: The differential used in most front-wheel-drive vehicles is incorporated into the transaxle assembly and is called the final drive assembly. The purpose and function of this final drive assembly is similar to the differential assembly used in rear-wheel-drive vehicles.

DIFFERENTIALS

The differential allows engine torque to be applied to both drive axles, which rotate at varying speeds during cornering and while traveling over bumps and dips in the road. The differential also changes the direction of engine torque 90° from the rotation of the driveshaft lengthwise with the vehicle. These two purposes of a differential can be summarized as follows:

- To change the direction of engine torque (● **SEE FIGURE 125–1**).
- To allow the drive wheels to rotate at different speeds (● **SEE FIGURE 125–2**).

A differential is a mechanical addition and subtraction assembly. By splitting the engine torque to the drive wheels when the vehicle is turning a corner, the torque forces cause the side gear and pinion gears to subtract torque from one side and add torque to the opposite side. ● **SEE FIGURE 125–3.**

PARTS OF A DIFFERENTIAL

A differential is also called a **rear end** or abbreviated simply as a **diff.** Whenever any vehicle makes a turn, the outside wheel must travel a greater distance than the inside wheel. The driveshaft applies torque to the **drive pinion gear** that meshes below the center line of a **ring gear** as shown in ● **FIGURE 125–4.** This type of gear set is called a **hypoid gear set** and requires gear lubrication specifically designed for this type of service. The ring gear is attached to a **differential case** that also contains small beveled **spider gears** or **pinion gears.** A **pinion shaft** passes through the two pinion gears in the case. In mesh with the pinion gears are two **side gears** that are splined to the inner ends of the axles. ● **SEE FIGURE 125–5.**

THE PINION AND RING GEARS DURING OPERATION

During operation, the position of the drive pinion gear on the ring gear changes. The ring gear mounts onto the differential case as shown in ● **FIGURE 125–6** on page 1518. Each slanted ring gear tooth has

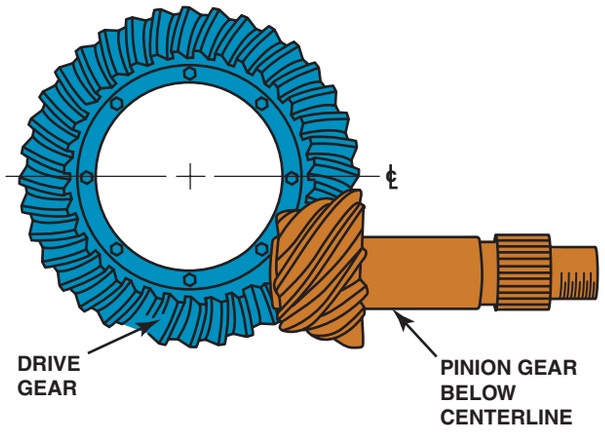

FIGURE 125–4 A hypoid gear set uses a drive pinion that meshes with the ring gear below the center line of the ring gear.

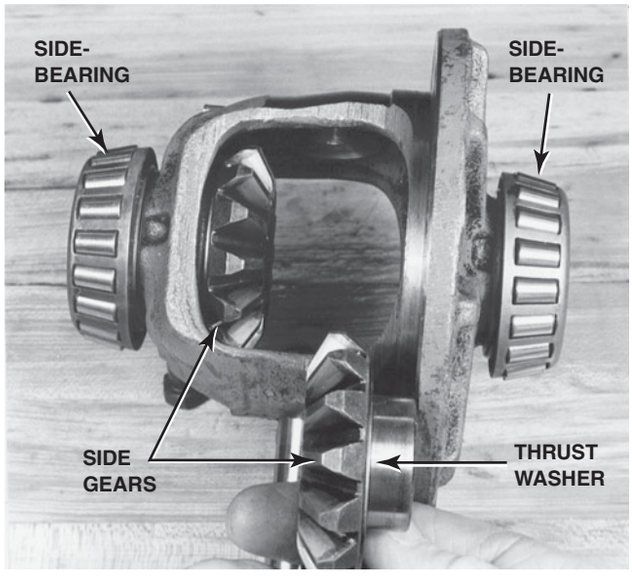

FIGURE 125–5 The differential case provides the support for the ring gear, side bearings, and side gears.

two ends. Its **toe** is closest to the ring gear center; its **heel,** closest to the outside circumference. The tooth **root** is the depression lying between two teeth, and the **crown** is the very top of each tooth.

While a vehicle accelerates, the drive pinion contacts the ring teeth on its **drive,** or **convex side.** While decelerating, the drive pinion contacts the ring teeth on its **coast,** or **concave side.** ● **SEE FIGURE 125–7.** The intermediate position between drive and coast, when neither the ring gear nor the pinion is driving each other, is called the **"floating" position.**

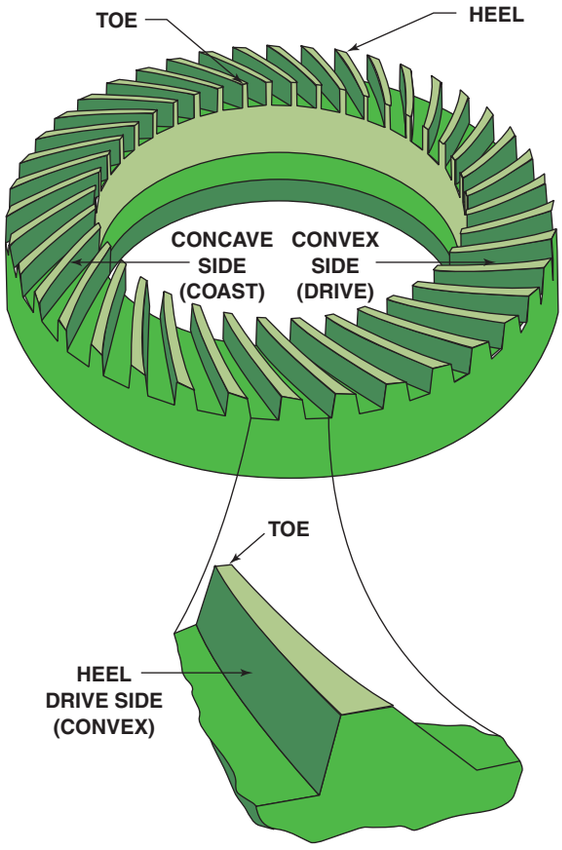

FIGURE 125–7 The drive side is the convex side of the ring gear except for some front axles used in four-wheel vehicles, and they often use the concave side on the drive side.

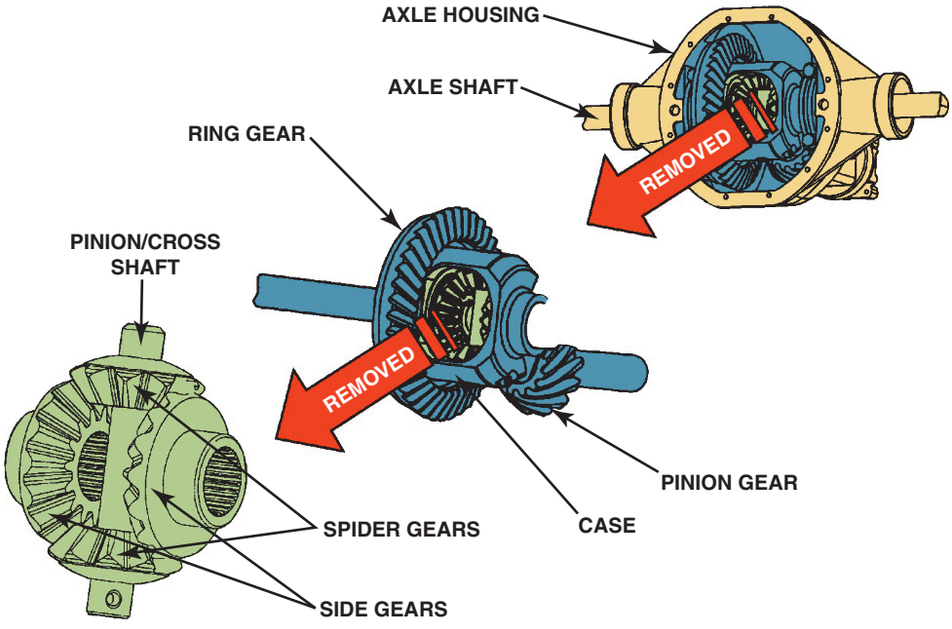

FIGURE 125–6 The relationship among the ring gear and drive pinion as well as the side and spider gears.

DIFFERENTIAL GEAR RATIOS

The final gear reduction in the drive train occurs in the differential assembly. The amount of torque a gear set delivers depends on the gear ratio between the drive pinion gear and the driven ring gear. The gear ratio of the final drive (differential) is called the **axle ratio.** To determine the axle ratio, divide the number of teeth of the ring gear (driven gear) by the number of teeth of the drive pinion gear (driving gear):

$$\frac{\text{Ring gear (41 teeth)}}{\text{Pinion gear (10 teeth)}} = 4.10 \text{ (Axle ratio)}$$

The higher the axle ratio number, the faster the engine rotates for each rotation of the drive wheels. See the High-Performance Tip "Change the Axle Ratio."

RING AND PINION GEAR SET TYPES The final drive gear ratio determines how many times a drive pinion tooth will make contact with a particular ring gear tooth during one revolution. This affects final drive gear set manufacture and service.

Final drive gear sets may be divided into three types, depending on the final drive gear ratio.

1. **Hunting gear sets** are gear sets with final drive ratios expressible in a fraction that cannot be reduced to any lower terms. An example of a hunting gear set is one that has 41 teeth on the ring gear and 11 teeth on the drive pinion. This combination creates a 3.73:1 axle ratio. This type of gear set requires no timing marks or alignment during assembly. As the pinion gear drives the ring gear, each pinion tooth will hunt for, or seek, contact with every ring gear tooth.
2. **Nonhunting gear sets** are gear sets with final drive ratios expressible as a whole number. An example of a nonhunting gearset is a differential that uses 39 teeth on the ring gear and 13 teeth on the pinion gear which gives a 3.00:1 gear ratio. Nonhunting gear sets require timing marks. As the pinion gear drives the ring gear, each pinion tooth contacts only a few ring gear teeth during each revolution.
3. **Partially nonhunting gear sets** are gear sets with final drive ratios expressible as a reducible fraction not equaling a whole number. An example of a partial nonhunting gearset is an axle ratio of 3.50:1.

Partially nonhunting gear sets also require timing marks. During final drive operation, each pinion tooth contacts only some of the ring pinion teeth. For the pinion teeth to make contact with the highest number of ring gear teeth, the pinion gear must drive the ring gear more than one revolution.

On nonhunting and partially nonhunting gears, manufacturers **lap** the contacting gear teeth to decrease wear. For this reason, these gear sets are marked to ensure proper alignment during assembly procedures. To preserve the wear patterns, the gear sets should be reassembled using the same alignment. This prolongs the life of the gear set and decreases operational noise.

DIFFERENTIALS

PURPOSE AND FUNCTION While a vehicle travels straight ahead, the speed of each driven wheel must be allowed to vary slightly as they go over bumps, potholes, railroad tracks, and other road surface irregularities. While cornering, the wheels must be able to turn at much greater differences in speed. Without some mechanism to allow for a difference in speed between the wheels, the left wheel would skid through the turn.

Inside the differential gear housing four to six bevel gears help drive the axles. In most differentials, there are two bevel gears called pinions that are constantly meshed with a beveled axle side gear on each axle. The pinion and axle side gears are contained in a housing called the carrier or case.

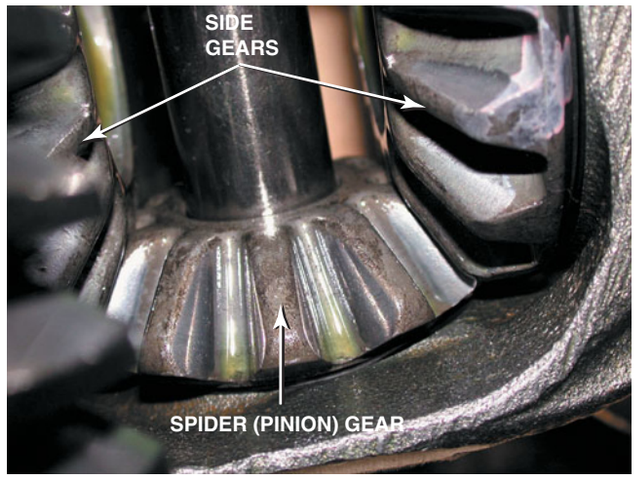

FIGURE 125–8 A close-up view of the side gears and spider (pinion) gear. Note the ridges on the gear teeth. These ridges are manufactured into the gear teeth to help retain lubricant so that no metal-to-metal contact occurs.

HIGH PERFORMANCE TIP **Change the Axle Ratio**

To increase vehicle performance, replace a high ratio (lower number) rear axle ratio with a lower ratio (higher number) rear axle. For example,

Stock rear end = 3.23:1 (drive pinion has 13 teeth and the ring gear has 42 teeth)

Replacement rear end = 3.73:1 (drive pinion has 11 teeth and the ring gear has 41 teeth)

The high-performance axle ratio (3.73:1) allows the engine to rotate faster than the stock 3.23:1 ratio. Because most engines produce greater torque with increasing RPM (up to a point), this allows more torque to be applied to the drive wheels. Not only is the engine producing more torque, but the higher-number gear ratio also multiplies the available torque times 3.73 instead of the original 3.23. However, there are several disadvantages associated with changing the rear end ratio:

- Decreased fuel economy
- Incorrect speedometer and odometer readings that can affect the shifting of the automatic transmission unless changes are made to the computer or vehicle speed sensors
- Increased engine noise due to the higher engine speed
- Increased engine wear, again due to the increased engine speed

If you can live with these disadvantages, a change in the rear end ratio generates a real performance gain.

TORQUE FLOW THROUGH A STANDARD OPEN DIFFERENTIAL Open differentials deliver equal torque to both wheels at all times. As the case rotates (driven by the engine through the ring and pinion gears), the cross-shaft applies a drive force to the spider gears. The two side gears apply reaction forces that counter this drive force. ● **SEE FIGURE 125–8.** Because the spider

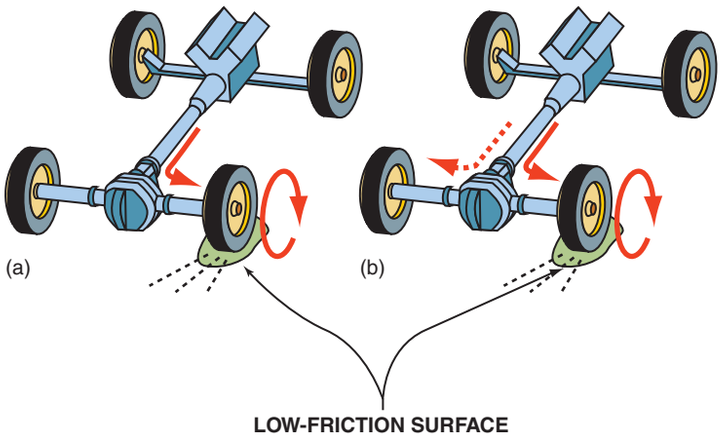

FIGURE 125–9 (a) A two-wheel-drive vehicle equipped with an open differential. (b) A two-wheel-drive vehicle equipped with a limited-slip differential.

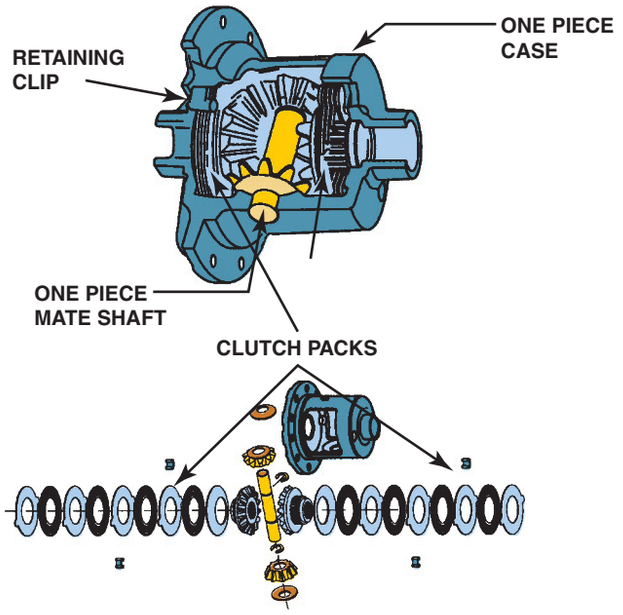

FIGURE 125–10 Trac-loc limited-slip differential. This type of limited-slip differential uses the preload force from a spring and the torque generated by the side gears as the two axles rotate at different rates to apply the clutches and limit the amount of difference in the speed of two axles.

gear is free to rotate about the cross-shaft, the two reaction forces are equal. As the side gear applies a force to the spider gear, the spider gear applies an equal and opposite force to the side gear. It is this force, on the side gear, that supplies the torque to the axle that drives the wheel. Because the force on each side gear is equal, the torque supplied to each wheel is also equal. This is true regardless of whether one wheel is rotating faster than the other or at the same speed.

TRAVELING STRAIGHT-AHEAD. Assuming that a vehicle has equal traction at both wheels, differential action does not occur. In other words, when traveling straight on smooth road surfaces the ring gear, carrier, and the drive axles are traveling at the same speed; they rotate as a unit and the spider gears are not rotating on the cross shaft.

TRAVELING AROUND CORNERS. The ability of the differential pinion gears to spin on their shafts allows each axle to rotate at a different speed.

Case speed is always equal to the average speed of the two side gears. Since the ring gear rotates with the case and each side gear rotates with its axle; when a vehicle corners, the outside wheel gains the same number of RPMs that the wheel on the inside loses, while ring gear RPM remains constant.

LIMITED SLIP DIFFERENTIALS

PURPOSE AND FUNCTION When a vehicle equipped with a standard differential spins a tire, the opposite wheel does not receive enough torque to move the vehicle. To solve this problem, most manufacturers use differentials that direct more power to the side gear attached to the spinning axle. Many differentials do this by forcing the side gear against the revolving case. This bypasses differential action, allowing the case to drive the side gear directly.

A limited-slip differential distributes torque to both wheels equally or unequally, allowing the wheels to turn at the same or at different speeds. ● **SEE FIGURE 125–9.**

The only means of having the standard differential apply different amounts of torque to each axle is to have the case drive the side gear directly, bypassing the pinion gears. One means of accomplishing this is to literally "push" the side gear out of mesh with the pinion gears against the rotating case.

PARTS AND OPERATION **Preloaded clutches** use two mechanisms to accomplish this action. First, a coil, Belleville, or leaf spring applies a force against the two side gears. ● **SEE FIGURE 125–10.** Second, a multidisc clutch pack or cones lie behind one or both of the side gears. Vehicle manufacturers refer to these differentials using various brand names, such as Positive Traction, Sure-Grip, Anti-Spin, and Traction-Lok.

When forces inside the differential push the side gear against the case, the clutch pack allows the gear to lock smoothly without jerking. The pack, lying between at least one of the backs of the side gears and the case, consists of two types of alternatively stacked steel discs with holes through their middle sections. The first is coated with friction material and the second is not. The interior splines of the friction disc holes mesh with the splines on the center hub protruding from the backside of the side gear. The holes of the steel discs are not splined. Instead, they have two or three tabs along their outside diameter that fit into slots machined into the differential case.

As the side gear is pushed farther against the case, each friction plate rubs against the steel plate in front of and behind it, gradually slowing the side gear's rotation until it smoothly locks against the case.

1. The rotating differential pinions apply pressure against the side gear. The amount of pressure depends on the traction beneath the tire connected to the side gear.
2. The spring applies the second force that allows the preloaded clutch to work. This spring, whether a coil, leaf, or Belleville, preloads the clutch discs, narrowing the clearances between them. Tighter springs cause the differential to lock up sooner than looser springs.

To vary the amount of traction a tire must have before its axle's side gear locks up, many differentials use adjustment shims. Available in different thicknesses, manufacturers install them between the rear of the clutch packs and the differential case. The thicker the shims, the sooner the differential locks up. Some differentials rely on the preload spring alone to determine when the side gear locks up. They use no shims.

During operation, the clutch discs slide against each other every time the vehicle turns and corners. This action creates friction, making it important to add the manufacturer-recommended lubricant that contains a friction modifier. This lubricant may already be included in the gear oil or may be a special additive. Using improper lubricants may cause the discs to wear prematurely and vibrate during turns.

CONE-TYPE The second type of preloading clutch differential uses two tapered cones instead of multidisc clutch packs. Positioned between the side gears and the case, the cone's tapered end fits inside a dished receptacle machined into the case. The same forces that push the side gears against the case in the clutch pack differential push the side gears against the case in the tapered-cone differential. When these forces press the cones into their dished receptacles, they come to a stop smoothly, locking the side gears to the case.

VISCOUS COUPLED LIMITED-SLIP UNITS Differentials can be designed to work on the principle of a **viscous coupling.** This design uses a series of closely positioned plates, which do not physically touch one another. Half of the plates are splined to the case, and the other half are alternately splined to each side gear. The plates are housed in a sealed chamber, which is filled with a thick and viscous silicone-based fluid. The silicone allows normal speed differences between two shafts, resisting high-speed differences associated with wheel spin on one shaft.

This type of viscous-coupled differential is used in the front differentials of some Japanese front-wheel-drive vehicles and in four-wheel-drive vehicles. See Chapter 99 for details.

THE EATON "LOCKER" DIFFERENTIAL The Eaton Locker's sturdier design makes it more efficient in transferring torque from the driveline to the axles while in the locked position than the clutch-type multidisc differential.

When a vehicle spins a rear wheel, both the preloaded multidisc differential and the Eaton "locker" compress their clutch packs lying between the side gears and the case. This allows the case to directly drive the axles, bypassing the effect of the rotating differential pinions.

The Eaton and preloaded multidisc differentials differ in how they compress their clutch packs. The preloaded multidisc uses either a coil, leaf, or Belleville spring to apply initial pressure against the side gears and the clutch pack. As the rotating pinion gears push against a slower moving side gear, it is forced against the case, thereby compressing the discs in the clutch pack together.

The Eaton differential, on the other hand, uses a unique mechanism to collapse the clutch packs. ● **SEE FIGURE 125–11.** It has four parts:

- A governor with two flyweights
- A cam plate and cam side gear on the left side
- A latching bracket
- A thrust block

These parts allow the Eaton to momentarily shift into the locked mode when side gear and case rotational speeds differ by more than 100 RPM.

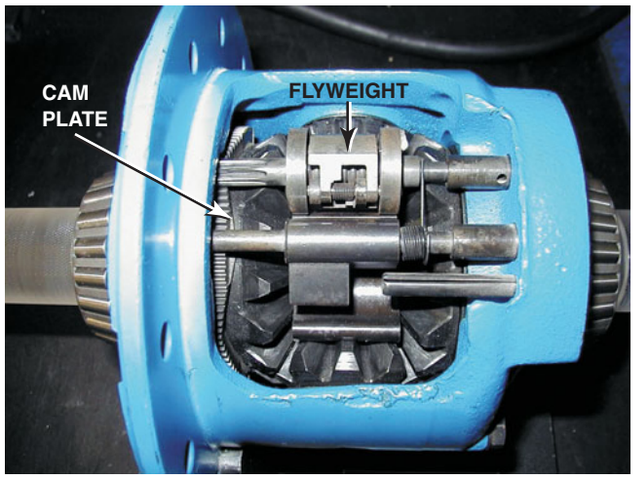

FIGURE 125–11 An Eaton locker differential.

REAL WORLD FIX

I Used to Have a Limited-Slip Differential

An owner of a Chevrolet S-10 pickup truck equipped with a V-6 and five-speed manual transmission complained that he used to be able to spin both rear tires on dry pavement, but lately only one tire spins. The service technician assigned to the repair order was very familiar with what might have occurred. Many General Motors pickup trucks are equipped with an Eaton locking differential that uses a torque limiting disc. The teeth of this disc are designed to shear to prevent the possibility of breaking an axle. ● **SEE FIGURE 125–12.**

The service procedure to correct the customer's concern is to replace the left-hand clutch plates. Usually, the shearing of the torque-linking teeth is associated with a loud bang in the rear axle. The differential will continue to operate normally as a standard (open) differential.

TORSEN DIFFERENTIALS The Torsen differential is a torque sensing, locking design that uses a set of worm side gears in mesh with individual worm wheel pinions that are supported by the differential case. ● **SEE FIGURE 125–13.** The pinions have spur gear sections machined on them at each end, which form the connection between left and right side pinions. Because of the worm and worm wheel configurations, the side gears can turn the pinions, but the pinions cannot turn the side gears. The result is a complex operation, which meets all drive requirements without excessive wheel slip.

This unit has been available as original equipment on several vehicles as well as for many aftermarket applications.

DIFFERENTIAL COMPONENTS

DRIVE PINIONS The drive pinion gear of the differential is driven by a flange often called a **companion flange.** The heavy bulk of the companion flange helps dampen vibrations and absorb

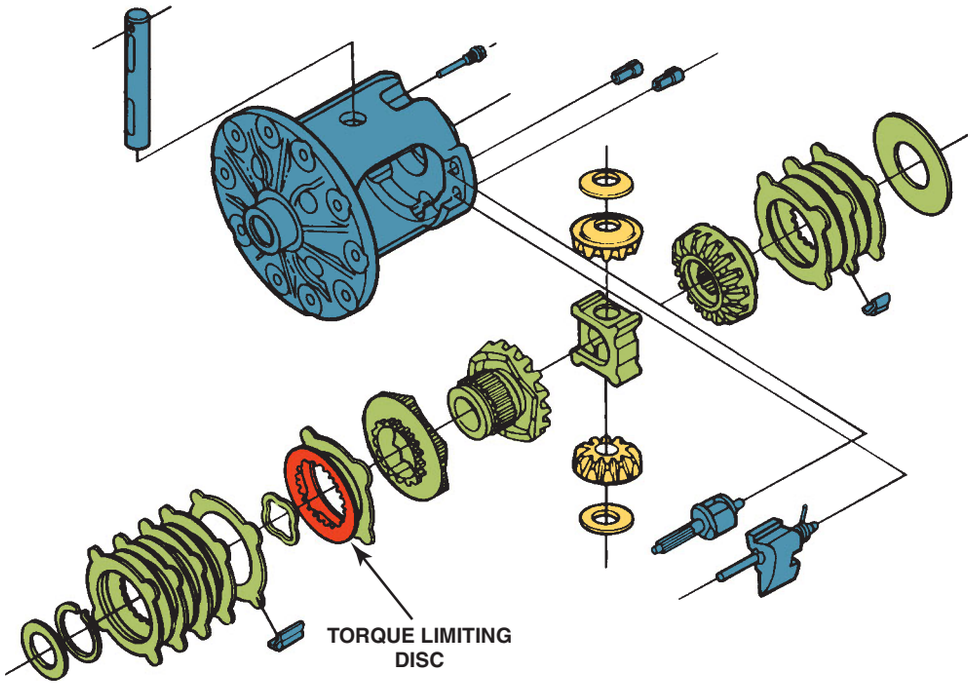

FIGURE 125–12 This Eaton design differential uses a torque-limiting disc to prevent the possibility of breaking an axle in the event of a high-torque demand. When the disc tangs shear, the differential will continue to function but as an open rather than as a limited-slip differential.

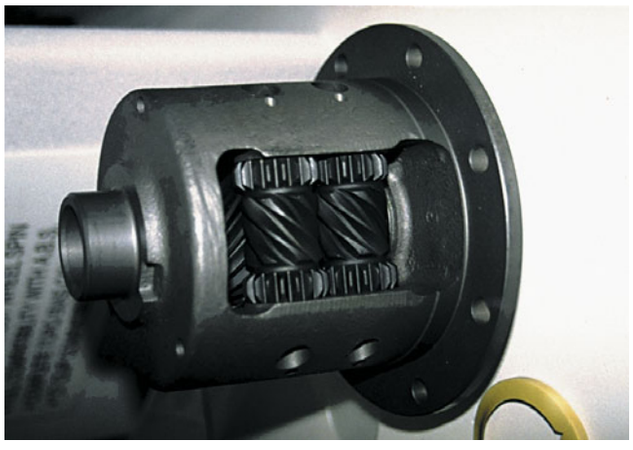

FIGURE 125–13 A Torsen differential. This type of differential provides torque to both drive wheels even if one tire is on ice. The complex system of gears allows this smooth transfer of torque without the use of clutches.

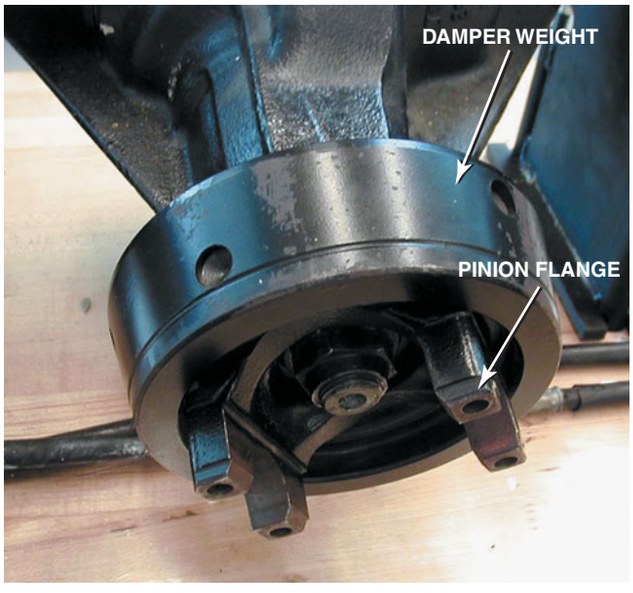

FIGURE 125–14 This pinion flange is equipped with a damper weight to help dampen driveline vibrations.

shocks in the driveline. ● **SEE FIGURE 125–14.** The final drive pinion shaft may be supported by bearings using one of two methods.

1. The first method and most common, uses two opposed taper roller bearings, with a collapsible (compressible) spacer separating the two inner races to support an overhung pinion. ● **SEE FIGURE 125–15.** The term "overhung" means all of the bearings supporting the pinion shaft lie on one side of the pinion gear. The bearings are preloaded, a state that minimizes wobble and endwise movement while the drive pinion shaft rotates.
2. The second method uses two opposed taper roller bearings to support a **straddle-mounted pinion,** but the distance between them is smaller than in the overhung design. Most noticeably, a third smaller bearing attaches to a stemlike machined pilot protruding from the gear-end of the drive pinion shaft. This third bearing, usually a straight roller type, fits into a bore

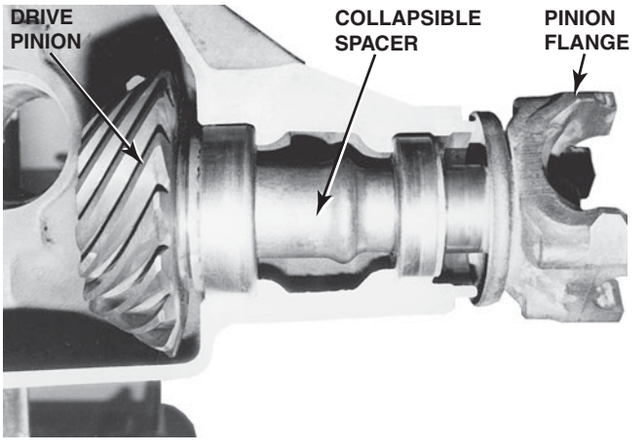

FIGURE 125–15 A collapsible spacer-type drive pinion shaft.

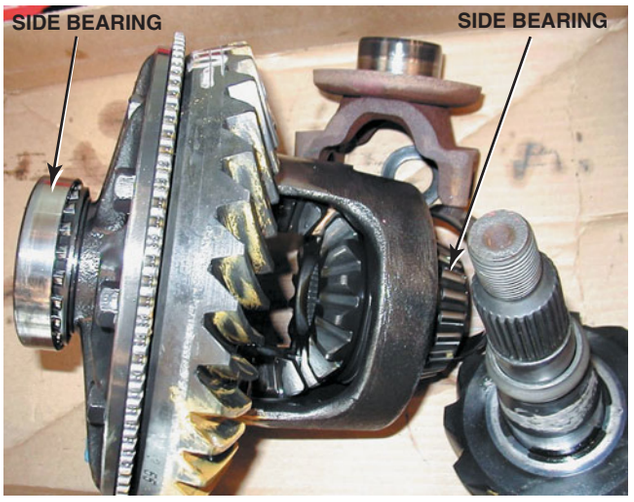

FIGURE 125–16 Side bearings are press fit on the differential case.

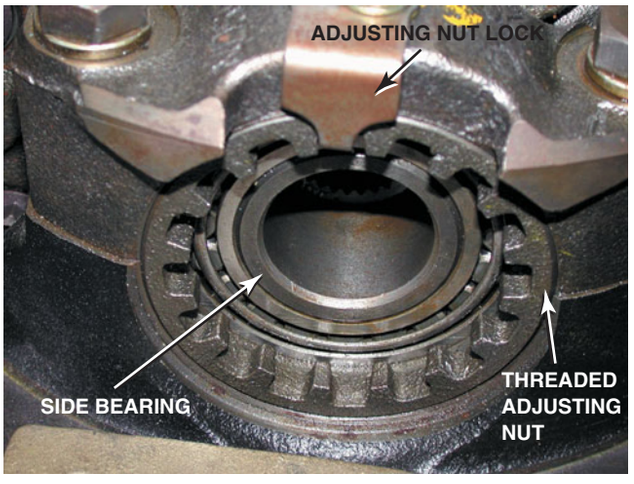

FIGURE 125–17 Some side bearings use threaded adjusters to adjust preload.

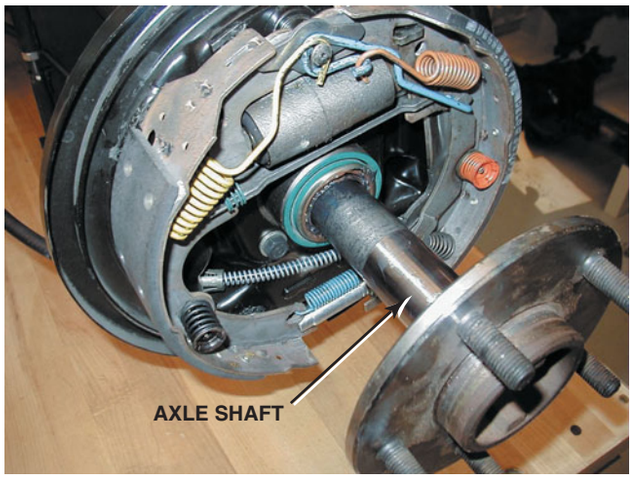
in the carrier. Unlike the overhung design, bearings supporting a straddle-mounted pinion lie on both sides of the pinion gear. Like the overhung design, a straddle-mounted pinion shaft usually has a compressible preloaded spacer positioned between the two larger differential case bearings. Straddle-mounted pinions are usually mounted in a pinion housing that can be removed from the carrier.

DRIVE PINION GEAR DEPTH The pinion shaft mounting method also determines how deeply the pinion gear meshes into the ring gear. This is called pinion depth and helps adjust the precise gear tooth relationship between the ring and pinion gears. You can vary the pinion depth adjustment by changing the thickness of a shim (spacer). This shim is located between the rear preloaded bearing and the pinion gear, or between the removable pinion housing and the carrier.

SIDE BEARINGS The differential case is supported by two side bearings pressed onto its sides. ● **SEE FIGURE 125–16.** These are usually tapered roller bearings and are preloaded to ensure case rotation without axial or radial movement.



Side bearing preload is adjusted either by threaded adjusting nuts as shown in ● **FIGURE 125–17,** or by placement of adjusting shims (spacers) on either side of the case between the bearing outer races and the inside of the carrier. The method used to adjust side bearing preload is also used to adjust ring gear-to-pinion backlash (tooth clearance between one gear and the other). This is necessary to ensure enough space between the teeth of the two gears to allow for expansion of the gear tooth dimensions as the unit warms up to operating temperature. When the unit is warm, there must be just enough space between the gear teeth to allow adequate lubrication of the tooth surfaces and still allow full tooth contact for good transfer of torque from one gear to the other. Too much clearance between the gears will allow one to travel too far before contacting the other when the powertrain goes from drive to coast and back again. Excess clearance can result in final drive noise and gear tooth damage.

DIFFERENTIAL AXLE BEARINGS

BALL BEARINGS/REAR AXLES If ball bearings are used, the bearing itself absorbs the radial forces. The bearing is placed on the axle and retained by a pressed-on collar. A stamped steel plate bolts to the axle housing and keeps the axle in place. The bearing is prelubricated when it is manufactured. An oil seal is located on the inboard side of the bearing retainer collar, and keeps the hypoid lubricant from reaching the bearing or the brake assembly. In this design, there is no axle shaft end play (thrust) adjustment.

STRAIGHT ROLLER BEARINGS/REAR AXLES If a straight roller bearing is used, the axle surface serves as the inner race. ● **SEE FIGURE 125–18.** The outer race is pressed into the housing, and a grease seal is pressed in afterward. The bearing is lubricated by the hypoid lubricant. This design uses a C-washer on the inboard end of the axle, which prevents the axle from moving outward. Outward thrust forces are taken by the C-washer through the axle's side gear and thrust washer, to the differential case and side bearing. Inward thrust forces are taken by the axle shaft inner end pushing on the spider pinion shaft, and passed on to the differential case and the opposite side bearing. There is no axle shaft end play adjustment with this design.

TAPERED ROLLER BEARINGS/REAR AXLES If a tapered roller bearing is used, axle shaft end play is adjustable. The bearing is pre-lubricated before it is installed and is held by a press fit on the axle shaft. A retaining ring is then pressed on the shaft next to the bearing to secure it in place. The axle is prevented from moving outward by a stamped steel retainer plate that bolts to the axle housing. The inner diameter of the plate is threaded to accept a bearing-adjusting nut, which is similar in appearance and function to a differential side bearing adjuster. A variation of this design has the end play adjustment made by shims between the axle housing and the brake backing plate. Thrust is taken from the inner end of the axle by a thrust block mounted on the spider pinion shaft, and passed on to the opposite axle, through its length to the opposite wheel bearing.

(a)

(b)

FIGURE 125–18 (a) The axle shaft itself is the inner race if a straight roller bearing is used. (b) The straight roller bearings are lubricated by the rear axle fluid, and a leak at the rear axle seal can cause this fluid to get onto brake components.

DIFFERENTIAL IDENTIFICATION

Before any service work is performed on a differential assembly, the *exact* axle specification must be determined. Vehicle manufacturers often use differentials from more than one axle manufacturer, and each manufacturer has its own individual ratios, parts, service procedures, and specifications. Differential assembly identification includes

- **Visual identification**—usually identifies the manufacturer and size only
- **Axle assembly number**—usually stamped in the axle tube of the differential assembly and identifies the gear ratio and other information
- **Limited-slip identification tag**—often the only external identification whether or not the axle assembly is an open design or limited-slip design
- **Differential cover shape** and number of bolts used to retain the cover

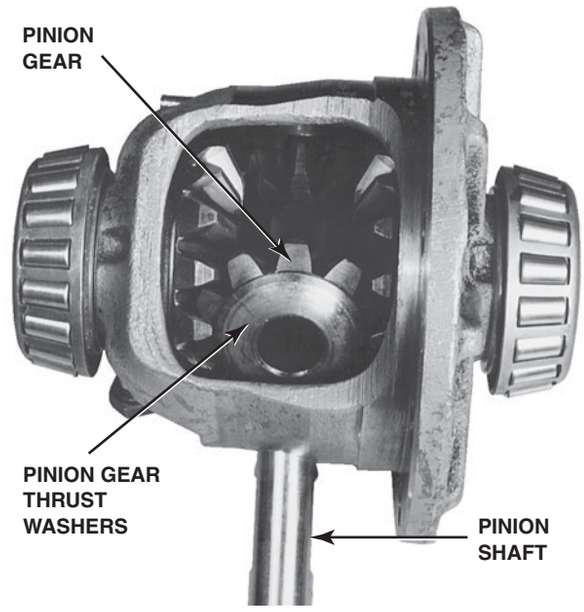


FIGURE 125–19 The pinion gear thrust washers can be destroyed by spinning one wheel for an extended period of time.

TECH TIP

Don't Spin Those Wheels!

While driving on ice or snow-covered roads, it is common to see drivers moving slowly up a hill by simply spinning one drive wheel. However, when one wheel is spinning and the other wheel is stationary (or close to stationary), the pinion gears are spinning twice as fast as the drive wheel. This spinning of the drive wheel has been known to completely wear down the pinion gear thrust washers in less than one minute! ● **SEE FIGURE 125–19.** The same wear can occur if different-size tires are used on the same drive axle. Therefore, to prevent expensive repairs, avoid unnecessary tire spinning and check that both tires on the same axle are the same size, brand name, and condition.

DETERMINING THE AXLE RATIO OF A DIFFERENTIAL

To determine the axle ratio of a differential without having to remove the axle housing cover, simply follow these steps:

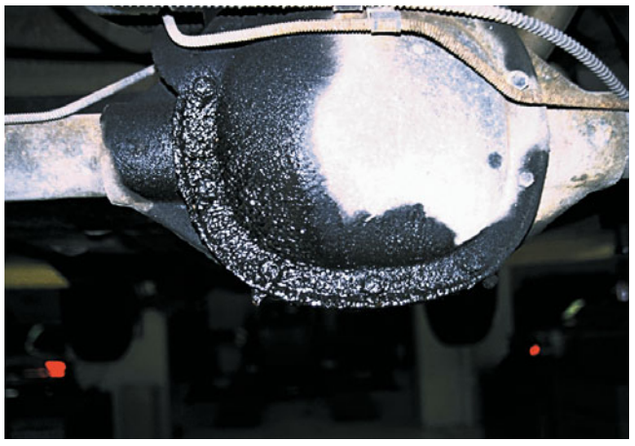
STEP 1 Hoist the vehicle safely.

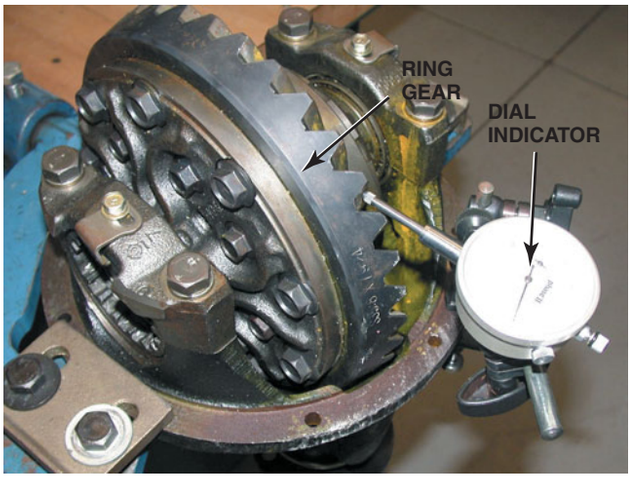
STEP 2 Mark the rear tires with masking tape at 12 o'clock position.

STEP 3 Mark the driveshaft with masking tape.

STEP 4 Have an assistant hold one drive tire to keep it from moving and slowly rotate the other drive tire exactly 10 times while the assistant counts the driveshaft revolutions.

STEP 5 Multiply the driveshaft revolutions by 2 (except for a limited-slip differential), and then move the decimal point one place to the left. For example, if 10 turns of the tire result in 18.5 turns of the driveshaft, that multiplied by 2 equals 37.0; then, moving the decimal point to the left one place equals a 3.70:1 gear ratio.





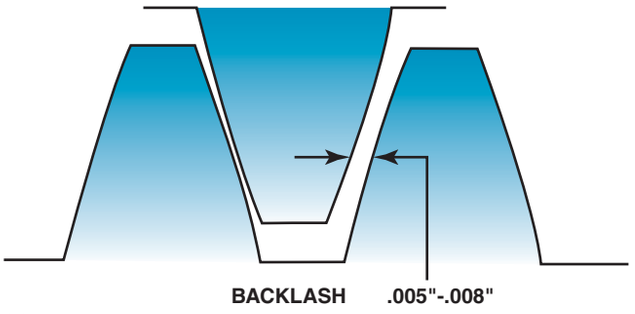


FIGURE 125–20 This differential has obviously been leaking. If the differential lubricant is low, wear may have occurred that would require further inspection.

(a)

(b)

FIGURE 125–21 (a) Backlash is determined by mounting a dial indicator to the differential housing and placing the button of the gauge against a tooth of the ring gear. Moving the ring gear back and forth will indicate on the dial indicator the amount of backlash. (b) Backlash is the clearance between the drive pinion and the ring gear teeth.

REAR END NOISE DIAGNOSIS

One of the major reasons why differentials are serviced is to correct a noise problem. Knowing when and under what conditions the noise is noticeable is a big help in identifying which bearing or component is the likely cause. Typical noise and its sources include

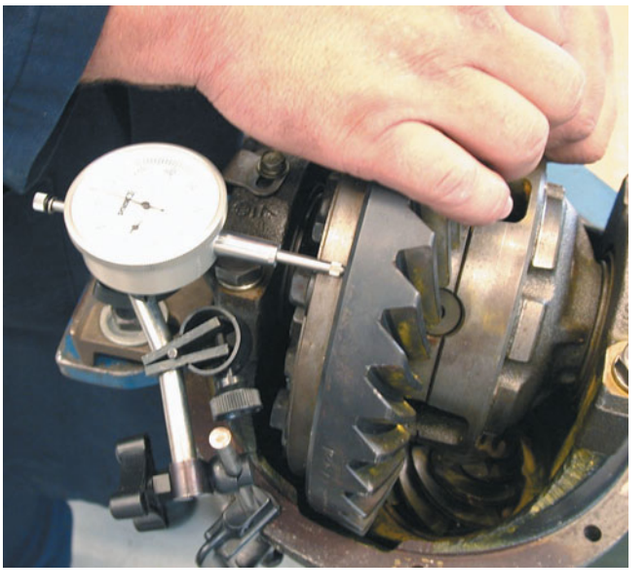

FIGURE 125–22 Ring gear runout should be less than 0.002 inch (0.05 mm) as measured by a dial indicator.

TECH TIP

A Quick-and-Easy Backlash Test

Excessive clearance (lash) between the drive pinion and the ring gear can cause driveline clash noise during a gear selector change. To check if the cause is due to the differential, simply hoist the vehicle and, while one wheel and the driveshaft are being held stationary, use your hand to move the opposite wheel. The maximum amount the tire should move is 1 inch (2.5 cm) measured at the tread of the tire. If backlash is greater than this, then further inspection of the differential assembly is required. Beside excessive clearance between the drive pinion and the ring gear, the wear may also be between the pinion and the side gears.

- **Grinding or growling noise while turning**—usual cause is a defective axle bearing.
- **Whine noise during cruise**—drive pinion bearings are the likely causes of this type of noise.

DIFFERENTIAL INSPECTION

Carefully inspect the differential for obvious damage or wear. ● **SEE FIGURE 125–20.** Check the backlash. The backlash is the amount of clearance between the drive pinion and the ring gear; excessive backlash could indicate excessive wear. Use a dial indicator as shown in ● **FIGURE 125–21** to check and compare the results with specifications.

Also use a dial indicator to check **ring gear runout** (● **SEE FIGURE 125–22**). If any of the visual measurement tests indicate a problem or a noise analysis indicates a bearing problem, the axle assembly should be disassembled for further analysis and service.

FIGURE 125–23 Force has to be applied to the ring gear to achieve a proper contact pattern.

TOOTH CONTACT PATTERN TEST

A tooth contact pattern test is an excellent method for checking proper drive pinion depth as well as proper backlash between the drive pinion and the ring gear. Any faults in these areas will be reflected in the pattern. The pattern test involves the following steps:

STEP 1 Clean the gear teeth of the ring gear and the drive pinion.

STEP 2 Using a small brush, apply a light coating of iron oxide compound.

STEP 3 Use a small pry bar to apply a load to the ring gear to achieve a more accurate contact pattern. ● **SEE FIGURE 125–23**.

STEP 4 Rotate the drive pinion until the ring gear turns one revolution (about three revolutions of the drive pinion gear).

STEP 5 Repeat rotating the drive pinion in the opposite direction. This will create a contact pattern on both the drive side and the coast side of the ring gear.

NOTE: The drive side is the convex surface of the ring gear teeth. The coast side is the concave side of the ring gear. This is true except for many differentials used on the front of four-wheel-drive vehicles. In this case, the drive side in the front differential is the concave surface and the coast side is the convex surface of the ring gear teeth. Always check the service information for the vehicle being serviced for the correct interpretation of the pattern results.

● **SEE FIGURE 125–24** for good and bad tooth contact patterns and what could have caused them.

DIFFERENTIAL DISASSEMBLY

Start the differential disassembly by removing the axle housing cover. Be sure that the old rear end lubricant is drained into a disposal container according to local, state, provincial, and federal laws and regulations. After the cover has been removed, complete the disassembly by following these steps:

STEP 1 After the cover has been removed, remove pinion shaft lock bolt.

STEP 2 Remove pinion shaft.

STEP 3 Remove two spider gears and two axle side gears.

STEP 4 Push axles in and remove C-clips.

STEP 5 Remove axles.

STEP 6 Mark and remove case caps.

STEP 7 Using a case spreader or two pry bars, pry up and remove carrier case keeping the shims separate. ● **SEE FIGURE 125–25**.

STEP 8 Remove pinion shaft nut and washer. Discard the nut.

STEP 9 Mark and remove companion flange with suitable puller.

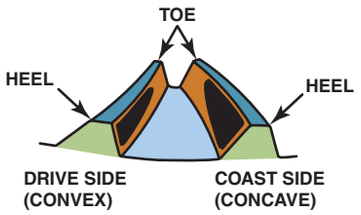
STEP 10 Remove front pinion seal and front pinion bearing.

STEP 11 Using suitable punch, drive pinion gear rearward until it is free of housing.

STEP 12 Remove crush collar (never re-use) ● **SEE FIGURE 125–26**.

CAUTION: Do not use an air impact wrench to remove or install the drive pinion nut. The hammer action of the impact wrench can cause the roller bearings to be pounded into the race. This denting of the race is called *brinelling* and can cause premature bearing failure.

PINION SHAFT BEARING REPLACEMENT



The pinion shaft usually has two tapered roller bearings; the small diameter of each bearing faces the other. This arrangement allows the two bearings to absorb thrust load in both directions. When tapered roller bearings are used in a differential, it is very important that they have the proper preload. If a tapered roller bearing is too loose (too little preload), then the bearing cannot properly support and position the pinion shaft. If the preload is too great, excessive heat will quickly destroy the bearing as it expands with heat during normal operation of the rear axle assembly. Two methods are used to ensure proper drive pinion gear preload (● **SEE FIGURE 125–27).**

- Preload shims
- Collapsible spacer

The rear pinion shaft bearing (closest to the drive pinion gear) is usually pressed out the drive pinion. A shim is usually located between the drive pinion gear and the rear drive pinion bearing to properly position the drive pinion in relation to the ring gear. The ring gear and pinion are manufactured as a matched pair and must be installed correctly to be assured of quiet operation and long service life. ● **SEE FIGURE 125–28.** The drive pinion bearing must be pressed off using a hydraulic press or a special tool.

DRIVE PINION DEPTH

The drive pinion gear and ring gear are manufactured as a matched set and must be installed as a set. Due to variances in the production of these gears, it is often necessary to vary the thickness of a shim

CONDITION

PINION DEPTH CORRECT.

BACKLASH INCORRECT - TOO MUCH CLEARANCE BETWEEN THE PINION AND RING GEARS.

(thin metal spacer) between the rear pinion bearing and the pinion gear to provide the correct contact tooth pattern when the gears are assembled. Correct drive pinion depth measurement can be determined in several different ways:

- **Wear pattern analysis.** This method is useful as a first step and a last step to verify correct setup (discussed earlier in the chapter). It is time consuming to use this method to determine the thickness of the drive pinion shim because the rear pinion bearing must be pressed off and then back on for each shim change.
- **Plus (+) and minus (−) markings on the drive pinion.** The end of the pinion gear is usually marked as to the variance

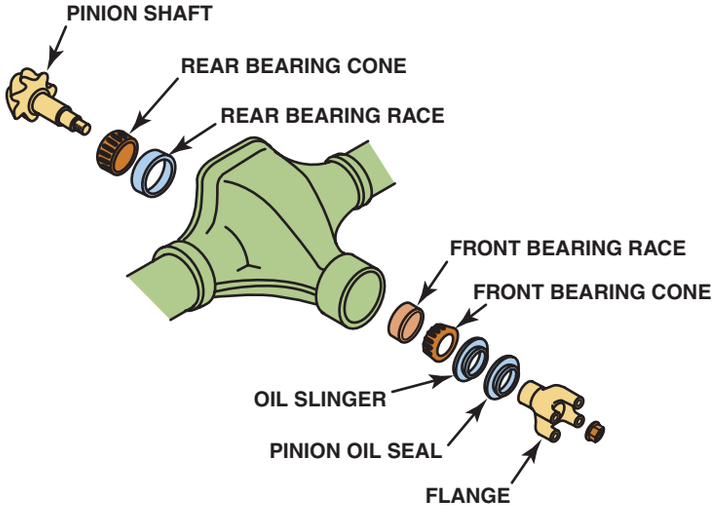

FIGURE 125–26 Pinion gear and associated parts. The pinion end yoke is also called the pinion flange.

needed to create the proper ring gear-to-drive pinion pattern:

A plus (+) sign means the gear is too long and removing a shim(s) is required when assembling the drive pinion into the axle housing.

A minus (−) sign means that the gear is too short and a shim(s) will be needed when assembling the drive pinion into the axle housing.

- **A gauging set and depth micrometer.** This is a common method used to determine the correct shim thickness necessary to provide the proper gear pattern. ● **SEE FIGURE 125–29.**

PINION GEAR PRELOAD

After the proper drive pinion depth has been determined, the correct size shim is installed and the rear drive pinion bearing is pressed onto the drive pinion. The outer races of the pinion bearing

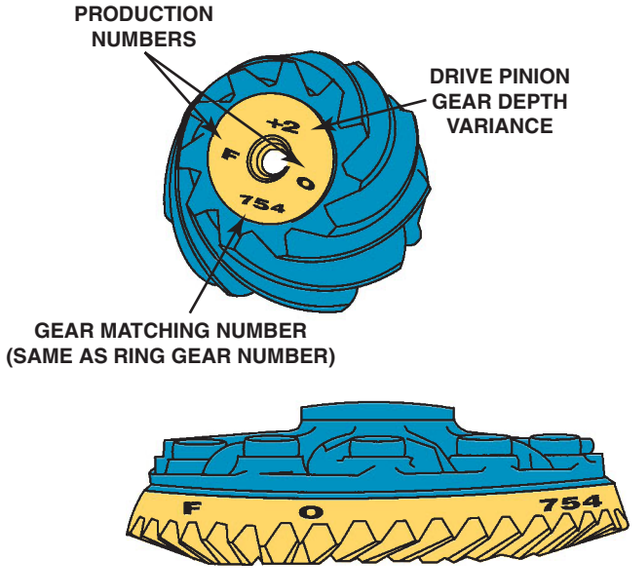

FIGURE 125–28 The ring and pinion gears are a matched set and are marked for correct pinion depth variance.

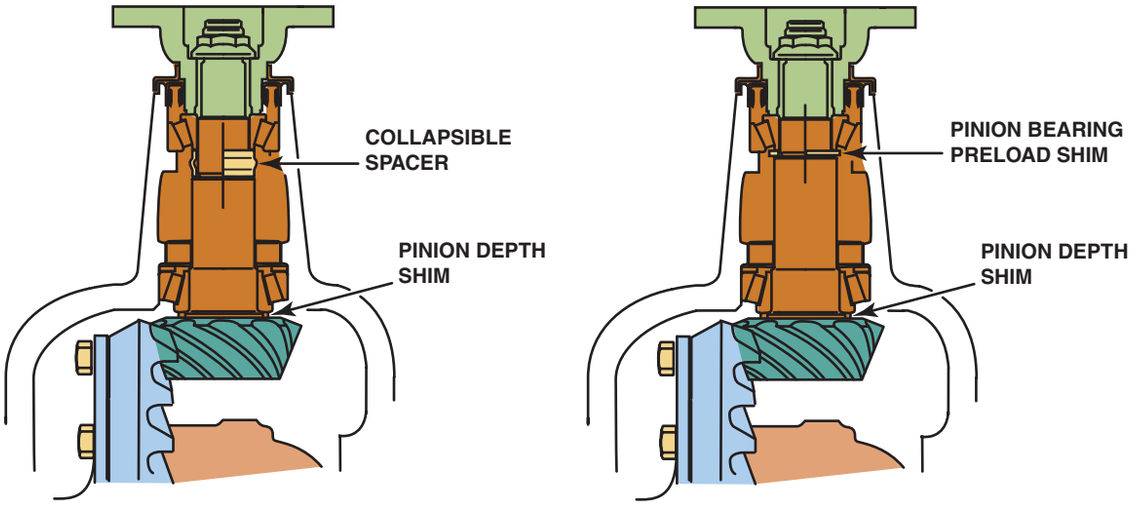

FIGURE 125–27 The pinion on the left uses a collapsible spacer, and the pinion on the right uses shims to provide the necessary preload to the pinion shaft bearings.

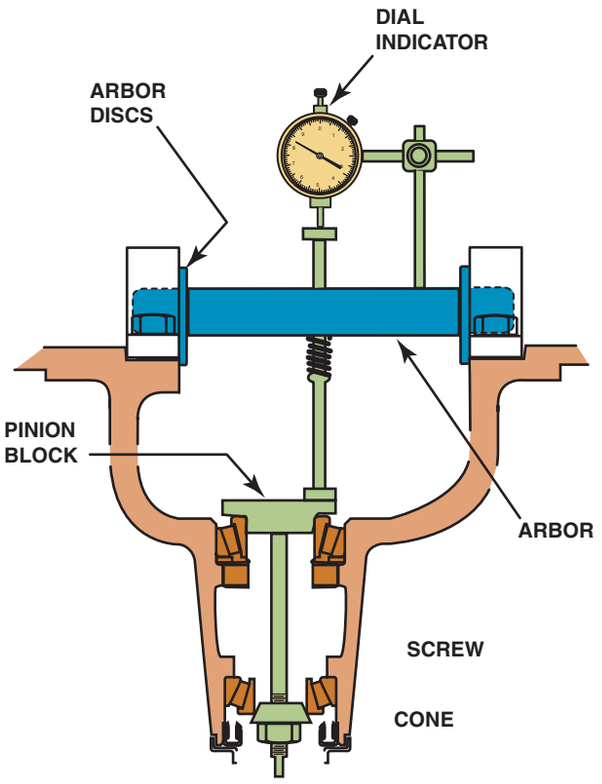

FIGURE 125–29 Special tool kit used for determining the correct pinion shaft shim thickness.

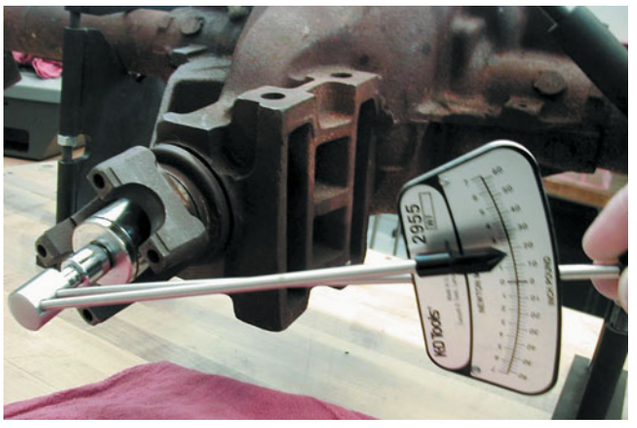

FIGURE 125–30 Using an inch-pound torque wrench to check the rotating torque of the drive pinion. This procedure is very important if the axle uses a collapsible spacer. The drive pinion nut should be gradually tightened and the rotating torque checked to prevent overtightening the nut. If the rotating torque is higher than specifications, the collapsible spacer will require replacement and the installation procedure must be repeated.

should be replaced in the axle housing and the pinion shaft placed in the housing. It is then necessary to apply the specified preload to the pinion bearings. A new drive pinion nut should be used and tightened to specifications. After the nut has been tightened, torque needed to rotate the drive pinion should be measured using a beam-type torque wrench. The drive pinion nut is then tightened farther until the **turning torque** is within specifications. ● **SEE FIGURE 125–30.**

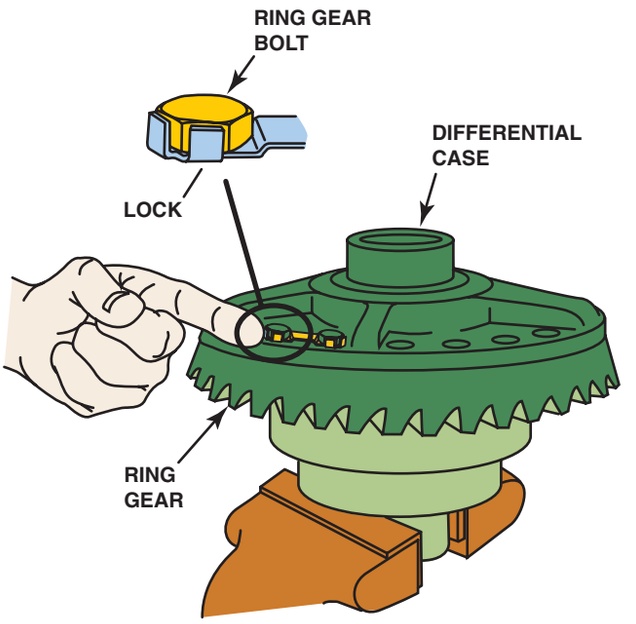

FIGURE 125–31 If the ring gear has been removed from the differential case or if a new ring gear is being installed, always replace the ring gear bolts.

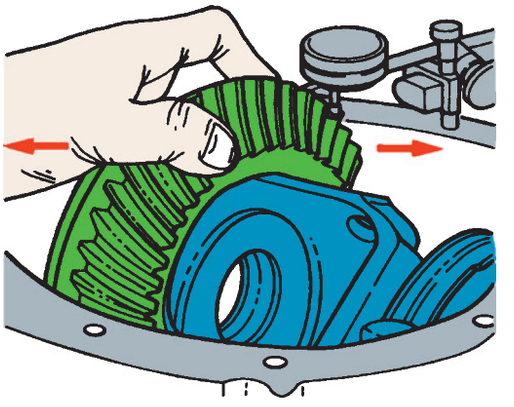

FIGURE 125–32 Backlash should be between 0.005 and 0.008 inch on most differentials. If the backlash is too great, add shim thickness to the ring gear side and subtract shim thickness from the opposite side.

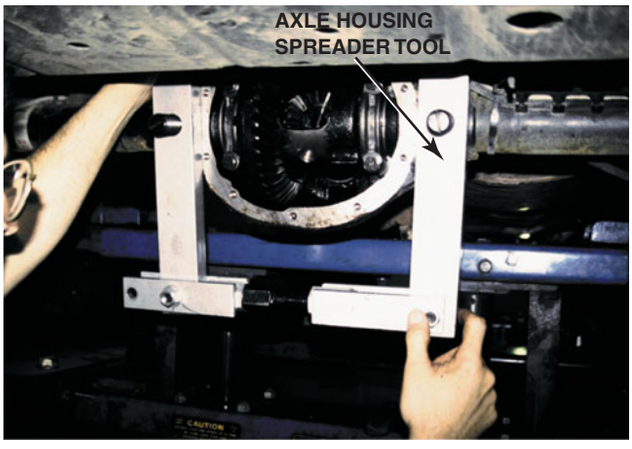
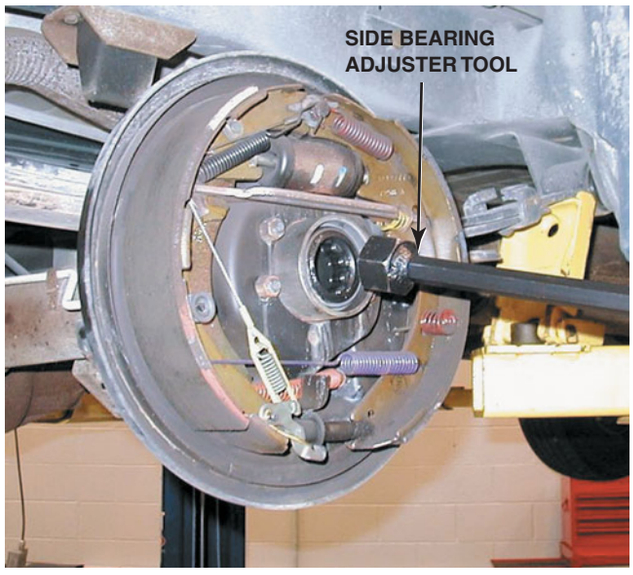


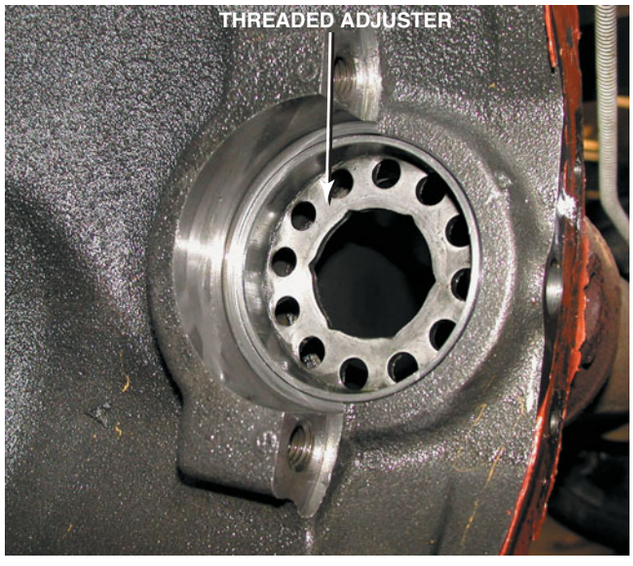
CHECKING AND CORRECTING BACKLASH

If the ring gear and pinion are being replaced, the bolts that hold the ring gear to the differential case *must* be replaced. ● **SEE FIGURE 125–31.** The differential case with the ring gear is then placed into the differential housing. Backlash is the clearance between the drive pinion gear and the ring gear. A dial indicator is used to measure backlash, as shown in ● **FIGURE 125–32.** The backlash should be checked at three or four points around the ring gear and the lash should not vary over 0.002 inch (0.05 mm). Backlash normally is between 0.005 and 0.008 inch (0.10 and 0.20 mm) for most axle assemblies. Always check the specifications for the differential being serviced. ● **SEE FIGURE 125–33.**

Backlash is corrected by moving the ring gear either closer or farther away from the drive pinion gear. The correction is made by



(a)



(b)

FIGURE 125–33 (a) Some vehicle manufacturers recommend using a housing spreader tool that fits into the round openings on both sides. (b) The spreader tool being installed. The housing is spread a specified amount and the differential is then installed into the housing.

(b)

(a)

FIGURE 125–34 (a) Note the hex shape of the threaded adjuster used to adjust side bearing preload and ring gear backlash on a Dodge Dakota truck. (b) A long handled adjuster tool is needed to turn the side bearing adjuster on this truck.

TECH TIP

"Click-Click" Is Okay—"Clunk-Clunk" Is Not

An experienced service technician was observed checking the backlash on a differential. The technician was simply turning the drive pinion by grasping the pinion flange and using wrist action to quickly rotate it first in one direction and then the other. The technician explained that if it made a "click-click" sound, the backlash was usually between 0.005 and 0.008 inch, which is usually within specifications for most differentials. If however, the sound made was more like a "clunk-clunk," then the backlash was greater than 0.010 inch and had to be corrected. To summarize what the sounds mean when the drive pinion is moved back and forth:

- **No sound when moved back and forth**—too little or no backlash; backlash must be adjusted.
- **A "click-click" sound**—backlash is usually within specifications; double-check with a dial indicator and compare against specifications for the axle being serviced.
- **A "clunk-clunk" sound**—usually too much backlash; correction is required to restore proper backlash.

either of two methods depending on the manufacturer and the type of differential:

- Transferring shims from one side of the axle housing to the other
- Turning threaded adjusters located in the differential housing bores, as shown in ● **FIGURE 125–34.**

SETTING SIDE BEARING PRELOAD

After the correct backlash has been determined, the side bearing must be correctly preloaded. To accomplish the proper preload, thicker shims than were used to set proper backlash are placed between the housing and the differential to provide for the proper preload on the side bearings. ● **SEE FIGURE 125–35.** Always follow

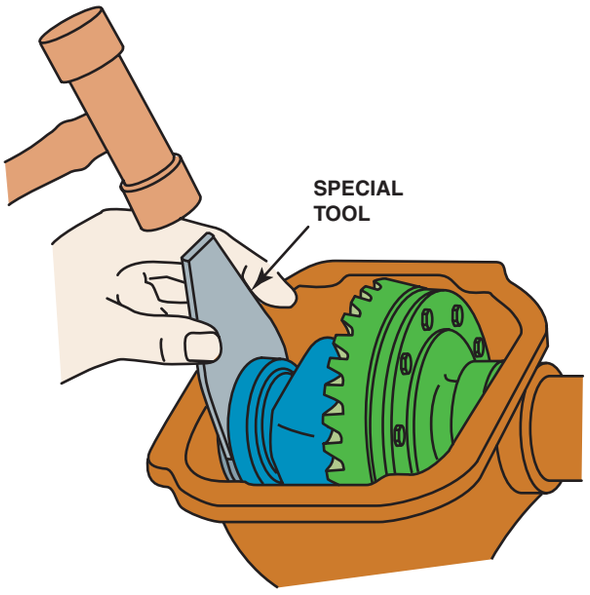


FIGURE 125–35 On many axles, it is necessary to use a special tool to install steel spacers (shims) to achieve the specified backlash and side bearing preload.

FIGURE 125–36 A spool used in a rear end for drag racing only.

FIGURE 125–37 Install the axle shaft, being careful to not damage the seal.

FREQUENTLY ASKED QUESTION

What Is a Spool Rear End?

A spool is a solid piece of metal that takes the place of the side gears and pinion gears in a differential assembly (● **SEE FIGURE 125–36).** A spool used in drag racing is not suitable for street driving because the spool does not allow for any differences in the speeds of the drive wheel during cornering. Obviously, drag vehicles do not turn corners while racing and the spool rear end is one of the reasons they bounce when turning around at the end of the strip to return to the pits.

FREQUENTLY ASKED QUESTION

What Do I Do About Drive Pinion Bearing Preload When I Replace Just the Pinion Seal?

To replace a pinion seal, the drive pinion nut and pinion flange must be removed.

CAUTION: Do not use an air impact wrench on the drive pinion nut. The pinion bearings can be damaged by the impact of the wrench.

Before the nut is removed, make a mark on the pinion nut and on the axle housing. After the new pinion seal is installed, tighten the pinion nut to the same position it was in before disassembly and then rotate the nut 1/16 inch (1.5 mm) farther. This extra rotation makes sure that the collapsible space (crush sleeve) is still able to maintain the proper preload on the pinion bearing. Another method is to measure the rotating torque of the drive pinion using an inch-pound beam-type torque wrench after removing both rear wheels and brake drums. After installing the replacement pinion shaft seal, tighten the drive pinion nut until the rotating torque is 3 to 5 in-lb more than the reading obtained before the pinion nut was removed.

the procedures specified for the axle being serviced. A typical axle may require the installation of a shim 0.004 thicker on both sides. After setting the preload, double-check that the backlash is within specification.

REASSEMBLY OF THE DIFFERENTIAL ASSEMBLY

After the backlash has been checked to be within factory specifications, the axle shafts can be installed. ● **SEE FIGURE 125–37.** Install the retaining "C" clip or bolt the retainer to the axle housing. Clean and install the differential cover and fill with the specified differential lubrication.

FIGURE 125–38 A container of GL-5 SAE 80W-90 gear lubricant.

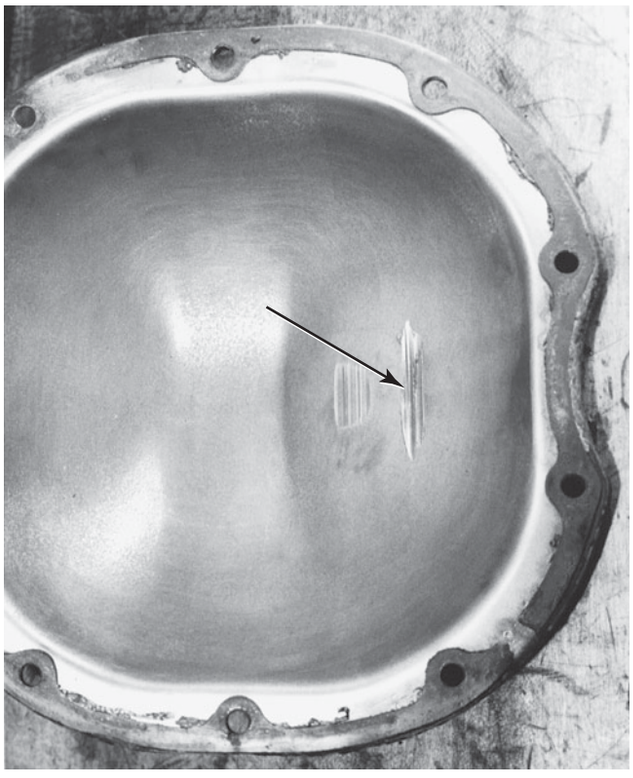

FIGURE 125–39 The beginning automotive student did not realize that the axle housing cover could fit the wrong way. The only problem was that the ring gear scraped against the cover.

DIFFERENTIAL LUBRICANT

Because all differentials use hypoid gear sets, a special lubricant is necessary because the gears both roll and slide between their meshed teeth. Gear lubes (GL) are specified by the American Petroleum Institute (API):

GL-1 Straight mineral oil

GL-2 Worm gear lubricant

GL-3 Mild EP lubricant (will *not* protect hypoid gears)

GL-4 Mild EP lubricant suitable for manual transmissions/transaxles

GL-5 EP lubricant okay for hypoid gears (meets military Mil-L2150B requirements)

● **SEE FIGURE 125–38.**

NOTE: EP additives contain sulfurized esters and organic sulfur phosphorous compounds. These ingredients give the lubricant a very strong pungent smell. To avoid possible skin irritation, always wear protective gloves or wash your hands thoroughly with soap and water if exposed to differential lubricant.

Most differentials require

1. SAE 80W-90 GL-5
2. SAE 75W-90 GL-5
3. SAE 80W GL-5

NOTE: Always check the *exact* specification before adding or replacing rear axle lubricant.

REAL WORLD FIX

I Didn't Know It Would Fit the Wrong Way!

An automotive student changed the differential lubricant by removing the housing cover. The cover was reinstalled and then filled with the correct lubricant. However, when the student drove the vehicle it made a grinding sound that was not there before the differential service. When the cover was removed, it was discovered that the cover had been installed with the raised area on the right side of the housing instead of on the left side and the ring gear had rubbed a groove in the cover, as shown in ● **FIGURE 125–39.** Installing the cover correctly stopped the grinding sound.

Limited-slip differentials (often abbreviated LSD) usually use an additive that modifies the friction characteristics of the rear axle lubricant to prevent chattering while cornering.

HINT: If chattering becomes noticeable while cornering, replace the old differential lubricant with the correct lubricant and add limited-slip additives if specified by the vehicle manufacturer. After refilling the differential, drive the vehicle in a figure-eight pattern at least four times to help all of the lubricant and additives get into the clutch plates. This usually stops the chattering-while-cornering problem.

REVIEW QUESTIONS

1. Explain how to determine the axle ratio without removing the housing cover.
2. Describe how to perform a ring gear tooth contact pattern test.
3. List three methods that may be used to determine the proper drive pinion gear depth.
4. Explain how to achieve proper drive pinion gear bearing preload.
5. Describe how to adjust the position of the ring gear to achieve the proper backlash.
6. List the steps for replacing a drive pinion gear seal while still maintaining proper preload on the drive pinion bearing.

CHAPTER QUIZ

1. Technician A says that the convex side of the ring gear is the drive side on most rear axle assemblies. Technician B says that the convex side of the ring gear is the drive side on differentials used in the front of many four-wheel-drive vehicles. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. The drive pinion gear is positioned with a shim that is too thick. This will cause contact with the ring gear teeth too close to the _____.
   a. Toe
   b. Heel
   c. Flank
   d. Face
3. The backlash exceeds specifications. The technician should position the ring gear _____.
   a. Closer to the drive pinion gear
   b. Farther from the drive pinion gear
4. The backlash is less than specifications (too low). This will cause the ring gear tooth pattern to be too close to the _____.
   a. Heel
   b. Flank
   c. Toe
   d. Face
5. A collapsible spacer is used in some differentials to provide _____.
   a. A lubrication path to the drive pinion bearing
   b. The proper preload for the side bearings
   c. The proper preload for the drive pinion bearings
   d. The proper amount of slippage in a limited-slip differential
6. A growling sound is heard from the rear of a rear-wheel-drive vehicle during cornering only. Technician A says that defective rear axle bearings may be the cause. Technician B says that defective drive pinion bearings may be the cause. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. The spacer used on a drive pinion gear is used to properly position the gear so that it can correctly mesh with the _____.
   a. Ring gear
   b. Side gear
   c. Differential pinion gears
   d. Both b and c
8. What part(s) wears rapidly if a vehicle equipped with an open differential spins one wheel on ice or snow for an extended period of time?
   a. Ring gear and pinion
   b. Side gear
   c. Pinion bearings
   d. Pinion and side gear thrust washers
9. Technician A says that if the backlash is okay, then the side bearing preload is also okay. Technician B says that a ring gear tooth pattern check will indicate if the drive pinion depth is correct. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. Two technicians are discussing which lubricants are used in a limited-slip differential. Technician A says to use SAE 80W-140. Technician B says that most vehicle manufacturers usually specify SAE 80W-90 be used with or without special limited-slip additives. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 126

FOUR-WHEEL DRIVE AND ALL-WHEEL DRIVE

OBJECTIVES: After studying Chapter 126, the reader will be able to: • Prepare for ASE Manual Drive Train and Axles (A3) certification test content area "F" (Four-Wheel Drive Component Diagnosis and Repair). • Explain the difference between a mode shift and a range shift. • Describe the purpose and function of the center differential. • Explain the purpose and function of a viscous coupling. • Describe the difference between four-wheel drive and all-wheel drive. • Explain how the front axle is disconnected when two-wheel drive is selected.

KEY TERMS: Annulus gear 1540 • Bevel gear differential 1541 • Electronically controlled clutch assembly 1536 • Input member 1541 • Interaxle differential (center differential) 1541 • Internal gear 1540 • Locking hubs 1534 • Low range 1539 • Mode shift 1539 • Output member 1541 • Part-time four-wheel drive 1534 • Planet carrier 1540 • Planet pinions 1540 • Range shift 1539 • Reaction member 1541 • Ring gear 1540 • Sun gear 1540 • Viscous coupling 1536

FOUR-WHEEL-DRIVE SYSTEMS

PURPOSE AND FUNCTION

Two-wheel drive vehicles use engine torque to turn either the front or the rear wheels. A differential is required to allow the drive wheels to travel different distances and speeds while cornering or driving over bumps or dips in the road. A four-wheel-drive vehicle, therefore, requires two differentials—one for the front wheels and one for the rear wheels.

NOTE: The term *4 × 4* means a four-wheeled vehicle that has engine torque applied to all four wheels (four-wheel drive). A *4 × 2* means a four-wheeled vehicle that has engine torque applied to only two wheels (two-wheel drive).

Four-wheel-drive vehicles require more than just two differentials. The front and the rear wheels of a four-wheel-drive vehicle also travel different distances and speeds whenever cornering or running over dips or rises in the road. There are three different methods used to allow for front-to-rear driveline speed variation.

TRANSFER CASE

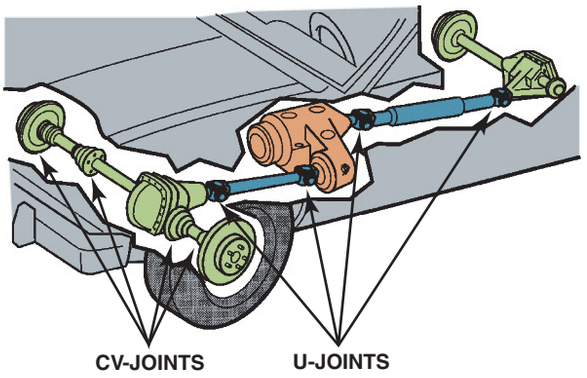
Engine torque from the transmission is applied directly to the rear differential through the transfer case. ● **SEE FIGURE 126–1.** The transfer case permits the driver to select a low-speed, high-power gear ratio inside the transfer case while in four-wheel drive. These positions and their meanings include

- 4H four-wheel drive with no gear reduction in the transfer case.
- 4L four-wheel drive with gear reduction. Use of this position is usually restricted to low speeds on slippery surfaces.
- 2H two-wheel drive (rear wheels only) in high range, meaning no gear reduction in the transfer case.

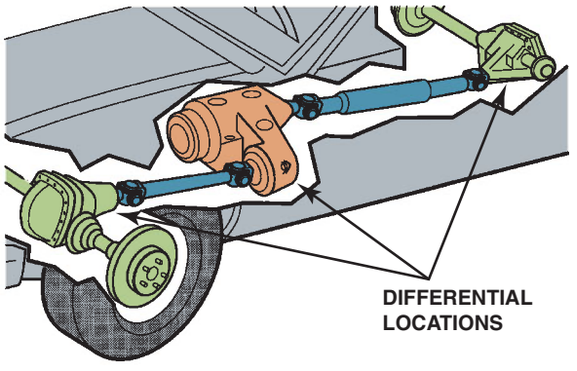
CAUTION: Check the owner's manual or service manual for the recommended procedure to follow when changing from one position to another in the transfer case. Some vehicles require that the vehicle be stopped before selecting between two- and four-wheel drive and between high and low range.

METHOD 1—LOCKING HUBS

The transfer case also applies power to the front differential. Power is then applied to the front wheels through the drive axles to the **locking hubs.** In normal 4H driving on hard surfaces, the front hubs *must* be in the unlocked position. The front hubs are locked whenever driving on loose road surfaces to absorb and allow for tire slippage due to the different tire speeds front to back. This type of four-wheel-drive system is called **part-time four-wheel drive** because it can only be driven in four-wheel drive on slippery surfaces. ● **SEE FIGURE 126–2.**



CAUTION: Failure to unlock the front wheel hubs while driving on a hard road surface can cause serious driveline vibrations and damage to driveshafts, U-joints, and bearings as well as to the transfer case, transmission, and even the engine.



METHOD 2—AUTOLOCKING HUBS

Another method of locking the hubs on a part-time four-wheel-drive system is with a clutch arrangement built into the hub assembly. Whenever driving on smooth, hard road surfaces, the hubs "free wheel" and allow the front wheels to rotate at different speeds from the rear wheels. When the speed difference between the wheels and the front drive axle is great, the hubs will automatically lock and allow engine torque to be applied to the front wheels. ● **FIGURE 126–3** shows an autolocking hub with the cover removed. Automatic-locking hubs are unlocked by disengaging four-wheel drive at the transfer case and driving in reverse for several feet.

METHOD 3—FULL-TIME FOUR-WHEEL DRIVE

This method uses a center differential to allow front and rear wheels to travel at different speeds under all operating conditions, as shown

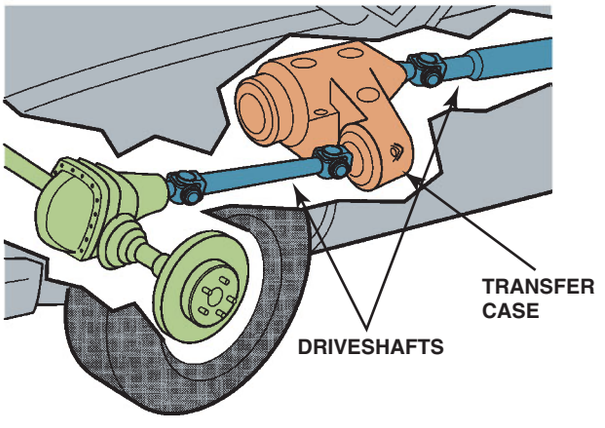


FIGURE 126–1 Many light trucks and sport utility vehicles use a transfer case to provide engine torque to all four wheels and to allow a gear reduction for maximum power to get through mud or snow. *(Courtesy of Dana Corporation, Perfect Circle Products)*

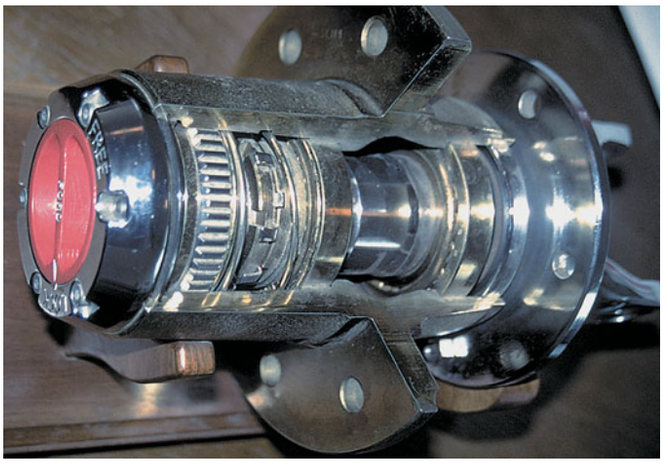

FIGURE 126–2 Cutaway of a manually-operated locking hub.

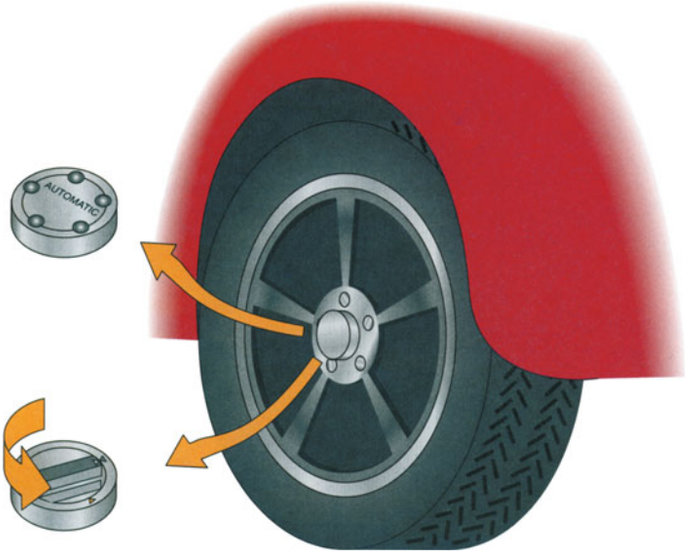

FIGURE 126–3 Manual locking hubs require that the hubs be rotated to the locked position by hand to allow torque to be applied to the front wheels. Automatic locking hubs enable the driver to shift into four-wheel drive from inside the vehicle.

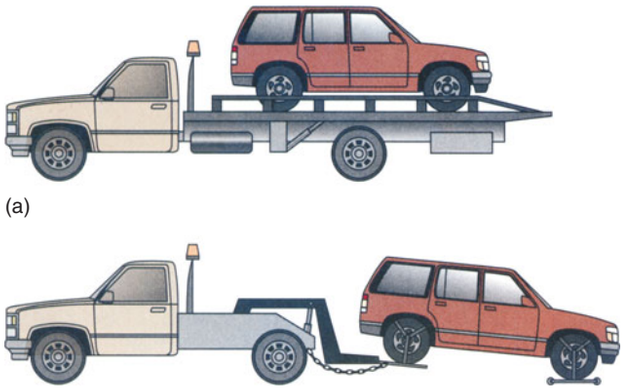
FREQUENTLY ASKED QUESTION

What Is the Difference Between Four-Wheel Drive (4WD) and All-Wheel Drive (AWD)?

The major difference between four-wheel drive and all-wheel drive is that four-wheel-drive units contain a transfer case with a low range. Most all-wheel-drive vehicles do not have low range and are in high four-wheel drive all the time. Both use a center (interaxle) differential and both usually use a viscous coupling or an electronically controlled clutch to control (lock) the center differential.



TECH TIP

How to Tow a Four-Wheel-Drive Vehicle Without Doing Harm

If any of the drive wheels are on the ground, the wheels are turning the axles. Depending on the exact type of four-wheel-drive vehicle being towed, this rotation of the wheels can cause severe wear; therefore most experts suggest the following options:

- **Placing the vehicle on a flatbed or trailer.** This keeps all four wheels off the ground and is the safest method for transporting a four-wheel-drive (or all-wheel-drive) vehicle without doing any harm.
- **Hoisting the front wheels off the ground and placing the rear wheels on a dolly.** This procedure also keeps all wheels off the ground and therefore prevents any damage being done to the powertrain as a result of towing. ● **SEE FIGURE 126–4.**

Always check with vehicle specific information for exact towing procedures.

(a)

(b)

FIGURE 126–4 If a four-wheel-drive vehicle must be towed, it should be either on (a) a flatbed truck or (b) a dolly.

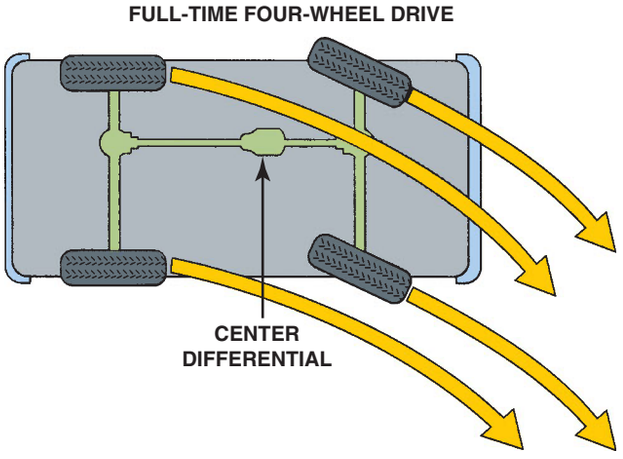


FIGURE 126–5 When turning a corner, each wheel takes a slightly different path and rotates at a slightly different speed. Unlike a part-time four-wheel-drive system, which when engaged locks the front and rear axles together, a full-time system uses a center differential that allows for any speed differences between the front and rear axles. It can therefore be activated on any surface—slippery or dry.

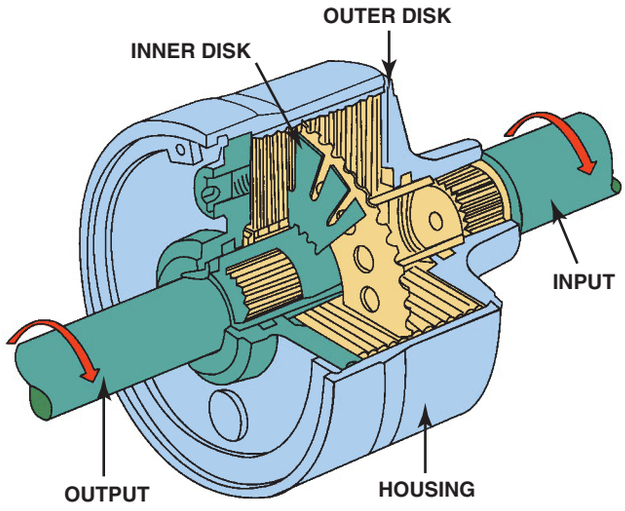
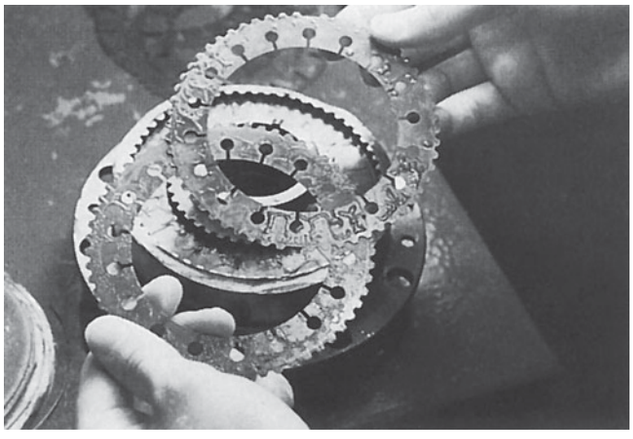
in ● **FIGURE 126–5.** Although this drive train design is the easiest to operate both on and off the road, the center differential can cause the vehicle to get stuck in mud or snow even though it is a four-wheel-drive vehicle.

All open-style differentials allow for speed differences and torque is applied equally, so if one wheel is on ice or mud, the other wheel receives the same low torque. This is why many vehicles spin just one wheel when stuck on ice or snow. But if one rear wheel starts to spin, the vehicle may not move forward at all!

There are two methods used to lock the center differential to prevent this from happening.

- A **viscous coupling** is commonly used on many four-wheel-drive vehicles to provide an "automatic" lockup of the center differential. A viscous coupling is a type of fluid clutch. When the speed difference between the front and rear wheels is high enough, the silicone fluid inside the coupling stiffens to reduce the speed difference between the front and rear drive shafts. ● **SEE FIGURES 126–6 AND 126–7.**





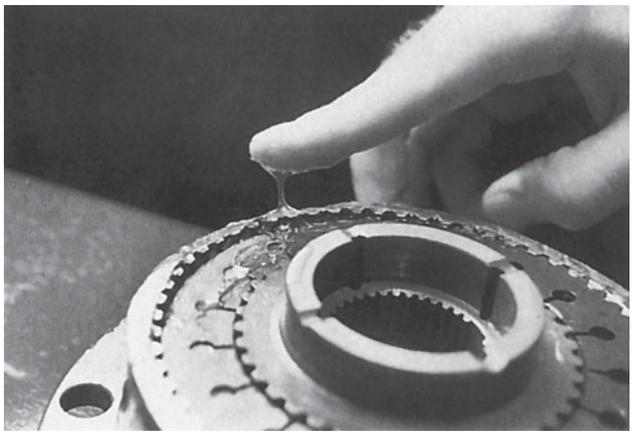


FIGURE 126–6 A viscous coupling is a sealed unit containing many steel discs. One-half of them are splined to the input shaft, with every other disc splined to the output shaft. Surrounding these discs is a thick (viscous) silicone fluid that expands when hot and effectively locks the discs together.

(a)

(b)

FIGURE 126–7 The inside of the viscous coupling consists of thin metal discs. (b) Viscous silicone fluid is used between the metal discs. (b) Viscous silicone fluid is used between the metal discs.

- An **electronically controlled clutch assembly** is actuated by the vehicle's computer based on inputs from the ABS wheel speed sensors. If a wheel starts to spin, the computer can pulse the clutch on and off as necessary to control the amount of wheel slippage.

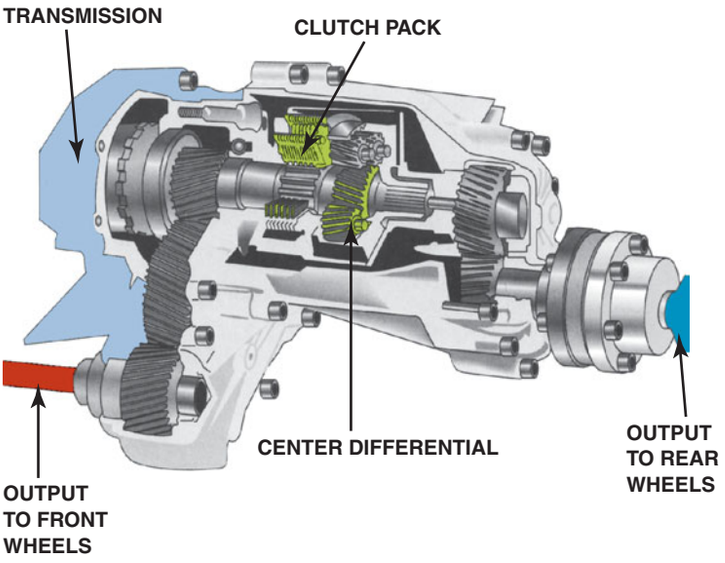

FIGURE 126–8 The center differential is the heart of a typical all-wheel-drive system. All-wheel-drive systems do not use a low range, and therefore the vehicle may not be able to go off-road like a vehicle equipped with a four-wheel drive with a low range.

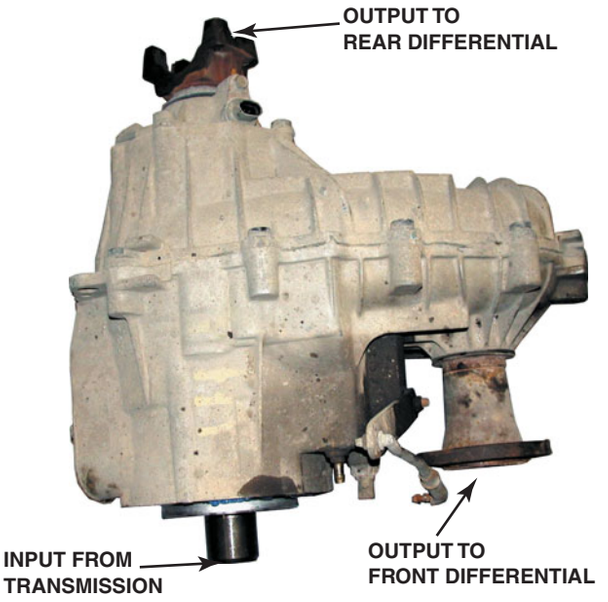

FIGURE 126–9 A typical transfer case is attached to the output of the transmission and directs engine torque to the rear or to the front and rear differentials.

? FREQUENTLY ASKED QUESTION

What Is Brake-Actuated Traction Control?

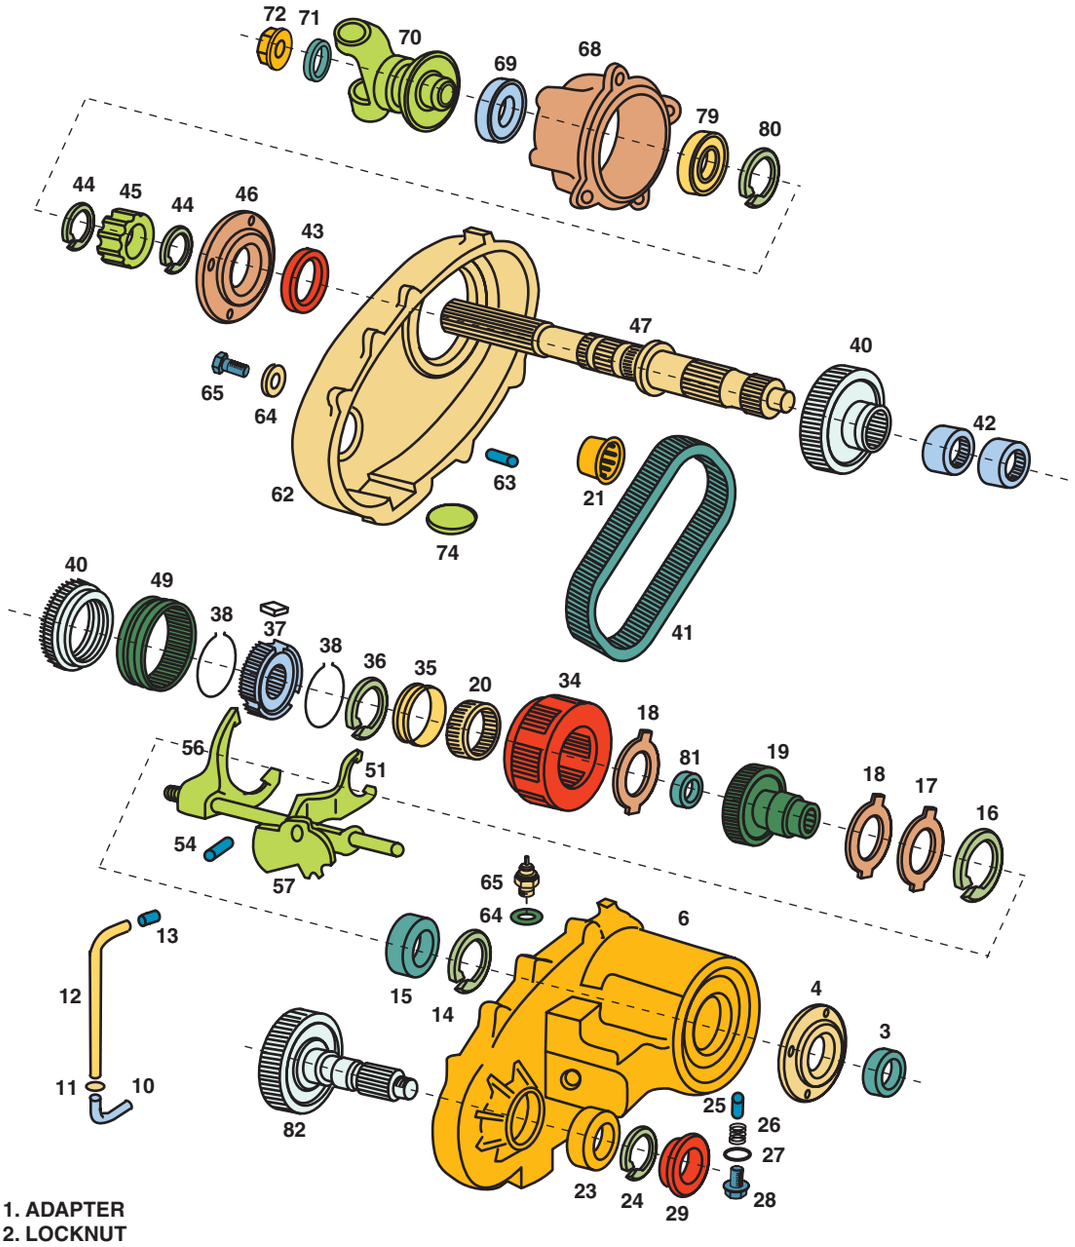
The engine torque of a full-time four-wheel-drive vehicle (with the center differential unlocked) is split into four nearly equal parts. One quarter of the torque is applied to each wheel. If a brake is applied to a spinning wheel, the torque to that wheel is increased, which will increase the torque to all of the other wheels. The increased torque applied to the wheels that have contact with a surface that has some traction will enable the vehicle to proceed. This is the principle involved in brake-controlled traction control such as is used on the Mercedes M4 sport utility vehicle (SUV).

ALL-WHEEL DRIVE

Some cars and light trucks are equipped with an all-wheel-drive system that uses a transfer case with a center differential and only one speed (high). Low-range gear reduction is not used. A viscous coupling is usually incorporated into the center differential to provide superior all-weather traction. Combined with a limited-slip differential in the rear, and sometimes also in the front, an all-wheel-drive system can provide ideal road traction under all driving conditions without any action by the driver. ● **SEE FIGURE 126–8.**

FRONT AND REAR DIFFERENTIAL AXLE RATIOS

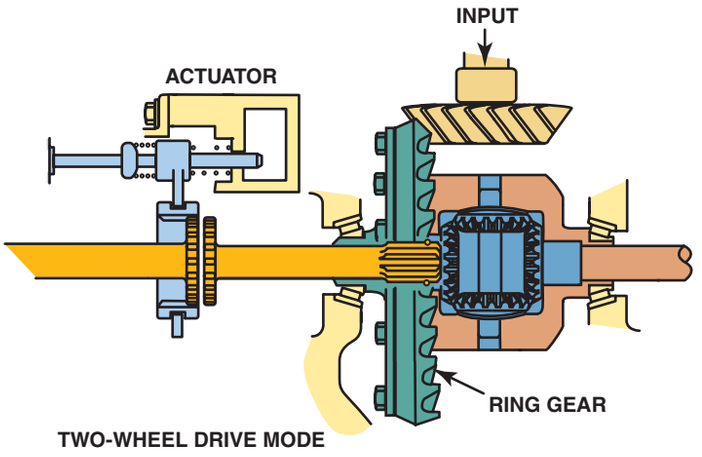
In most four-wheel-drive vehicles, the overall gear ratio of the front differential is slightly higher than the overall ratio of the rear differential. The overall ratio is determined by multiplying the gear ratio by the differential ratio. See the following chart comparing the ratios for the front and rear differentials of a typical four-wheel-drive vehicle equipped with a manual five-speed transmission.



Manual Transmission and Final-Drive Gear Ratios

Speed	Gear Ratio	Final-Drive Ratio	Overall Ratio
1st	3.083:1	4.933 front 4.927 rear	15.208 front 15.190 rear
2nd	1.684:1	4.933 front 4.927 rear	8.307 front 8.297 rear
3rd	1.115:1	4.933 front 4.927 rear	5.500 front 5.494 rear
4th	0.833:1	4.933 front 4.927 rear	4.109 font 4.104 rear
5th	0.666:1	4.933 front 4.927 rear	3.285 font 3.281 rear

Although the difference between the ratios is small, the purpose is to prevent the drive train from binding. With the front differential ratio being just slightly higher, the tendency is for the front of the vehicle to pull the vehicle thereby eliminating the problem of having the rear pushing at the exact same ratio as the front is pulling. The different ratios also help reduce resonant vibration and noise created in the driveline.



TRANSFER CASE

The purpose and function of the transfer case is to direct engine torque to the front and rear axle assemblies. ● **SEE FIGURE 126–9.** A four-wheel-drive transfer case is basically an auxiliary 2-speed transmission. It uses the transmission output as an input to a secondary gear train or planetary gear set, which provides a low and high range. The transfer of torque to the front axle output shaft can be accomplished either by a gear-to-gear transfer or a gear and chain transfer. The gear ranges can be engaged a number of ways, such as a manual lever, electrical, or vacuum actuators. A transfer case has one input shaft (connected to the output of the transmission) and two output shafts (● **SEE FIGURE 126–10).** The two

FIGURE 126–10 An exploded view of a New Venture 241 transfer case.

(a)

(b)

FIGURE 126–11 (a) When one axle shaft is disconnected, both front wheels can rotate independently, reducing excessive tire wear. (b) In four-wheel-drive mode, vacuum is applied to the front part and the opposite side is vented to atmospheric pressure retracting the shift motor stem. The shift fork and collar move into engagement with both axle shaft gears. Engine torque from the front differential can now be applied to both front axles. When the transfer case is placed in two-wheel drive, the vacuum is applied to the other side of the diaphragm and the shift collar moves, unlocking the front axles.

output shafts are connected to the driveshafts and transfer torque to the front and rear differentials. Most transfer cases also provide for two types of shifts:

- **Mode shift.** Either two-wheel drive or four-wheel drive may be selected. Many transfer cases also have a neutral position. The mode shift is achieved by the use of a floor-mounted lever to engage and disengage a clutch inside the transfer case. This shift is usually performed when the vehicle is stopped. However, new designs allow the mode shift to be performed under most driving conditions.

  NOTE: The mode shift is not available on all-wheel-drive vehicles.

- **Range shift.** A **low range** may be selected to deliver high torque at low speeds to the drive wheels. Low range usually provides a 2:1 to 3:1 gear reduction. High range (usually 1:1) simply transfers engine torque at the same speed as the output shaft of the transmission.

NOTE: Part-time four-wheel drive means that the transfer case does not include a differential.

GEAR-TO-GEAR TRANSFER CASES

Gear-to-gear transfer cases are simple in design. Three gear shafts are in mesh within the transfer case. One gear shaft is attached to the transmission output shaft. The second shaft acts as an idler, and the third shaft is the output to the front axle. Gear-to-gear transfer cases, in most cases, have two speeds. The first, 4-wheel-drive low, is a gear reduction that is usually around two to one (2:1). The second gear in the transfer case is a direct drive. The gears are engaged by sliding collars or synchronizers to lock the gears to the shaft. Neutral is accomplished when neither gear collar is locking a gear in place.

TWO-WHEEL-DRIVE OPERATION. When the transfer case controls are in two-wheel drive, the front differential assembly is disconnected from the transfer case. This disconnection is usually accomplished by disconnecting one of the drive axles, as shown in ● **FIGURES 126–11 AND 126–12.** The disconnect mechanism

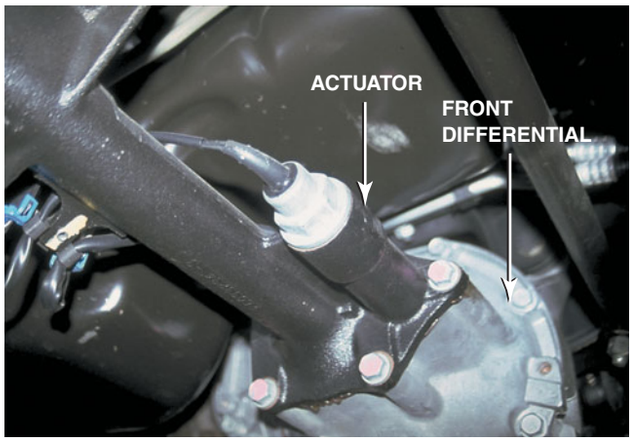

FIGURE 126–12 A General Motors sport utility vehicle front axle showing the electric axle disconnect actuator.

FIGURE 126–13 The range shift selector on a Hummer H1 sport utility vehicle. This vehicle is always in four-wheel drive, but the driver can select neutral (N) or low range.

in the front axle and a synchronizer assembly in the transfer case combine to remove torque for the front wheels.

FOUR-WHEEL-DRIVE OPERATION. To achieve four-wheel drive, two things must occur:

- A synchronizer assembly connects the torque from the engine to the front driveshaft in the transfer case.
- The drive axles must be connected to allow the torque from the front differential to be applied to the drive wheels. ● **SEE FIGURE 126–13.**

PLANETARY GEAR SET TRANSFER CASES

Many transfer cases use a planetary gear set for gear reduction in low range. A planetary gear set includes the following three elements:

1. **Sun gear.** This gear is in the center like the position of the sun is in our solar system.
2. **Planet pinions.** The planet pinion gears rotate around the sun gear, like the planets around the sun, and are attached by a **planet carrier.**
3. **Ring gear.** The outer ring gear has teeth on the inside that mesh with the teeth of the planet pinion gears. The ring gear is also called the **annulus gear** or **internal gear** because the gear teeth are on the inside (rather than the outside) portion of the gear.

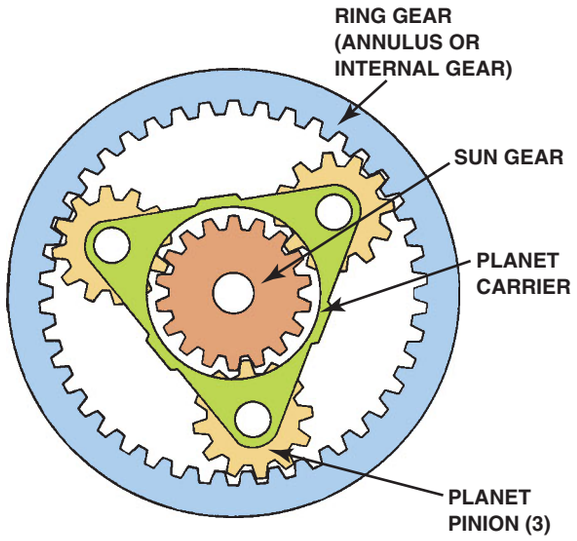

FIGURE 126–14 A typical planetary gear set used in a transfer case.

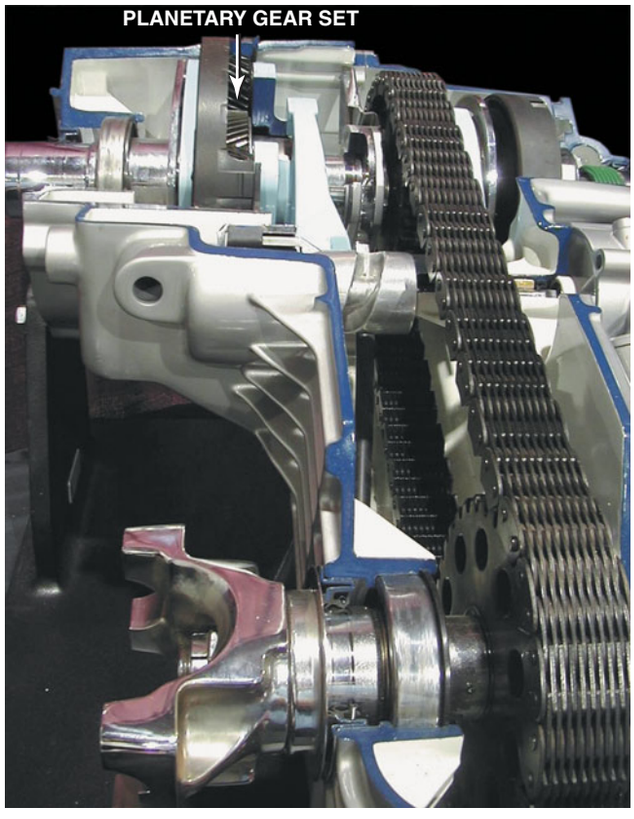

FIGURE 126–15 Cutaway of a planetary gear set transfer case.

The gear teeth of a planetary gear set remain in constant mesh. When gear reduction is needed, the sun gear is often the drive gear and the planet carrier is often the driven gear. The gear ratio reduction depends on the number of teeth on the various gears used in a planetary gear set. ● **SEE FIGURES 126–14 AND 126–15.** To achieve direct 1:1 output from the transfer case, any two of the three elements can be locked together and the entire assembly will rotate as a unit.

Power flows through a planetary gear set in several steps to get from the drive action of the first member to the driven action of the last member. The terms “drive” and “driven” simply describe

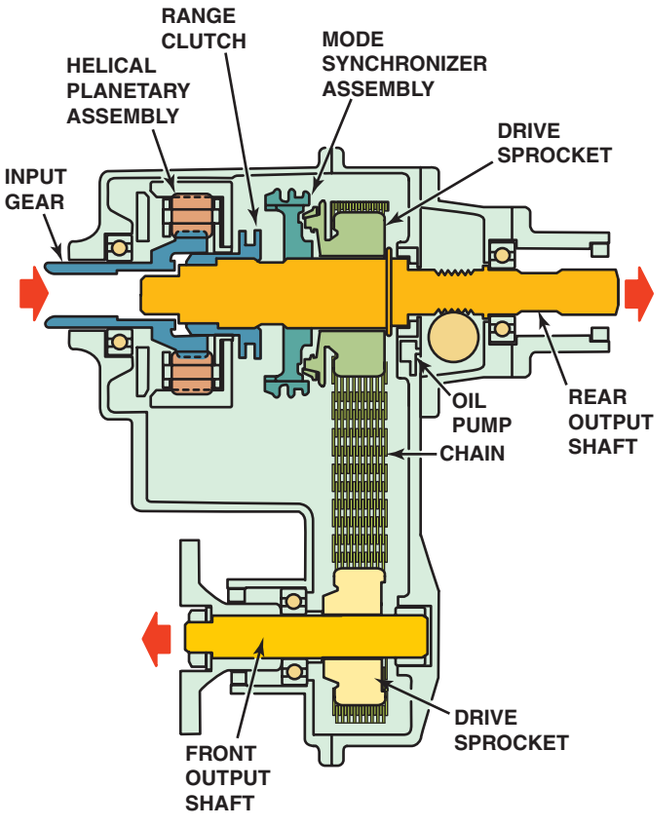

FIGURE 126–16 Two-wheel-drive/high-range torque flow in a NV231 transfer case. The sliding range clutch is shifted to the forward position by the range lever and fork, which connects the input gear to the output shaft and rear axle. The mode synchronizer sleeve is moved out of engagement from the drive sprocket to remove torque from the front axle.

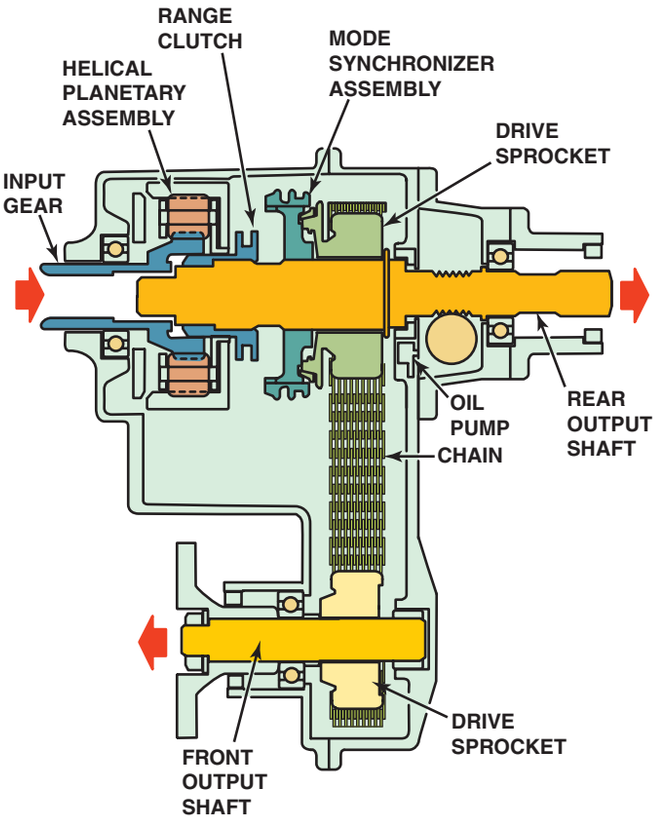

FIGURE 126–17 Four-wheel-drive/high-range torque flow in a NV231 transfer case. The range clutch position remains the same as in two-wheel drive/high-range, but the synchronizer sleeve is moved rearward and engages the drive sprocket clutch teeth. This action connects the drive sprocket to the rear output shaft, thereby applying equal torque to both front and rear output shafts.

how any two gears work together. When three or more gears are involved, the second gear is a *driven* gear in relation to the first, but a *drive* gear in relation to the third. For this reason, the drive member of a planetary gear set is called the **input member,** the held member, the **reaction member,** and the driven member, the **output member.** ● **SEE FIGURES 126–16 THROUGH 126–18.**

INTERAXLE DIFFERENTIAL

All-the-time four-wheel-drive, all-wheel-drive, and full-time four-wheel-drive systems use an **interaxle differential (center differential)** to prevent driveline harshness and vibration, commonly referred to as driveline windup. An interaxle differential can be found in various configurations including:

- Standard bevel gear differential
- Planetary gear differential
- Viscous coupling

Although they are different in appearance, interaxle differentials serve the same purpose, to maintain smooth operation while making turns in a four-wheel-drive/all-wheel-drive vehicle. The **bevel gear differential** uses two bevel gears or spider gears attached to the output shaft of the transmission. Two to four differential pinion gears are attached to a carrier, which is attached to the transfer gears. In other words, it operates in the same fashion as the differential in a rear axle; power is transferred to the tire with the least traction. When there is unequal traction between the front and rear axles, the axle with the most traction is allowed to slip enough to prevent damage to driveline components. ● **SEE FIGURE 126–19.**

With this setup, the loss of traction at one wheel could effectively disable the vehicle. For example, if one wheel had zero traction, the majority of engine torque would be applied to that wheel. In a standard bevel gear setup, torque is split between the front and rear axles. If there is a loss of traction in the front, the transfer of torque to the rear axle will be significantly lowered. To remedy this condition, auto manufacturers incorporate an internal clutch mechanism, much like a limited-slip unit, to increase torque transfer and still lessen driveline vibration and harshness.

A planetary gear set is often incorporated in transfer cases to act as a differential.

A viscous coupling is nothing more than a selection of steel plates housed in a sealed steel drum. ● **SEE FIGURE 126–20.** The viscous coupling is not active during equal traction conditions. The viscous coupling does actively transfer torque during light to moderate cornering, but there is a certain amount of slippage under these conditions to prevent driveline windup. If there is a significant loss of traction, the speed differences between the front and rear axles increase, and this increase in plate speed heats the silicon fluid in the viscous coupling, causing it to thicken to the point that it transfers more torque to the axle that is losing traction. During a severe loss of traction, the viscous fluid thickens enough to lock the plates together, dividing engine torque equally 50/50 between the front and rear axles.

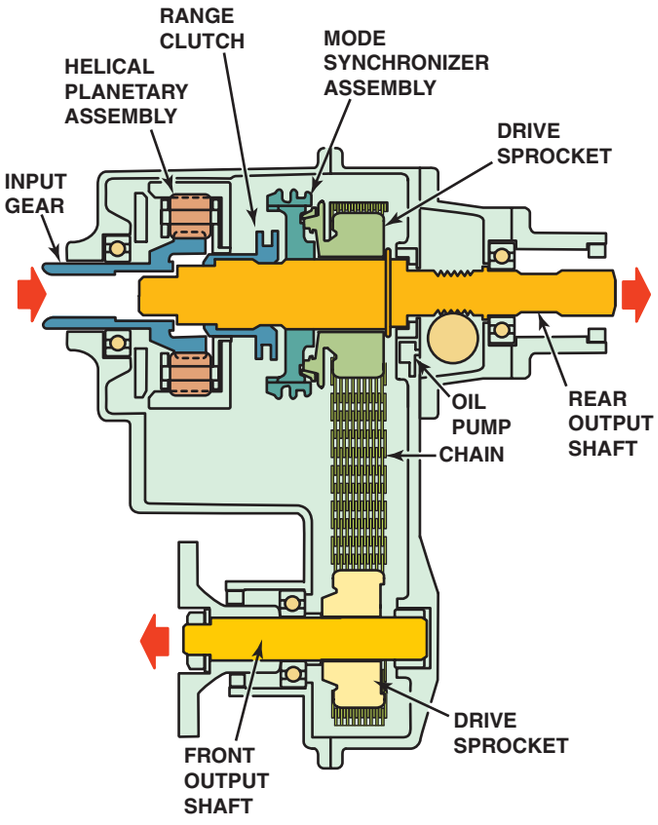

FIGURE 126–18 Four-wheel-drive/low-range torque flow in a NV231 transfer case. The mode synchronizer assembly remains engaged and the range clutch is moved to the rearward position. The annulus (ring) gear is fixed to the case and the input (sun) gear drives the pinion gears, which walk around the stationary annulus gear and drive the planetary carrier and output shaft at a speed lower than the input gear.

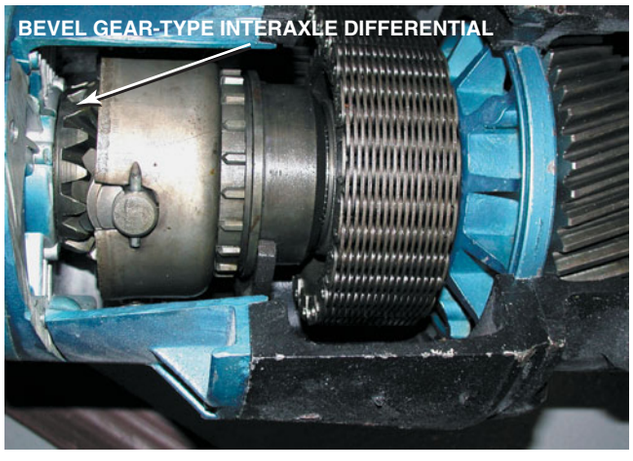

FIGURE 126–19 A bevel gear-type interaxle differential.

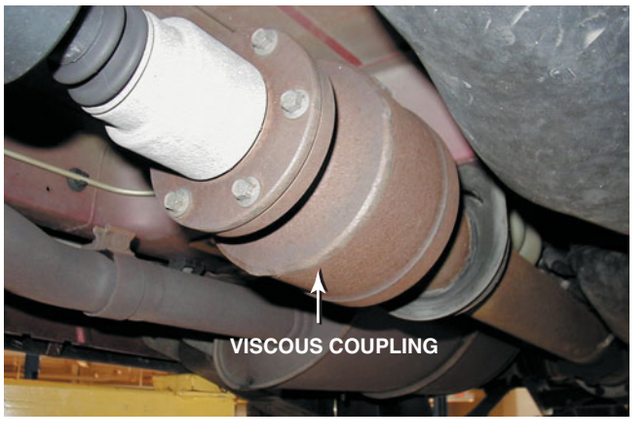

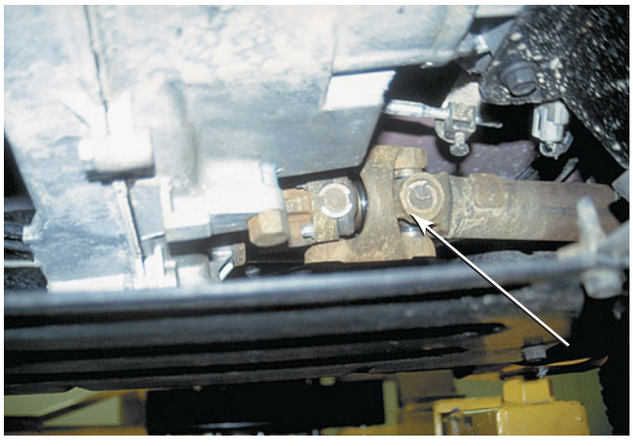

FIGURE 126–20 A viscous coupling. Note that the unit is attached to the output shaft between the transfer case (or transaxle) and the rear differential. A typical viscous coupling in a sealed unit is serviced as a complete assembly.

(b)

FIGURE 126–21 (a) A standard Cardan U-joint used on the output driveshaft from the transfer case to the front differential assembly. (b) A Cardan-type U-joint at the front drive wheels on a Jeep Wrangler.

FOUR-WHEEL-DRIVE AXLES

Four-wheel-drive vehicles use a variety of driveshafts and U-joint designs:

- **Standard Cardan-type U-joints.** ● **SEE FIGURE 126–21.** If this type of U-joint is used on the front wheels of a four-wheel-drive vehicle, the different speeds it creates can cause the front wheels to skip, hop, and shake if engine torque is applied while on dry pavement and turning a corner at the same time. This is normal for this type of U-joint used on the front wheels of a four-wheel-drive vehicle.

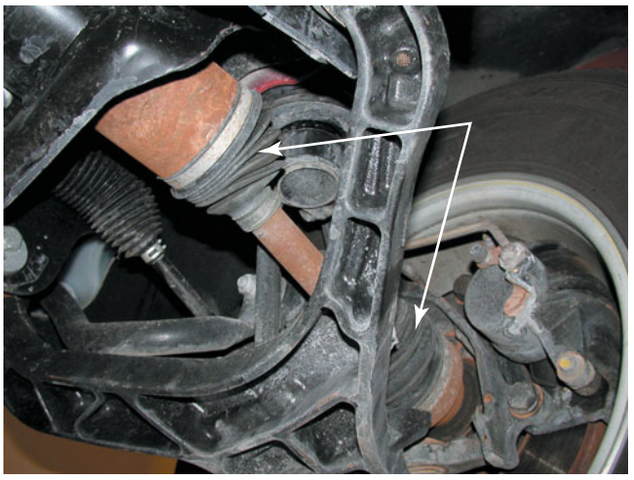

FIGURE 126–22 Constant velocity (CV) joints are used on the front axles of many four-wheel-drive vehicles like this Chevrolet Blazer.

FIGURE 126–23 Most transfer cases use an internal oil pump to force the lubricant throughout the unit. Using the correct lubricant is critical to the proper operation of the transfer case.

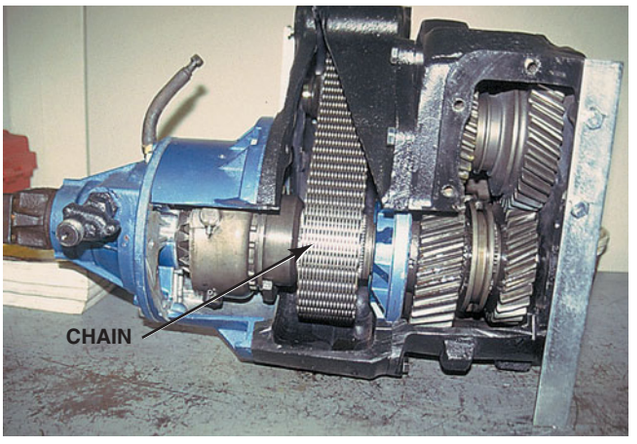
- **Constant velocity (CV) joints.** The use of CV joints at the front wheels allows engine torque to be applied without changes in wheel speed, as can often occur if standard U-joints are used. ● **SEE FIGURE 126–22.**

NOTE: Constant velocity (CV) joints are commonly used on vehicles that have the differential assembly attached to the frame of the vehicle. This design reduces the amount of weight that has to move up and down during suspension movement and helps provide a smooth ride.

TRANSFER CASE SERVICE AND PROBLEM DIAGNOSIS

Four-wheel-drive transfer cases and related components are usually built strong enough for heavy-duty use. However, there is some preventative maintenance that may need to be done:

- **Draining and refilling the transfer case.** Most transfer cases require automatic transmission fluid (ATF), yet some (especially older) units require SAE 80W-90 GL-4 gear lube. Obviously, any fluid leaks should be corrected as soon as possible to avoid damage from low lubricant level. ● **SEE FIGURE 126–23.**
- **Drive chain.** The chain in chain-drive transfer cases can stretch and start hitting the inside of the transfer case. ● **SEE FIGURE 126–24.** This occurs most frequently in vehicles that use four-wheel drive under heavy loads for extended periods of time. The noise the chain makes is very loud, and the chain should be replaced as soon as possible to avoid excessive damage to the case.
- **Bearings.** Transfer case bearings may cause noise whenever the input shaft is rotating even if the transfer case is in neutral. Consult the factory service information for details on transfer case bearing noise diagnosis procedures.
- **Shifting.** Shifting problems can be caused by several items: shift linkage bent or binding, worn shift fork or synchronizer assembly (● **SEE FIGURE 126–25),** incorrect transfer case lubricant.



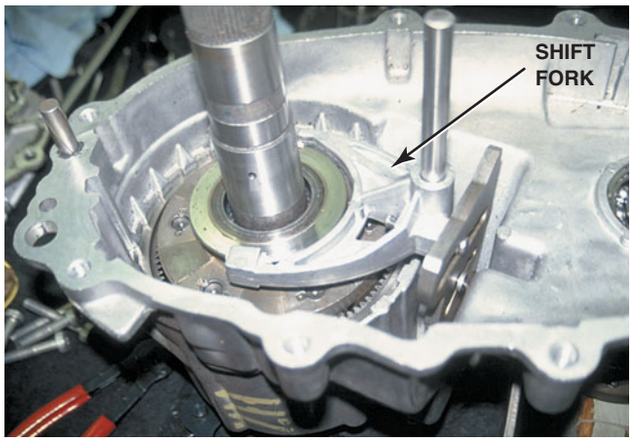


FIGURE 126–24 A cutaway view of a transfer case showing the drive chain.

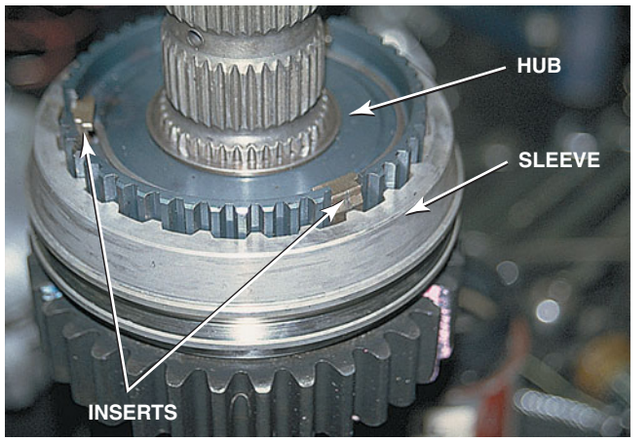
TECH TIP



Please Install Snap Rings Correctly

Many snap rings are tapered at their opening, as shown in ● **FIGURE 126–26.** This allows the snap ring pliers to grasp the points of the snap ring so that it can be expanded and easily removed. If the points are facing down, it is very difficult for snap-ring pliers to grasp the end of the snap ring. Therefore, to make it easier to disassemble a transfer case later, always install snap rings as they were designed to be installed.

NOTE: The transfer case may be difficult to shift if the recommended procedure is not followed. For example, many manufacturers recommend that the vehicle be completely stopped before attempting to make a mode and/or a range shift. Verify proper shifting procedures before further testing or disassembly.

(a)

(b)

FIGURE 126–25 The transfer case shift forks attach to the synchronizer sleeve. (b) The sleeve, hub, and inserts are similar in design except larger than those used in a manual transmission/transaxle.

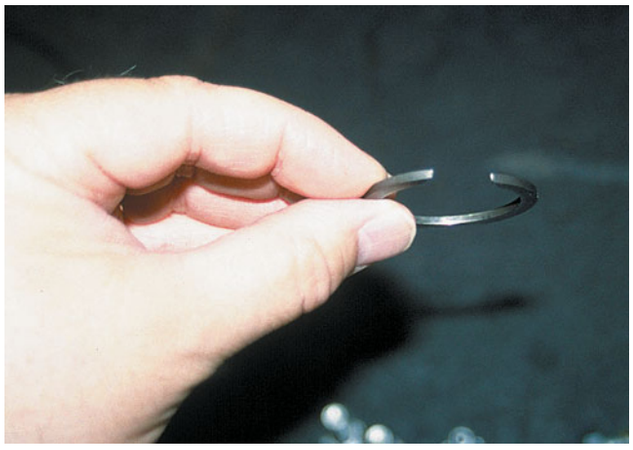


FIGURE 126–26 When reassembling a transfer case (or another automotive component) that includes a snap ring, always be sure that the upper opening is tapered from the top to allow snap-ring pliers room to get a grip on the open end.

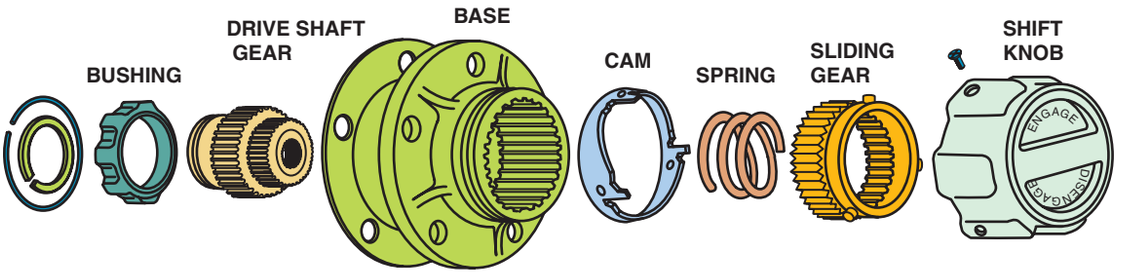
TECH TIP

Keep the Differential Vents Clear

All differentials are vented to allow for expansion and contraction of differential lubricant in all temperature ranges. Typically, these vents are shielded openings near the top of the differential. Most trucks, especially four-wheel-drive vehicles, use an extended vent hose to prevent water from getting into the differential if the vehicle is driven in deep water.

If mud gets into the vent, pressure can build up inside the differential and cause lubricant leakage past the rear axle seals. Therefore, whenever replacing rear axle seals, always check to make sure that the differential vent is clear. Remember that four-wheel-drive vehicles use two differentials and that both the front and rear vents plus the vent on the transfer case should be checked.



REAL WORLD FIX

The Differential Lubricant Story

A four-wheel-drive vehicle was serviced and both differentials were drained and refilled as recommended by the vehicle manufacturer. The owner returned shortly after picking up the vehicle and complained that the vehicle drove as if the parking brake was still applied. The vehicle lacked power and would decelerate rapidly whenever the accelerator pedal was released. Careful inspection of the parking brake revealed that everything was functioning correctly. Because all that was done was the differential fluid service, the fluid level was checked and again, the level was correct and not overfull. Then the technician checked the container of gear lubricant that was used and discovered that the parts store had accidentally sent SAE 80W-140 instead of the requested, and more commonly used, SAE 80W-90. Both lubricants were listed GL-5 meaning that they were acceptable for differentials. The container of lubricant had been installed in the portable lubricating dispenser when it was delivered, and therefore the label on the container was not visible to the technician. The correct lower viscosity lubricant was installed in the differential and normal vehicle performance was restored. The technician and the parts store learned to double-check the product before shipping or using it.

DIAGNOSING AND SERVICING LOCKING HUBS

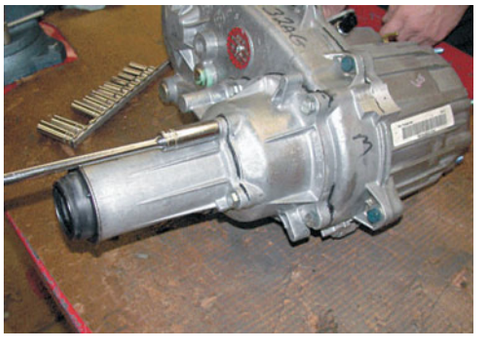
Locking front hubs should be cleaned periodically, especially if the vehicle has been driven under water or in dusty conditions. Most vehicle manufacturers recommend that the hubs be cleaned and lightly coated with grease at the same time the front wheel bearings are serviced. Check the service information for the exact procedure for the vehicle being serviced. ● **SEE FIGURE 126–27.**

(a)

(b)

FIGURE 126–27 (a) An exploded view of a Dualmatic® manual locking hub. (b) A Warn® manual locking hub.

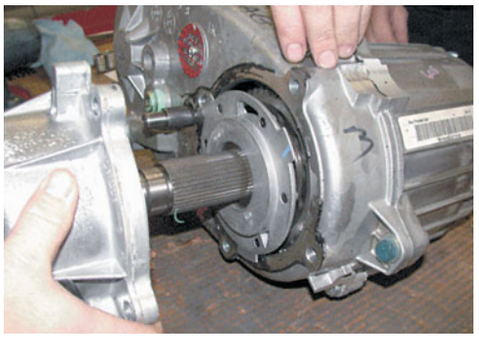
Start the inspection of the front hubs by removing the cover plate. Many problems associated with locking hubs can be corrected by cleaning and lubricating the components. If noise is heard from the hubs, carefully inspect the inner components on both sides of the vehicle. A damaged part can cause noise in the hub on the other side. Service kits are often available for the hubs. These kits contain the gaskets, seals, and retaining rings necessary for installing the hubs correctly after wheel bearing or front brake work has been completed.



NOTE: Check the amount of axle end play. Excessive end play caused by defective bearings can cause the drive axle to move enough to damage the hubs.

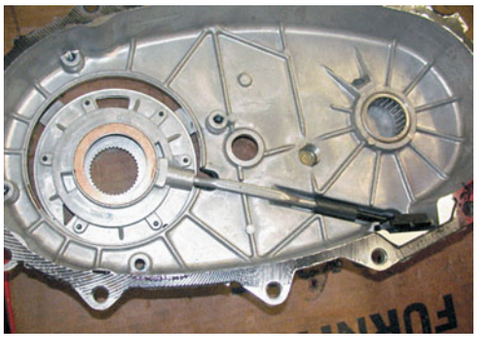
TRANSFER CASE SERVICE

Transfer cases usually require occasional lubricant change during normal service life. However, driver abuse often causes parts to break, requiring the overhaul or replacement of the entire assembly. Always follow the vehicle manufacturer's recommended servicing procedure.

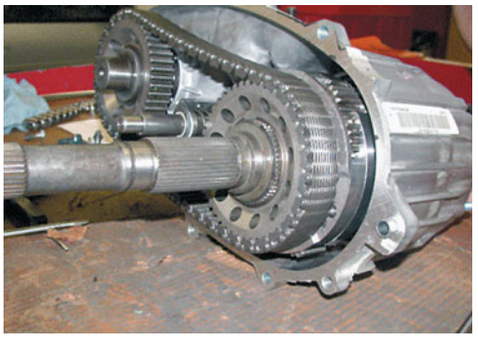


1 The identification plate on the housing indicates the transfer case is a New Venture (New Process) model #242 and has a low-range gear ratio of 2.72.1.

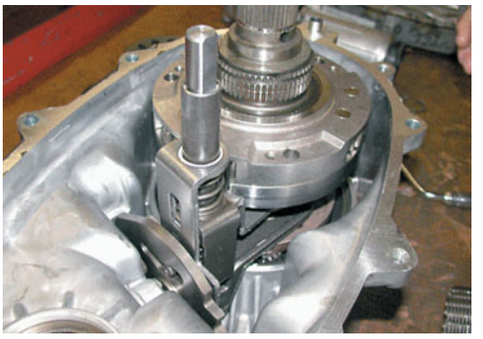
2 Rear output shaft housing being removed.



3 Before the case can be separated, the bearing retaining snap ring must be removed using snap-ring pliers.



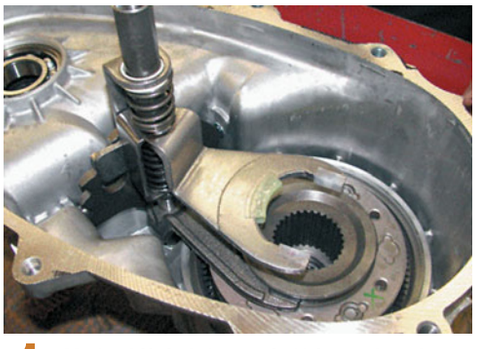
4 The lubricating oil pump is visible after the cover and bearing assembly have been removed.



5 The two case halves are being separated.

6 The oil pump assembly, pickup screen, and tube are visible on the backside of the case cover.

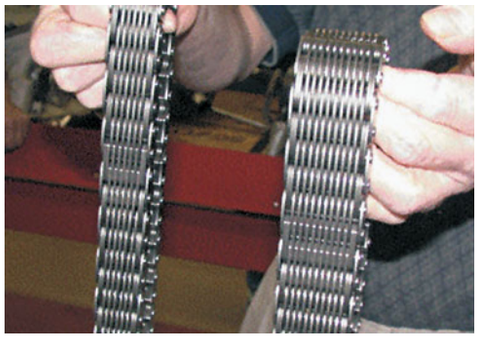
7 The rear output shaft and sprocket are visible on the right. The front output shaft and sprocket are visible on the left connected by the drive chain.



8 View of the shift levers and the center differential after the chain has been removed.

9 Differential being removed.

10 Center differential assembly after removal from the transfer case.



11 Mode shift fork (upper fork) is used to change two-wheel drive and four-wheel drive. The fork is attached to the range hub, which changes four-wheel drive high to four-wheel drive low.

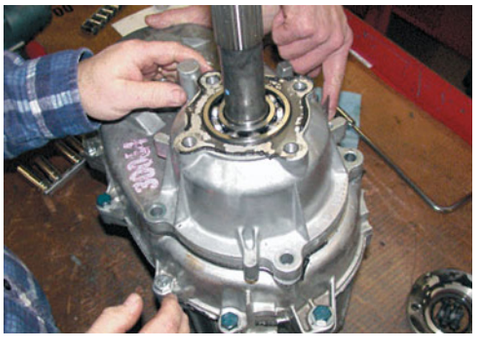
12 Main shaft showing the range hub (left), which changes the transfer case between four-wheel high and four-wheel low.

CONTINUED ▶

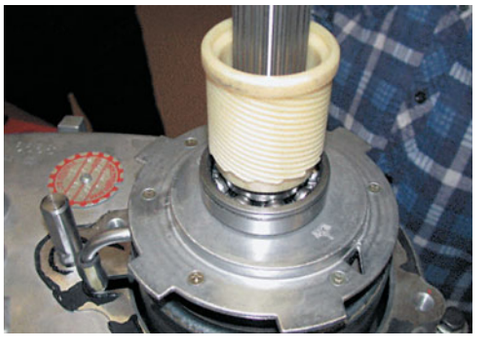
13 The chain used on the NV-242 (right) is larger than the chain used in the smaller version NV-231 (left).

14 Reinstalling the components and the drive chain.

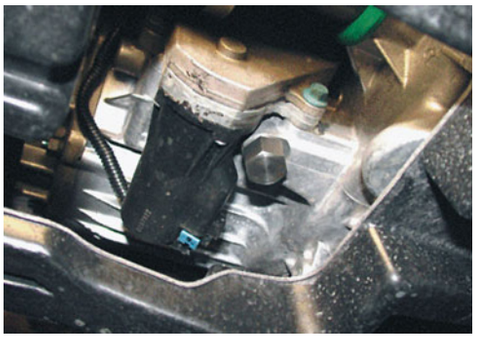
15 The drive chain should be installed with the black (dark) link(s) up.



16 Install all snap rings so that the sharpest tips face up so snap-ring pliers can grab onto the tips for easier removal.



17 Assembling the case halves.



18 The parting surface should be sealed with RTV silicone. Do not use too much or the oil pump screen can become clogged.

19 After attaching the oil pump and tube, the output shaft housing is installed.

20 The output shaft speed sensor drive gear is correctly installed in this photo. The slip yoke of the drive shaft slips onto the splines and inside the nylon gear.

21 The electronically-shifted version of the case is identical except that the shifting is achieve an electric motor, shown here installed in a vehicle.

REVIEW QUESTIONS

1. Explain the difference between four-wheel drive and all-wheel drive.
2. Explain why part-time four-wheel-drive vehicles use locking front hubs.
3. Describe the difference between a mode shift and a range shift in a transfer case.
4. Describe how a viscous coupling works.
5. List the elements of the planetary gear set used in many transfer cases.

CHAPTER QUIZ

1. A customer complained of excessive vibration while cornering and accelerating at the same time. Technician A says that a fault in the transfer case is the most likely cause. Technician B says that the vibration may be normal if the vehicle is equipped with Cardan U-joints at the front wheels. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

2. Technician A says that the gear ratios of both differentials are the same in a four-wheel-drive vehicle. Technician B says that the rear differential has a slightly higher ratio (lower number) than the front differential. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

3. Technician A says that most transfer cases have a built in oil pump. Technician B says that most transfer cases use a heavy grease as a lubricant. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

4. Technician A says that a vehicle equipped with part-time four-wheel drive should be driven in four-wheel drive only on slippery surfaces. Technician B says that full-time four-wheel-drive vehicles use a center differential in the transfer case. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

5. Which type of system uses a one-speed transfer case and a center differential with a viscous coupling?
   a. Part-time four-wheel drive
   b. Full-time four-wheel drive
   c. Full-time four-wheel drive with automatic locking front hubs
   d. All-wheel drive

6. Technician A says that a transfer case may use GL-4 gear lube such as SAE 80W-90. Technician B says that a transfer case may use automatic transmission fluid (ATF) such as Dexron III. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

7. A transfer case is extremely noisy in all selections except neutral (N) whenever the vehicle is moving. Technician A says the drive chain may be stretched, causing the noise as it hits the inside of the case. Technician B says that one or more of the transfer case bearings could be defective. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

8. A transfer case is difficult to shift (range shift). Technician A says that the shift linkage or shift fork may be worn or damaged. Technician B says that the shift fork may be worn or damaged. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

9. Two technicians are discussing the towing of a four-wheel-drive vehicle. Technician A says that the vehicle should be transported on a flatbed truck to avoid the possibility of doing damage to the drive train. Technician B says that the wheels not lifted off the ground by the tow truck should be placed on a dolly to prevent doing damage to the drive train. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

10. Two technicians are discussing the front axle disconnect mechanism. Technician A says that the front axles are only disconnected if the vehicle is being towed. Technician B says that this unit is only used on all-wheel-drive vehicles. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

chapter 127

AUTOMATIC TRANSMISSION/ TRANSAXLE PRINCIPLES

OBJECTIVES: **After studying Chapter 127, the reader will be able to:** • Prepare for the ASE Automatic Transmission/Transaxle (A2) certification test content area "A" (General Transmission/Transaxle Diagnosis). • Explain how a torque converter can transmit and multiply engine torque. • Describe how a planetary gear set can be used for gear reduction and reverse. • Explain how continuously variable transmissions work. • Describe how a dual clutch automatic transmission works.

KEY TERMS: Continuously variable transmission (CVT) 1561 • Coupling phase 1555 • Creep 1555 • Impeller 1551 • Input member 1559 • Lapelletier gear set 1560 • Output member 1559 • Planet carrier 1558 • Ravigneaux gear set 1560 • Reaction member 1559 • Ring (annulus) gear 1558 • Rotary flow 1554 • Simpson gear set 1559 • Stall speed 1555 • Stator 1551 • Sun gear 1558 • Torque converter clutch (TCC) 1556 • Turbine 1551 • Vortex flow 1554

BACKGROUND

Automatic transmissions were first used on a large scale in the early 1950s, and now about 85% of the vehicles in North America are so equipped. Unlike manual transmissions, most automatic transmissions shift gears by applying clutches (or bands) to hold or drive various elements of two or more planetary gear sets that provide different gear ratios.

The history of automatic transmission goes back over 100 years. ● **SEE CHART 127–1** for a timeline for automatic transmissions.

TORQUE CONVERTERS

PURPOSE AND FUNCTION The torque converter is located between the engine and the transmission/transaxle and performs the following functions.

1. Transmits and multiplies engine torque
2. Acts as a clutch between the engine and the transmission/transaxle
3. Allows slippage, which makes it possible for the transmission to be engaged in gear even when the vehicle and wheels are stopped

PARTS The three major parts of the torque converter include:

1. **Impeller.** The **impeller** is the driving member and rotates with the engine, and is located on the transmission side of the converter. The impeller inside the torque converter is also called the *pump* (not to be confused with the pressure pump).
2. **Turbine.** The **turbine** is located on the engine side of the converter. The impeller vanes pick up fluid in the converter housing and direct it toward the turbine. Fluid flow drives the turbine, and when the flow between the impeller and the turbine is adequate, the turbine rotates and turns the transmission input shaft.
3. **Stator.** A torque converter also contains the **stator,** or reactor, which is a reaction member mounted on a one-way clutch.

YEAR	BRAND NAME	NUMBER OF FORWARD SPEEDS	DESCRIPTION
1904	Sturtevant Brothers	2	Two forward speed gear ratios automatically shifted by flyweights
1908	Ford	2	Model T (two speeds plus reverse using a planetary gear set shifted with foot pedals)
1934	REO, GM***	2	A semiautomatic transmission with a foot clutch
1939	Chrysler Corp.**	3	First to use "fluid coupling" (Hy-Drive) with a manual three speed transmission
1940	Oldsmobile	4	Hydra-Matic unit used a fluid coupling plus three planetary gear sets, giving four forward speeds plus reverse (Other vehicles that used this transmission are Nash, Cadillac, Pontiac Bentley, Mercedes Benz, and Rolls-Royce.)
1948	Buick	2	First transmission to use a fully automatic torque converter (with fluid coupling and a planetary gear set); named the "DynaFlow" (1949–1967)
1949	Packard	2	First vehicle to have a lockup torque converter (Ultramatic transmission)
1950	Chevrolet	2	Powerglide (1950–1973)
1950	BorgWarner	3	Developed three speed torque converter transmissions for American Motors,**** Ford Motors (Ford-O-Matic), and Studebaker (1950–1968)
1953	Chrysler Corp.**	2	First two speed torque converter transmission called the PowerFlite (1953–1961) ● **SEE FIGURE 127–1.**
1956	Chrysler Corp.**	3	First three speed torque converter transmission called the TorqueFlite (1956–1977); first construction was a cast iron case, then changed to aluminum in 1962
1956	General Motors***	4	Introduced the Jet-A-Way unit; used two fluid couplings to improve shift quality; first transmission to use a "park" position (1956–1969)
1964	General Motors***	2	Two speed transmission (Jet-A-Way) (1964–1969)
1979	General Motors***	3	First transmission to use an electronically activated torque converter clutch (lockup torque converter) (THM-200C) (1979–1987)
1980	Ford	4	First overdrive transmission (AOD) (1980–1992)
1989	Chrysler Corp	4	First computer controlled transmission (A604/41TE) (1989–current)
2002	BMW	6	First to introduce a six speed transmission (2001–current)
2003	Mercedes	7	First to introduce a seven speed transmission (2003–current)
2007	Lexus	8	First to introduce an eight speed transmission (2007–current)
2007	Mercedes	7	Introduced an automatic transmission that replaced the torque converter with a lockup clutch

*Ford Motor Co. includes Ford, Lincoln, Mercury, and Ford trucks
**Chrysler Corp. includes Dodge, Plymouth, Chrysler, DeSoto, Jeep, and Dodge/Plymouth trucks
***General Motors Corp. includes Chevrolet, Oldsmobile, Buick, Cadillac, Pontiac, and Chevrolet/GMC trucks
****American Motors Corp. includes Nash, Rambler, Jeep, and Pacer

CHART 127–1

Automatic transmission use, while available in some models much sooner, increased in great numbers in the 1950s.

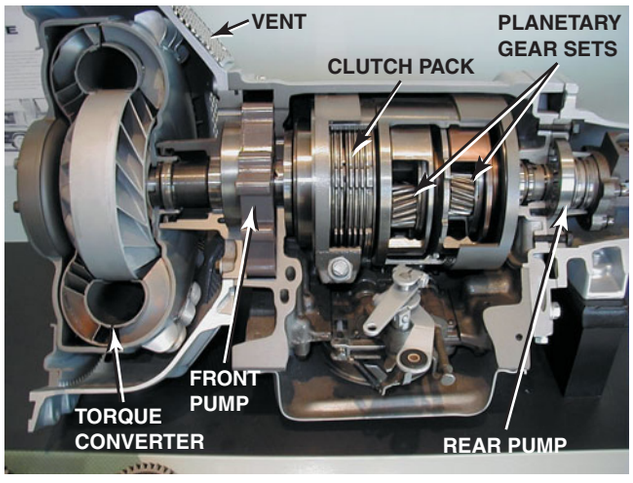

FIGURE 127–1 A cutaway of a Chrysler PowerFlite two speed automatic transmission used in the 1950s.

● **SEE FIGURE 127–2.**

The vanes used in each of the three elements of a torque converter are curved to increase the angle of the fluid flow. This also increases the force exerted by the fluid and improves the hydraulic advantage. The outlet side of the impeller vanes accelerates the fluid as it leaves the impeller to increase torque transfer to the turbine. The impeller and the turbine contain a curved shelf known as *split rings* to more efficiently move the fluid. ● **SEE FIGURE 127–3.**

OPERATION A torque converter acts like two fans pointing toward each other. Air pushed by the powered fan causes the blades of the nonpowered fan to rotate. In the case of a torque converter, the two fans are the turbine and the impeller. The transmission fluid is the air that is being forced to turn the nonpowered fan. ● **SEE FIGURE 127–4.**

The fluid only connection between the impeller and the turbine allows for absorption of sudden and harsh shocks in speed and/or

torque. The curve of the stator vanes is opposite to the curve of the impeller and turbine vanes.

Since the stator is located between the impeller and turbine, it changes the direction of the fluid as it leaves the turbine, and thereby multiplies the torque from the impeller.

Torque converters are single-piece, welded and balanced assemblies that cannot be disassembled or easily repaired. Although they can be rebuilt using specialized equipment, most shops simply replace converters as a unit if they fail.

TORQUE CONVERTER FLEXPLATE The torque converter is typically bolted to a thin metal disc called a flexplate. The center of the flexplate often has a pilot indention for the nose of the converter, and the flexplate itself is bolted to the rear flange of the engine. ● **SEE FIGURE 127–5.**

The flexplate replaces the heavy flywheel used with a manual transmission. An important function of a flywheel is to smooth out engine pulsations and dampen vibrations. An automatic transmission does not require a conventional flywheel because the weight of the torque converter provides enough mass to dampen engine vibrations.

An external ring gear generally attaches to the outer rim of the flexplate, while on some applications the ring gear may be welded to the outside of the torque converter cover. This ring gear engages the starter motor pinion gear to turn the engine during starting. Some manufacturers also place the crankshaft position sensor tone ring in the outer lip of the flexplate.

NOTE: Hybrid vehicles may use a torque dampener plate in place of the torque converter. The dampener plate contains springs to absorb driveline shock, similar to a manual transmission clutch disc. It also drives the mechanical fluid pump and input shaft; however, it does not have transmission fluid, turbine, impeller, or stator elements inside it.

TORQUE CONVERTER DRIVES THE PUMP Oil pump drive shafts generally pass through the converter inside a hollow input or transfer shaft and internally connect to the converter housing by splines or a hexagon-shape shaft. The torque converter is also responsible for driving the transmission oil pump, sometimes called the *front pump,* because some early 1950s transmissions used a *rear pump* attached to the output shaft to allow "push starting" of automatic transmission equipped vehicles. The inner portion of

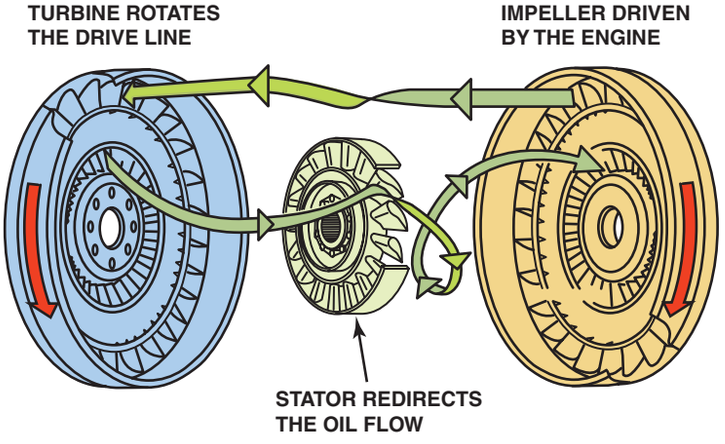

FIGURE 127–2 A torque converter is made from three parts: The impeller is located at the transmission end, attached to the housing, and is driven by the engine. The turbine is located at the engine side and is driven by the fluid flow from the impeller and drives the input shaft of the transmission. The stator redirects the flow to improve efficiency and multiply torque.

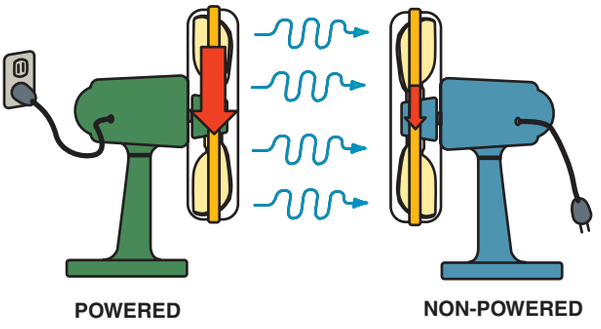

FIGURE 127–4 Two fans can be used to show how fluid, or air in the case of fans instead of automatic transmission fluid, can be used to transfer energy. If one fan is operating, the blades of a second fan will be rotated by the flow of air past the fan that is unplugged, causing the blades to rotate.

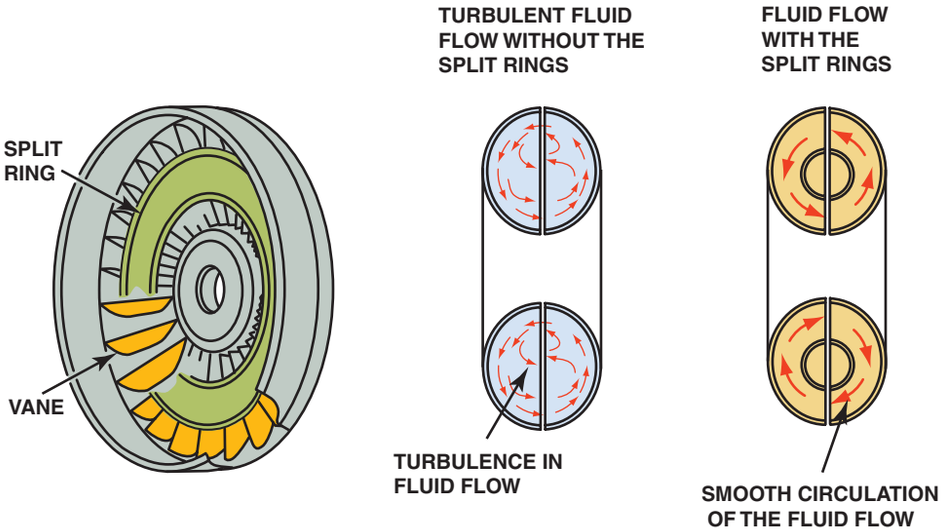

FIGURE 127–3 The slip rings help direct the flow of fluid and improve the efficiency of the torque converter by reducing turbulence.

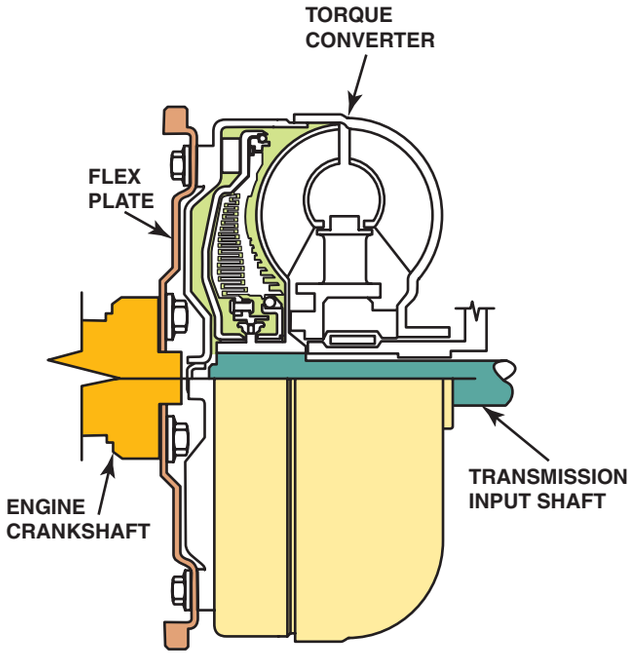

FIGURE 127–5 The torque converter bolts to the flexplate which is attached to the engine crankshaft and rotates at engine speed.

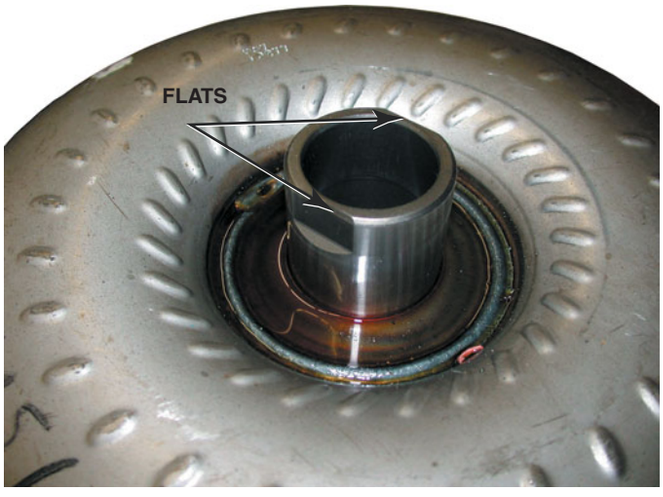

FIGURE 127–6 The flat sections that are cut into the hub of the torque converter are used to drive the fluid pump.

the front pump couples to the torque converter hub by using either "flats" or "tangs." The converter drive hub at the rear of the torque converter housing passes over the stator support and through the front oil seal to engage with and drive the oil pump. Because the shell of the torque converter is bolted to and rotates with the engine, this ensures that the fluid pump will only spin when the engine spins. ● **SEE FIGURE 127–6.**

One method is to attach the inner pump gear/rotor to the converter hub (most RWD transmissions); and the other is to use a separate oil pump drive shaft that connects the torque converter to the front oil pump (most FWD transaxles).

NOTE: Hybrid vehicles supplement the converter driven pump with an electric driven pump to ensure fluid flow and pressure even when the engine is stopped.

TRANSMISSION INPUT SHAFT

Most rear-wheel-drive transmissions use an inline method to drive the converter and provide a direct mechanical connection between the turbine and the transmission input shaft. In a typical design, splines on the turbine connect it to the transmission input shaft and the stator hub mounts on a one-way overrunning clutch. The one-way clutch mounts on splines to a stationary extension of the oil pump called the *stator support,* or *reaction shaft.* ● **SEE FIGURE 127–7.**

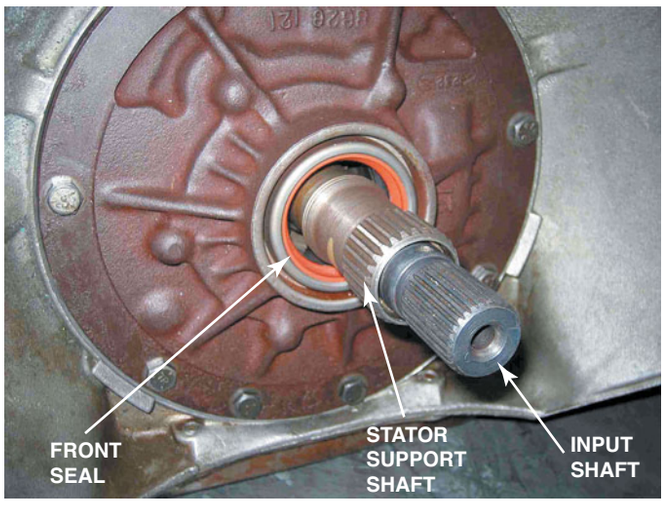

FIGURE 127–7 The internal splines inside the torque converter are connected to the splines on the stator support shaft and the turbine splines to the input shaft.

TORQUE CONVERTER OPERATION

Fluid sent to the torque converter from the transmission oil pump is picked up by the rotating vanes of the impeller and transferred to the turbine vanes. The two types of fluid flow inside a torque converter are rotary flow and vortex flow.

1. **Rotary flow** is created by the rotation of the torque converter and causes the oil (ATF) to flow around the circumference of the torque converter.
2. **Vortex flow** is the flow of the fluid from the impeller to the turbine and back to the impeller.

TORQUE MULTIPLICATION PHASE

Torque multiplication in a torque converter occurs due to the following series of events inside the torque converter.

1. Fluid leaving the turbine vanes strikes the concave, or front side, of the stator vanes.
2. The stator vanes change the direction of the fluid so that it pushes the back side of the impeller vanes.
3. The stator redirects fluid flow because it remains stationary during the torque multiplication phase.
4. The stator hub mounts on a one-way clutch, freewheeling in a clockwise direction, but locking when driven in a counterclockwise direction.
5. The stator redirects fluid flow because it remains stationary during the torque multiplication phase.
6. When fluid from the turbine strikes the concave face of the stator vanes, it tries to drive the stator counterclockwise. By locking the stator, it can redirect the fluid back to the impeller.
7. The force of the fluid redirected from the stator adds to the force of the fluid flowing to the impeller, to increase the overall torque being transferred from the impeller to the turbine. This is called the *torque multiplication phase.* ● **SEE FIGURE 127–8.**

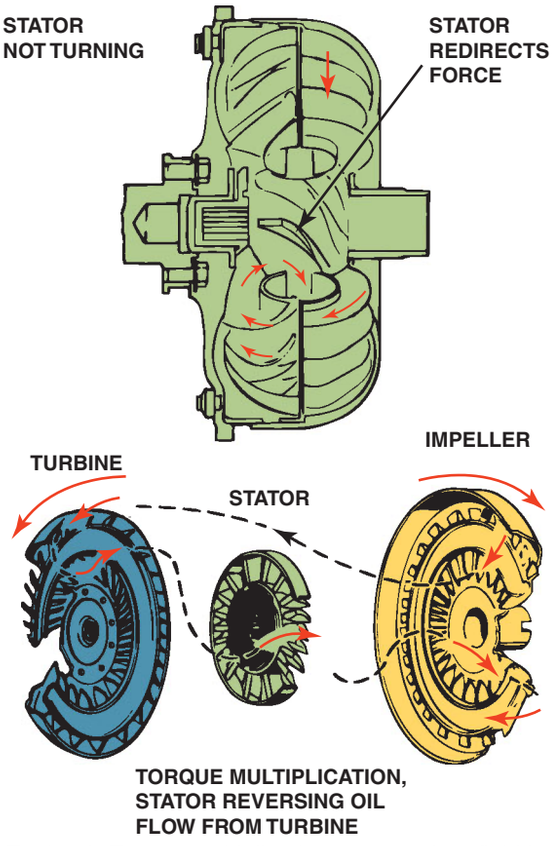

FIGURE 127–8 Torque multiplication occurs when fluid leaving the turbine strikes the front of the stator vanes and is redirected back to the impeller.

Torque multiplication occurs whenever the vortex flow makes a full cycle from impeller to turbine, through the stator and back to the impeller. A torque converter multiplies torque in relation to the speed ratio.

- At low speed ratios, the impeller (engine speed) is turning much faster than the turbine (transmission input shaft speed), so vortex flow is high and torque multiplication occurs.
- As turbine speed increases and approaches impeller speed, rotary flow increases, which reduces both vortex flow and torque multiplication.
- As the speed ratio approaches 90%, torque multiplication becomes minimal and a torque converter functions like a fluid coupling.

The stator hub mounts on a one-way clutch, freewheeling in a clockwise direction, but locking when driven in a counterclockwise direction. When fluid from the turbine strikes the concave face of the stator vanes, it tries to drive the stator counterclockwise. By locking the stator it can redirect the fluid back to the impeller. ● **SEE FIGURE 127–9.**

COUPLING PHASE When the speed ratio is 90° or more, fluid flow in the torque converter is mostly rotary flow and the angle of flow from turbine to stator increases. This is called the **coupling phase.** When the torque converter reaches this phase, the turbine is traveling at nearly the same speed as the impeller, rotary flow is much greater than vortex flow, and the torque multiplication drops. During this phase, fluid from the turbine strikes the convex side, or backside, of the stator vanes rather than the concave side. As the force of fluid striking the backside becomes great enough to drive the stator clockwise, the stator one-way clutch overruns. With the

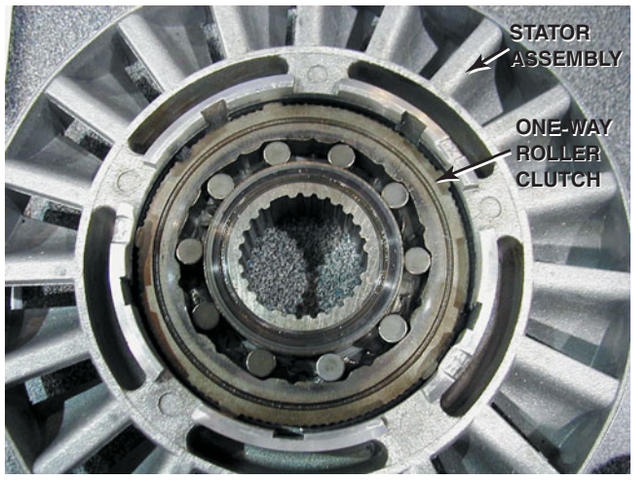

FIGURE 127–9 A stator contains a one-way roller clutch which locks it from rotating in one direction and allows it to rotate freely in the opposite direction.

clutch overrunning the turbine, impeller, and stator, all rotate in the same direction and at approximately the same speed. The stator unlocks and freewheels once the angle of fluid flow changes enough to strike the opposite side of the stator vanes and rotate the stator clockwise.

Torque multiplication drops as the torque converter approaches the coupling phase because the stator no longer redirects fluid to increase the flow from impeller to turbine. When the torque converter reaches coupling speed, the turbine is traveling at nearly the same speed as the impeller, rotary flow is much greater than vortex flow, and the torque converter simply transmits torque like a fluid coupling. During the coupling phase, most converters lose about 10% coupling efficiency, which means that there is a 10% speed difference between the impeller and turbine.

STALL SPEED **Stall speed** is the engine speed when the engine drives the impeller at the maximum speed possible without moving the turbine. The engine speed at which this occurs is called the torque converter stall speed. When the impeller rotates but the turbine does not, the speed ratio is zero. This is the lowest possible speed ratio and the greatest possible torque multiplication. Most modern torque converters multiply torque in the range of 2:1 to 2.5:1 at the stall speed. Typical stall speeds are designed to match the needs of individual vehicles and engines and range from a low of about 1,450 RPM to as high in some stock vehicles as 2,500 RPM or even higher for high-performance torque converters.

NORMAL OPERATION When the transmission selector is moved from park (P) or neutral (N) into a drive gear, some engine torque is transferred to the input shaft of the transmission or transaxle. The vehicle will move slightly if the brakes are released. This slight movement of the vehicle when the engine is at idle speed and the brakes are released is called **creep.** Therefore, a slight movement is normal for a vehicle equipped with an automatic transmission.

NOTE: Vehicle creep is more noticeable when the engine is cold due to the higher idle speed.

TORQUE CONVERTER DIAMETER The outside diameter of a torque converter and the angle of its stator blades determine the stall speed of the converter. When both a small and large diameter

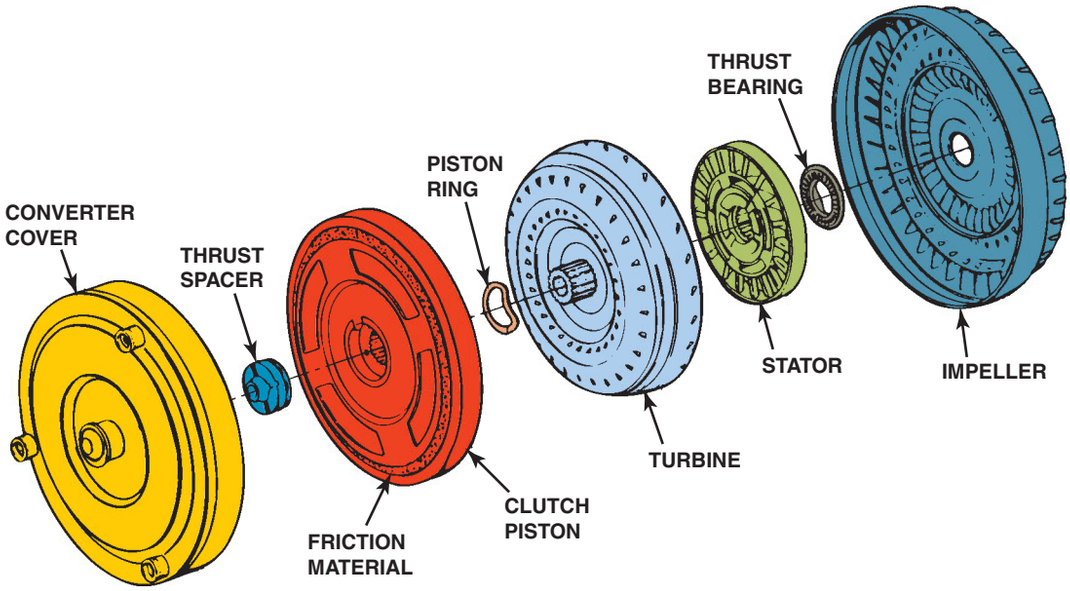

FIGURE 127–10 An expanded view of a typical torque converter assembly showing the torque converter clutch (TCC).

converter share the same stator blade angle and turn at the same speed, the smaller converter creates less centrifugal force to move the fluid inside. As a result, the small diameter converter has a higher stall speed, multiplies torque at higher engine speeds, and will not couple until the engine reaches high speeds. In comparison, the large diameter converter has a lower stall speed, multiplies torque at lower engine speeds, and also couples at a lower engine speed.

Vehicle manufacturers select torque converters to match the powertrain requirements and operating demands of each vehicle application.

- A vehicle with a large engine that produces a lot of torque at low RPM will often use a torque converter that couples at low speeds for greater fuel economy and lowest possible exhaust emissions.
- Vehicles with smaller engines that produce less torque at low RPM will use a torque converter that allows the engine to operate higher in its torque curve, where more power is available. High-performance vehicles with automatic transmissions use small diameter converters for the same reason.
- Therefore, the vehicle manufacturer selects the best stall speed based on the power band of the engine and the weight of the vehicle.

LOCKUP TORQUE CONVERTER

PURPOSE AND FUNCTION Even the most efficient torque converters slip 8% to 12% during operation, because the fluid that transmits torque exhibits a type of slippage known as fluid shear. Fluid shear creates friction heat, but performs no work when the different layers of fluid slide past each other.

Eliminating torque converter slippage can improve fuel economy approximately 4% to 5% during freeway cruising. With the increased emphasis on fuel economy and low exhaust emissions for late model vehicles, this became an important goal for automotive engineers. An additional benefit to reducing slippage is a reduction of transmission operating temperature, which increases transmission life expectancy. Lockup torque converters reduce slippage by using a **torque converter clutch (TCC)** to lock the impeller to the cover (shell). Similar to a clutch for a manual transmission, a TCC uses a friction disc operated by a hydraulic piston to mechanically couple the turbine to the converter (cover /shell). Engaging the clutch creates mechanical connection between the engine and transmission, resulting in a direct 1:1 drive ratio without slippage. ● **SEE FIGURE 127–10.**

CONVERTER CLUTCH CONTROL The first hydraulic lockup converters were controlled entirely by hydraulic pressure and spool valves in the transmission valve body. Some older designs added simple electric switches and solenoids to control pressure to the converter clutch. Since the early 1990s, the powertrain control module (PCM) or the transmission control module (TCM) regulates the timing and application of the clutch. The torque converter clutch operates under the following conditions.

- Lockup may also be limited to specific vehicle speeds or operating conditions. For most vehicles, lockup can occur at speeds over 25 to 30 mph (40 to 48 km/h) but can occur sooner in many newer transmissions/transaxles.
- Once lockup occurs, the clutch may disengage automatically during certain operating conditions such as part- or full-throttle downshift. At these times, the increased acceleration requirements generally override the need for better fuel economy.
- Most computer systems can lock and unlock or modulate a converter clutch hundreds of times per minute to meet the vehicle demands of the moment and some recent systems also allow partial lockup of the torque converter. Traditional lockup torque converters operate either locked or unlocked. Partial lockup converters allow a regulated amount of slippage at the clutch. Each type of torque converter requires a certain type of friction material. ● **SEE FIGURE 127–11.**
- This allows the converter to lock up smoothly, improving fuel economy and performance, without the drawback of shock to the driveline. Using the wrong type of automatic transmission fluid (ATF) can alter the frictional properties of the lockup clutch, leading to shudder or other similar customer complaints.

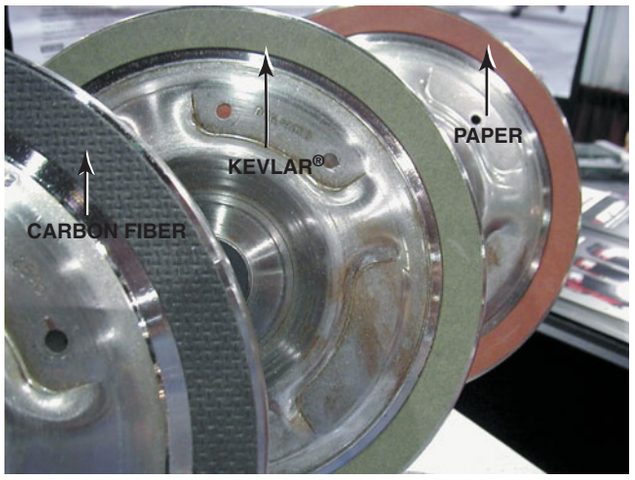

FIGURE 127–11 Torque converter clutch friction material is determined by the vehicle manufacturer to provide the needed coefficient of friction needed. For example, many older units use a paper-type friction material because they are fully applied or released, whereas most newer units use a synthetic material such as Kevlar® or carbon fiber because the torque converter clutch is pulsed on and off, therefore requiring a more robust material for long service life.

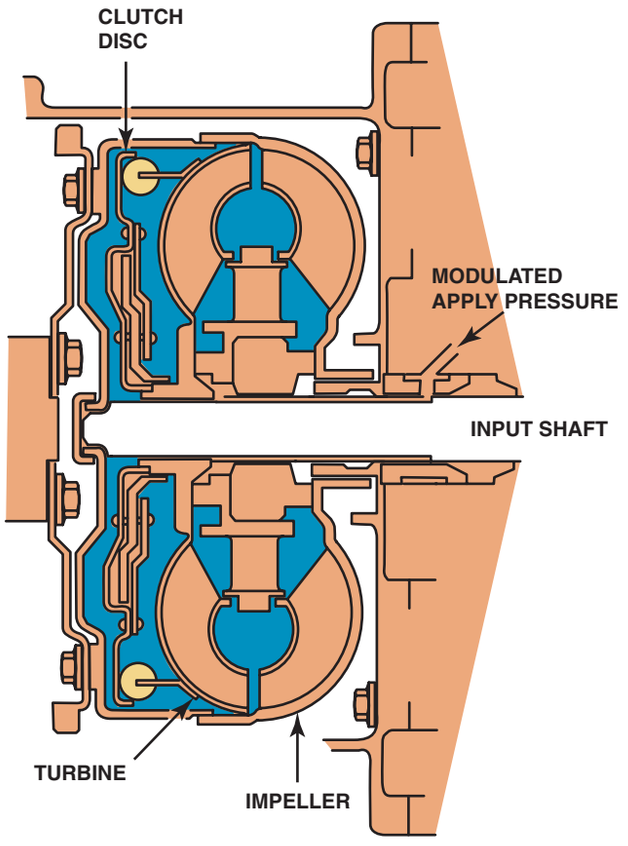

FIGURE 127–12 A cross-sectional view of a pulse-width-modulated (PWM) torque converter clutch. The powertrain control module (PCM) pulses the control solenoid which then controls the fluid flow to apply the torque converter clutch.

HIGH PERFORMANCE TIP

Use a Smaller Diameter Torque Converter for Improved Performance

A smaller-than-stock-diameter torque converter will not be capable of absorbing as much torque as a larger (stock) torque converter. As a result, the stall speed is increased. Because an engine develops more torque with increased speed (up to a point), the smaller torque converter will allow the engine to increase to a higher speed and create more torque to the transmission than would be capable with the stock torque converter.

This is especially helpful for modified engines because an engine having a camshaft with increased lift and duration usually lacks low RPM torque. By using a smaller torque converter, the stall speed is increased to better match the engine torque.

CAUTION: Using a torque converter with a different stall speed rating is likely to increase exhaust emissions and decrease fuel economy as well as void the warranty on the vehicle.

FIGURE 127–13 The gear selector is often called the "PRNDL," pronounced "prindle," regardless of the actual letters or numbers used.

- Most lockup converters automatically disengage the torque converter clutch each time the brake pedal is depressed by the driver or if the accelerator pedal is released for more than a couple of seconds, which is necessary for vehicle deceleration without stalling the engine. ● **SEE FIGURE 127–12.**

SHIFT MODES

Most automatic transmissions and transaxles include the following shift modes. ● **SEE FIGURE 127–13.**

- **Park.** In the park position, the output shaft is locked to the case of the transmission/transaxle, which keeps the vehicle from moving. No power is transmitted through the unit so the engine can remain running while the vehicle is held stationary. In the park position:
  1. The engine can be started by the driver.
  2. To move the shifter out of the park position on a late model vehicle, the brake pedal must be depressed to release the brake transmission shift interlock.
- **Reverse.** The reverse gear selector position is used to move the vehicle in reverse. Reverse usually uses a lower gear ratio than any of the forward gears.

- **Neutral.** In the neutral position no torque is being transmitted through the automatic transmission/transaxle. In this position the engine can be started by the driver.
- **Overdrive (OD).** The OD is the normal position for the shift selector for most driving conditions. This position allows the transmission or transaxle to shift through all forward gears as needed for the best fuel economy and lowest exhaust emissions.
- **Drive (D).** The D position includes the overdrive ratios in most vehicles. If there is an overdrive shift mode, however, then D is used to provide all forward gears except overdrive. Use this position when driving in hilly areas or when towing in the vehicle equipped with an overdrive selection.
- **Third (3).** In third position the transmission/transaxle will upshift normally to third gear but will not upshift to a higher gear. When the third (3) position is selected while driving in a higher gear, the transmission will downshift into third if the vehicle speed is low enough to prevent the engine from being overrevved. This gear selection is used for the gentle grades at a moderate vehicle speed.
- **Second (2).** The second position is used for slowing the vehicle while descending long grades. In this gear selection, the vehicle speed is controlled and the engine speed is increased to provide engine compression braking. This gear selection is used for the gentle grades at a moderate vehicle speed.
- **First (1 or Low).** The first (or low) position is used for slowing the vehicle while descending long grades. In this gear selection, the vehicle speed is controlled and the engine speed is increased to provide engine compression breaking. This gear selection is used for the steepest grades at the lowest possible speed.

NOTE: The overdrive button on many automatic transmissions is used to turn off the overdrive gear. It is used to prevent overdrive while towing or when driving in city traffic to prevent the transmission from shifting in and out of overdrive.

PLANETARY GEAR SETS

PURPOSE AND FUNCTION In a manual transmission, different gear ratios are obtained by sliding the gears into mesh. However, torque flow must be momentarily interrupted (accomplished by using a clutch) before the gears are shifted. With an automatic transmission there is no driver-operated clutch, so gear shifts are not made by sliding gears into mesh. Most automatic transmissions use a planetary gear set system that does not require manual gear shifting or an interruption of torque flow to change gear ratios.

PARTS AND OPERATION A simple planetary gear set consists of three primary components.

- Sun gear
- Planet carrier (including planet pinion gears)
- Ring (annulus) gear

As discussed in the last chapter on transfer cases, the **sun gear** gets its name from its position at the center of the gear set. The **planet carrier** holds the pinion gears, also known as planet gears, which revolve around the sun gear. The planet carrier assembly is commonly referred to simply as "the carrier."

The outermost member of the gear set is the **ring gear,** the internal type with teeth inside. The ring gear is sometimes called an annulus or internal gear. The pinion gears are in simultaneous mesh with both the sun gear and the ring gear. ● **SEE FIGURE 127–14.**

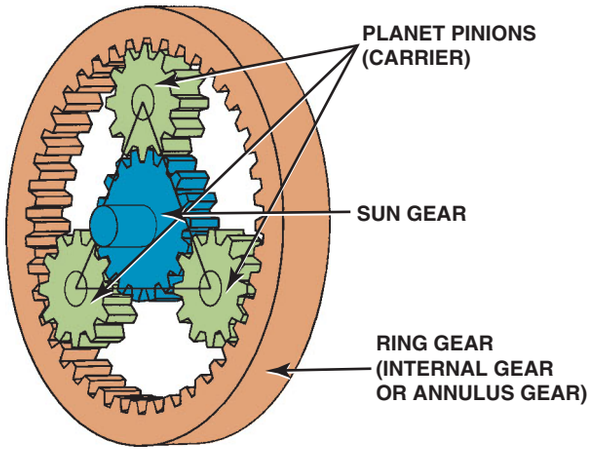

FIGURE 127–14 A typical planter gear set showing the terms that are used to describe each member.

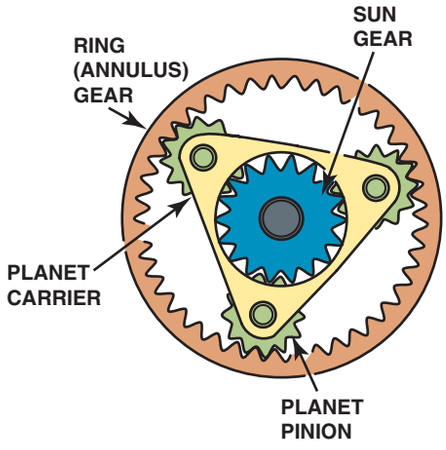

FIGURE 127–15 A typical planetary gear set showing the planet carrier which supports all of the pinion gears (also called planet pinion gears).

The pinion gears are free to rotate on pins that are part of the carrier, and the entire assembly rotates to direct torque flow. Most transmission gear sets use three, four, or even five planet pinions.

The pinions are fully meshed with both the sun gear and internal ring gear *at all times.*

The planetary gears never disengage to change gear ratios; torque is simply redirected.

The torque flow through a planetary gear set, both input and output, occurs along a single axis.

The parts in a planetary gear system may be known by several different names.

PLANETARY GEAR SET TORQUE FLOW In a planetary gear set, the following is done to achieve the various gear ratios and reverse.

- One of the members is being driven (input).
- One of the members is being held (reaction member).
- One of the members is the output.

Therefore, driving one gear will cause all of the other gears to rotate as well. This allows the gear set to provide different gear ratios, depending upon how torque is distributed through the assembly. To transmit torque through a planetary gear set, a drive member rotates while a second member is held, which causes a third member to be driven. ● **SEE FIGURE 127–15.**

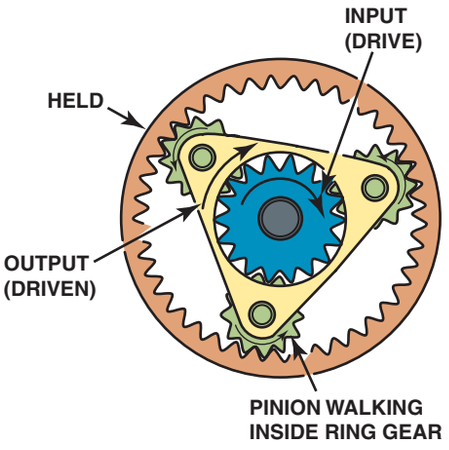

FIGURE 127–16 Maximum reduction can be achieved by using the sun gear as the input, holding the ring gear and using the planet carrier as the output.

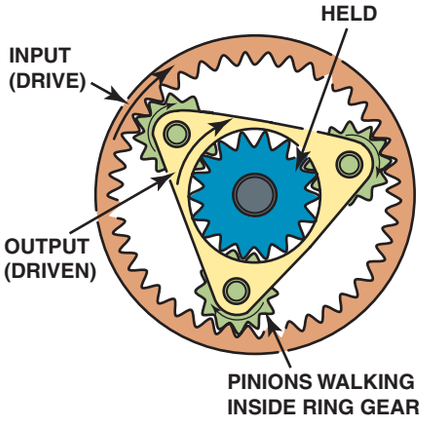

FIGURE 127–17 Minimum reduction can be achieved by using the ring gear as the input, holding the sun gear and using the planet carrier as the output.

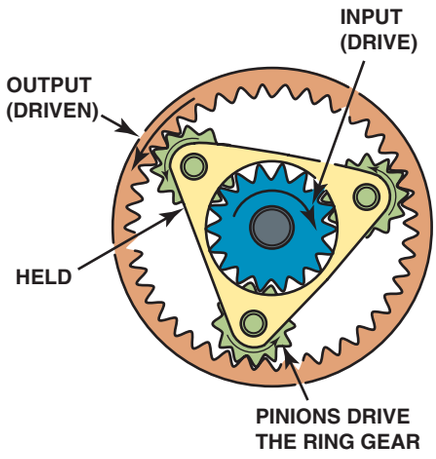

FIGURE 127–18 Reverse can be achieved by using the sun gear as the input, holding the planet carrier and using the ring gear as the output.

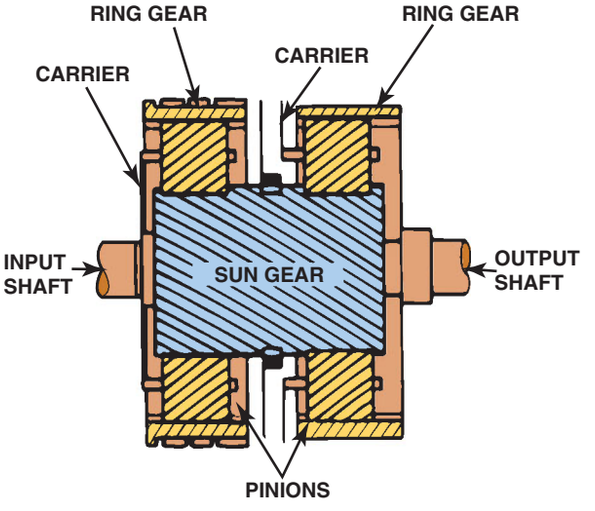

FIGURE 127–19 A Simpson planet gear set is composed of two ring gears and two planet carrier assemblies that share one sun gear.

Each member of a planetary gear set can play any one of these three roles to transmit torque. The various combinations of drive, held, and driven members result in the number of gear ratios available and change the direction of rotation as well for reverse.

NOTE: The held member can also be allowed to move one direction or another as it is being held and does not necessarily need to be held to zero RPM to create a variable gear ratio. This is done in hybrid electric vehicle transmissions.

Torque flows through a planetary gear set in several steps to get from the drive action of the first member to the driven action of the last member.

- The terms “drive” and “driven” simply describe how any two gears work together.
- When three or more gears are involved, the second gear is a *driven* gear in relation to the first, but it becomes a *drive* gear in relation to the third gear.
- For this reason, the drive member of a planetary gear set is known as the **input member,** the held member is the **reaction member,** and the driven member is the **output member.**

SIMPLE PLANETARY GEAR SET SYSTEMS A simple planetary gear set system consists of one sun gear, the carrier, and a ring gear. A single planetary gear set can provide all of the necessary gear ratios for a basic automatic transmission. ● **SEE FIGURE 127–16 THROUGH 127–18.**

A simple planetary gear set is often used together with a compound planetary gear set to provide additional gear ratios.

● **SEE CHART 127–2** for the six possible gear ratios and how they are achieved.

COMPOUND PLANETARY GEAR SET

A *compound planetary gear set* system is a configuration that contains more than just the three basic members of a simple planetary system. A compound planetary gear set is one or more simple planetary gears sets with one or more common gears. Compound planetary gear sets are capable of providing various combinations of gear reduction, direct drive, neutral, reverse, and overdrive.

SIMPSON GEAR SET One of the most popular compound planetary design is the **Simpson gear set.** Named for its inventor, Howard Woodworth Simpson (1892–1963), an American automotive engineer, the Simpson gear set consists of two simple planetary gear sets that share a common sun gear. ● **SEE FIGURE 127–19.**

SUN GEAR	PLANET CARRIER	RING GEAR	SPEED	TORQUE	DIRECTION
Input (Drive)	Output (Driven)	Held	Maximum reduction	Increase	Same as Input
Output (Driven)	Input (Drive)	Held	Maximum increase	Reduction	Same as Input
Held	Output (Driven)	Input (Drive)	Minimum reduction	Increase	Same as Input
Held	Input (Drive)	Output (Driven)	Minimum increase	Reduction	Same as Input
Input (Drive)	Held	Output (Driven)	Reduction	Increase	Reverse of Input
Output (Driven)	Held	Input (Drive)	Increase	Reduction	Reverse of Input

CHART 127–2

If any two members are locked together, then the resulting output is 1:1 ratio in the same direction as the input (direct drive). If no member is held (locked) then there is no output (neutral).

FREQUENTLY ASKED QUESTION

What Companies Build Automatic Transmissions?

Many larger automobile manufacturers make their own automatic transmissions, including General Motors, Ford, Chrysler, and Honda. However, several companies manufacture automatic transmissions and transaxles that are used in a variety of vehicles. These include:

- **ZF Friedrichshafen AG.** This German company manufactures manual and automatic transmissions and transaxles for many vehicle manufacturers, including Mercedes, BMW, Volvo, VW, Audi, Jaguar, Chrysler, Bentley, and Maserati.
- **Aisin AW.** This Japanese company makes automatic transmissions for many vehicle manufacturers including Ford, Toyota, Nissan, Mazda, Mitsubishi, Subaru, Kia, and VW.
- **JATCO (Japan Automatic Transmission Company).** This is a Japanese manufacturer of automatic transmissions and transaxles for many vehicle manufacturers, including Nissan, Mazda, Infinity, VW, Mitsubishi, and Suzuki.

This combination is capable of providing three forward gears, as well as neutral and reverse. Basic operation, construction, and methods of obtaining various gear ratios with a simple planetary gear set also apply to the Simpson gear set. The main difference is the number of gear ratios that are available using more than one planetary gear set.

RAVIGNEAUX GEAR SET Another popular compound planetary design is the **Ravigneaux gear set.** The Ravigneaux system has the following:

- Two sun gears
- Two planet pinion sets, one longer than the other, supported in one carrier
- A single ring gear

SEE FIGURE 127–20.

This design provides four forward gears (two in reduction, one direct, and one overdrive) as well as neutral and reverse. Basic planetary gear set operation, construction, and control methods also apply to the Ravigneaux gear set. An overdrive ratio means the following:

- The output shaft is rotating faster (higher RPM) than the engine crankshaft.
- The ratio is always expressed to the relative ratio of the input shaft speed so that all overdrive ratios are less than 1. For example, 0.75:1 is an overdrive ratio meaning the output is rotating 25° faster than the input shaft speed.

FREQUENTLY ASKED QUESTION

What Do All the Letters and Numbers Mean in Transmission Designations?

The numbers and letters usually mean the following:

- **Number of forward speeds.** The number of forward speeds may include four, five, or six (such as GM 4T60-E four speed unit).
- **Front-wheel drive or rear-wheel drive.** The letter **T** usually means *transverse* (front-wheel-drive transaxle) such as the Chrysler 41-TE; the **L** means *longitudinal* (rear-wheel-drive transmission) such as the General Motors 6L80; and the **R** means *rear-wheel drive* such as the Ford 5R55E.
- **Electronically controlled.** The letter **E** is often used to indicate that the unit is electronically controlled, and **M** or **H** is used to designate older mechanically (hydraulically) controlled units. All automatic transmissions built since the early 1990s are electronically controlled; therefore, **E** is often included in the designation of newer designs of transmission or transaxles.
- **Torque rating.** The torque rating is usually designated by a number where the higher the number, the higher the amount of torque that the unit is designed to handle. In a GM 6L80-E the torque rating is 80.

Always check service information for the exact transmission designation for the vehicle being studied or serviced.

LAPELLETIER GEAR SET The **Lapelletier** (pronounced "la-plet-e-ay") **gear set** was invented by Pierre Lapelleties, a retired engineer who devised a unique way to create a simple and efficient six-speed automatic transmission gear set. It was first produced by ZF in 2002. The Lapelletier gear set is constructed by connecting a planetary gear set in front of a Ravigneaux gear set. Besides ZF, General Motors uses the Lapelletier gear set in the 6L45, 6L50, and 6L90 rear-wheel-drive transmissions and Ford uses it in the 6R60, 6R75, and 6R80 transmissions.

AUTOMATIC TRANSAXLES

TERMINOLOGY Automatic transaxles include a differential assembly as well as the planetary gear sets of an automatic transmission. The engine torque also needs to be transferred by the use of a chain or gears to provide a shorter overall length so it can be used with an engine mounted transversely in the engine compartment. Some use gears and others use a chain to transfer engine torque to either the planetary gear sets or to the differential (final drive) assembly. ● **SEE FIGURES 127–21 AND 127–22.**

A transaxle can be used in the following applications.

- Front engine, front wheel drive
- Rear engine, rear wheel drive
- Front engine, all wheel drive
- Mid engine rear wheel drive

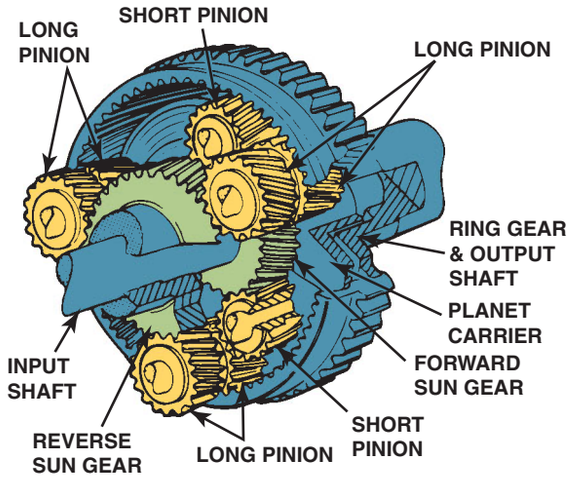

FIGURE 127–20 A Ravigneaux gear set is composed of two sun gears, one planet carrier that supports two sets of pinion gears, and a single ring gear.

FINAL DRIVE UNITS A transaxle includes a differential assembly, often called a *final drive* assembly as part of the transaxle. This final drive assembly connects the output from the gear sets to the drive axle shafts. The final drive assembly includes the side gears and pinions gears as well as the housing. ● **SEE FIGURE 127–23.**

NONPLANETARY GEAR AUTOMATIC TRANSAXLES

Honda and Saturn vehicles use an automatic transmission with no planetary gear sets. This type is similar to and uses many of the same parts as their manual transaxles. This design uses hydraulic clutches instead of synchronizers to make the shift between gears. By using the same parts as manual transaxles, this automatic transaxle has the following advantages.

1. It allows both manual and automatic transmissions to be manufactured in the same plant, therefore reducing cost.
2. By using many of the same parts for both manual and automatic transaxles, manufacturers see a cost reduction.
3. Honda automatic transaxles are diagnosed, and if an internal fault is detected, the entire assembly is replaced with a remanufactured unit. Honda dealership technicians do not repair automatic transaxles. ● **SEE FIGURE 127–24.**

CONTINUOUSLY VARIABLE TRANSMISSION

TERMINOLOGY A **continuously variable transmission (CVT)** is usually found on some front-wheel-drive vehicles that use a transaxle. Instead of using three or more gears, a continuously

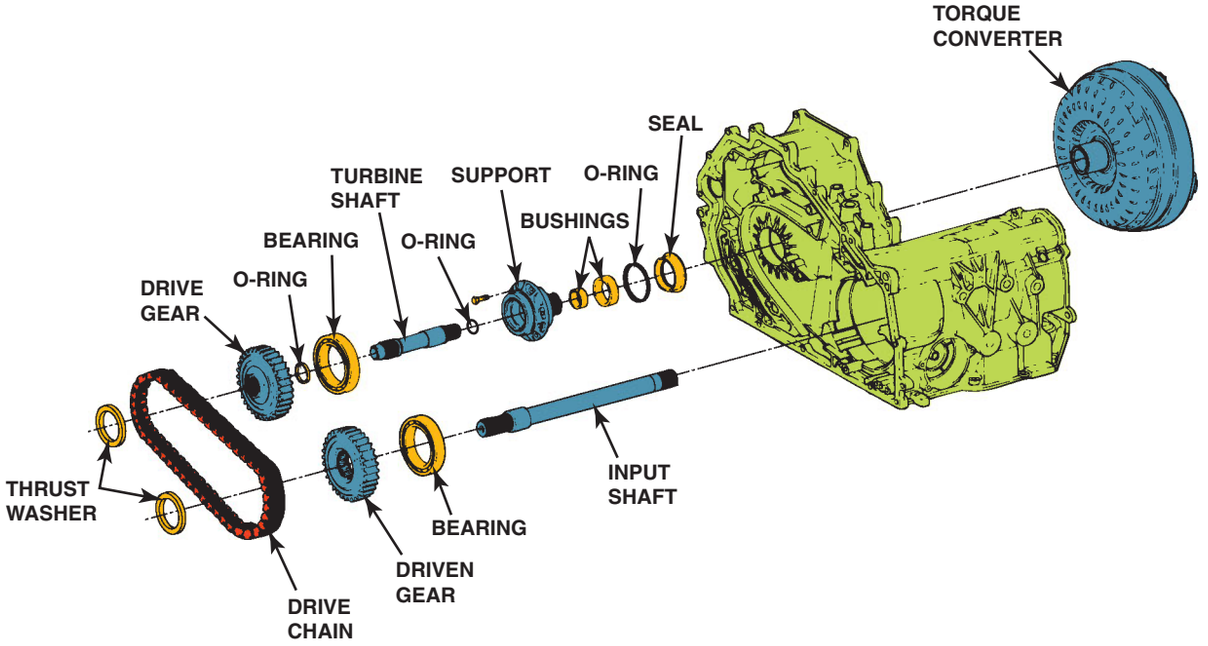

FIGURE 127–21 On one style of transaxle the turbine shaft drives the input shaft through a drive chain assembly.

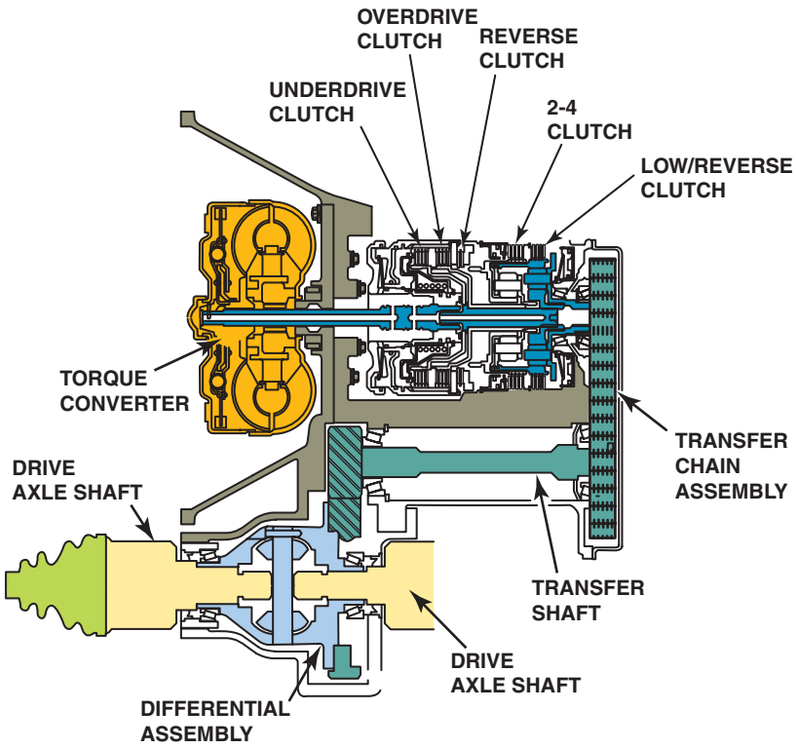

FIGURE 127–22 Another type of transaxle uses a chain to transfer engine torque from the output of the gear sets to the differential assembly (final drive).

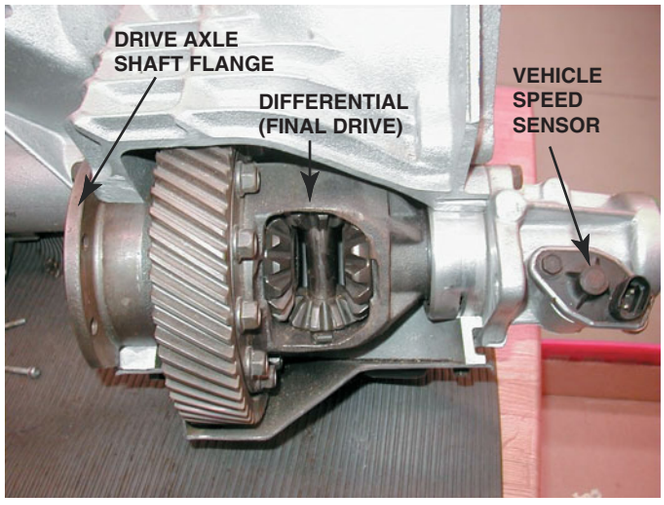

FIGURE 127–23 A cutaway showing the final drive assembly of a transaxle.

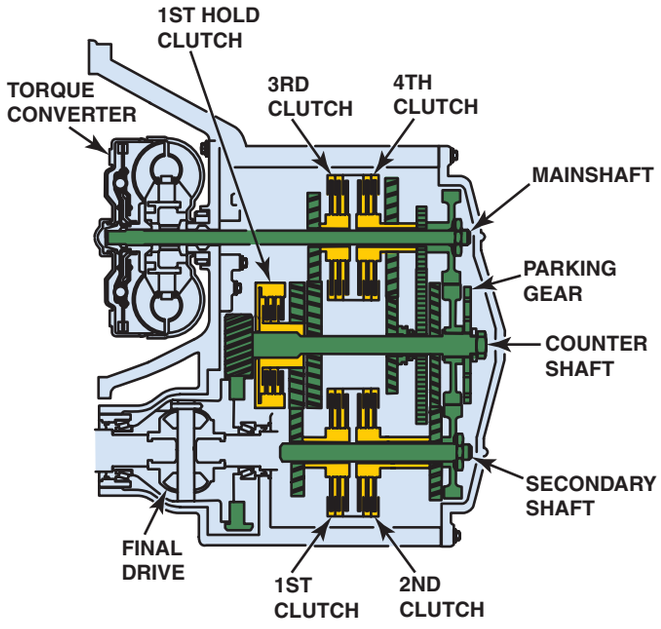

FIGURE 127–24 A Honda nonplanetary gear set type automatic transmission that uses helical cut gears instead of planetary gears. Hydraulically applied clutches as commanded by the PCM with fluid flow controlled by shift solenoids to make the shifts.

variable transmission uses two variable width pulleys, sometimes called *variators,* to change the gear ratio from about 2.5:1 to an overdrive ratio of 0.5:1. ● **SEE FIGURE 127–25.**

PURPOSE AND FUNCTION The purpose and function of a continuously variable transmission is to allow the engine to operate in a speed range where it is most efficient. Therefore, instead of causing the engine speed to vary as the transmission shifts gears, the engine speed is more constant as the pulleys change to increase the speed of the vehicle. The result of using a CVT is improved fuel economy and reduced exhaust emissions.

PARTS AND OPERATION The two pulleys are moved at the same time. One pulley is made smaller in diameter while at the same time the other pulley is enlarged. This change in pulley effective diameter allows the drive chain to move, thereby changing the ratio between the input and output pulleys. The chain is *pushed* rather than pulled through the pulleys and is made of hundreds of individual steel elements. ● **SEE FIGURE 127–26.**

The Honda CVT is constructed very similar to other electronically controlled transaxles, with the primary difference being the use of a belt-and-pulley system instead of multiple planetary gear sets or meshed helical gears.

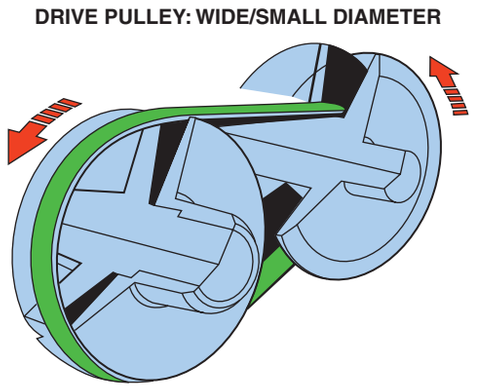

FIGURE 127–25 A belt and pulley CVT uses variable width pulleys and a special chain to provide an infinite number of speed ratios.

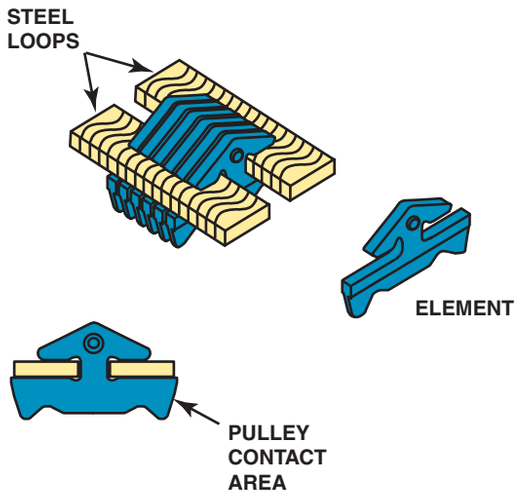

FIGURE 127–26 Honda CVT belt construction.

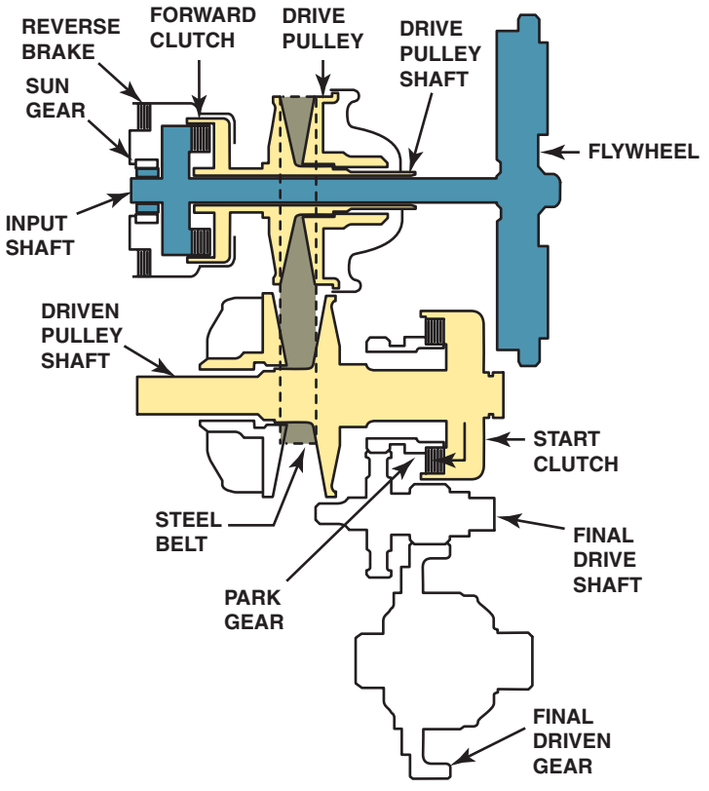

FIGURE 127–27 Honda CVT power flow in park (P) and neutral (N).

The transmission has a total of four parallel shafts:

- Input shaft
- Drive pulley shaft
- Driven pulley shaft
- Secondary gear shaft

The secondary gear shaft is comprised of the secondary driven gear and the final drive gear. The final drive gear is meshed with the final driven gear, which is attached to a conventional open differential assembly. When the transmission is placed in park, the parking pawl interlocks with the park gear, which then holds the secondary drive gear stationary. ● **SEE FIGURE 127–27.**

HONDA CVT OPERATION

The Honda CVT is used as part of the hybrid system on some Honda vehicles. The pulleys used in this CVT design can vary their width by varying the hydraulic pressure applied to them. Each pulley has a movable face and a fixed face. The movable face for each pulley is attached to a piston that has hydraulic control pressure applied to it.

- Higher application pressure on the movable face causes the pulley to become narrow, which makes the steel belt ride closer to the outside diameter of the pulley.
- A lower application pressure will allow the pulley to become wider and the belt to ride closer to the pulley's axis. If a low hydraulic pressure is applied to the drive pulley and a high hydraulic pressure is applied to the driven pulley, a low speed ratio is achieved.
- As the vehicle speed increases, the drive pulley will have progressively higher pressure applied to it, while the driven pulley application pressure is lowered. This results in a higher speed ratio, allowing the engine to operate at a lower RPM. See Figure 127–25.

There are three multiple-disc clutches used in the internal gear train, one for each of the following:

- Forward clutch
- Reverse brake
- Start clutch

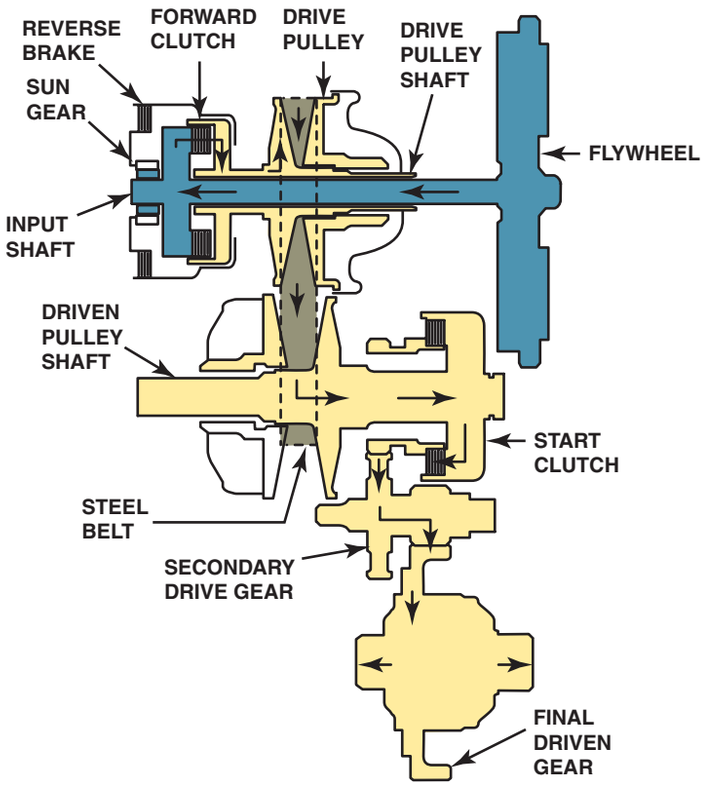

FIGURE 127–28 Honda CVT operation in drive (D) or low (L).

In the Honda Civic CVT, a start clutch is used instead of a torque converter which slips when the vehicle is stopped with the engine running. ● **SEE FIGURE 127–28.**

In park (P) or neutral (N), none of the clutches have hydraulic pressure applied to them, which prevents engine torque from being applied to the drive pulley shaft.

The forward clutch and the start clutch are in operation whenever the transmission is placed in a forward gear position (D or L). ● **SEE FIGURE 127–29.**

The start clutch has multiple responsibilities, including:

1. The start clutch is engaged whenever the vehicle is moving, either in forward or reverse.
2. It helps the vehicle accelerate from a standstill by slipping and then fully engaging once the vehicle is moving, similar to a manually operated clutch.

The Honda CVT, like any other automatic transmission, uses hydraulic pressure to perform its various functions. The belt drive, the multiple-disc clutches, and the control system would all stop functioning without hydraulic pressure. This pressure is supplied by a chain-driven pump that is driven by the transmission input shaft. Since the input shaft is driven directly by the internal combustion engine (ICE), hydraulic pressure is only present when the ICE is running. Automatic transmission fluid (ATF) is held in a pan that is bolted to the bottom of the transmission case. The ATF pump draws fluid through a strainer that is located in the pan, and sends this fluid on to the system through a pressure regulator valve.

NOTE: Some vehicles equipped with a continuously variable transmission (CVT) have shifter paddles on the steering wheel or a manual shift mode on the gear selector. When using these paddles to upshift or downshift, the transmission control module selects preprogrammed ratios, which give the driver a sense that it is actively shifting gears.

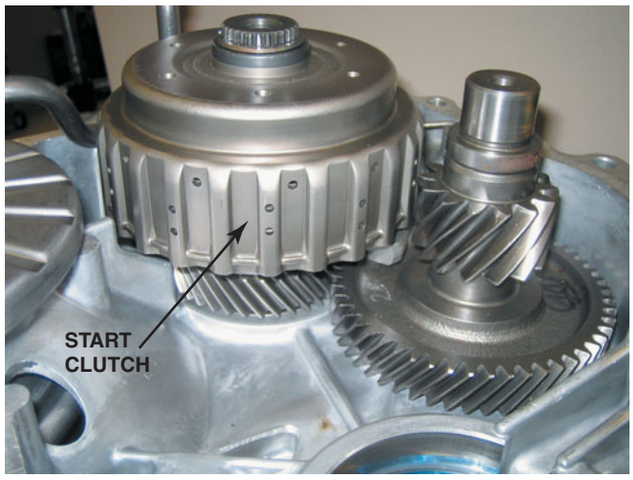

FIGURE 127–29 Location of the Honda CVT start clutch.

? FREQUENTLY ASKED QUESTION

What Is It Like to Drive a Vehicle Equipped with CVT?

For most, driving a vehicle equipped with a continuously variable transmission (CVT) is the same as driving the vehicle equipped with a conventional automatic transmission/transaxle. The vehicle creeps slightly when the brake is released and the vehicle accelerates normally when the throttle is opened. Because no shifts occur, the first thing the driver and passenger notice is that it is very smooth. If the vehicle is equipped with a tachometer, the driver may notice that the engine speed increases when first accelerating and often remains higher until the vehicle speed increases. During periods of rapid acceleration, the engine speed may be close to its maximum and thereby create noise and vibration often not experienced in a similar vehicle. However, the fuel economy savings of a CVT compared to a conventional automatic transmission makes the slight difference a reasonable trade-off.

SERVICING A CVT TRANSMISSION

The Honda CVT can be pressure tested and stall tested just like any other automatic transaxle when diagnosing transmission malfunctions. These tests must be performed according to manufacturer-approved procedures, and test results compared to charts published by the manufacturer.

One service item that is unique and very important is the *start clutch calibration.* This procedure must be performed whenever any of the following vehicle components is replaced or removed.

1. Battery
2. Backup fuse
3. Transmission control module (TCM)
4. Transmission assembly
5. Lower valve body assembly
6. Engine assembly replacement or overhaul

Details for performing these procedures can be found in Honda service information. The purpose of the procedure is to allow the TCM to memorize the feedback signal for the start clutch control. Malfunctions in the start clutch control system can occur if this procedure is not performed at the appropriate times. ● **SEE FIGURE 127–30.**

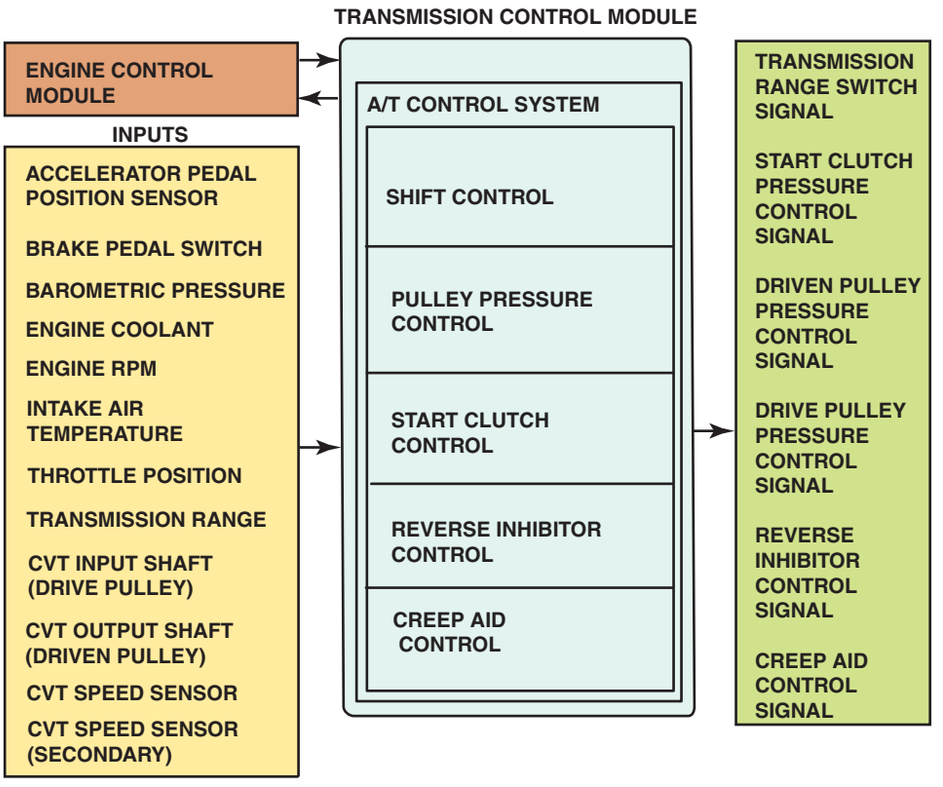

FIGURE 127–30 The Honda CVT transmission control module (TCM) showing the inputs (sensors) on the left and the outputs on the right.

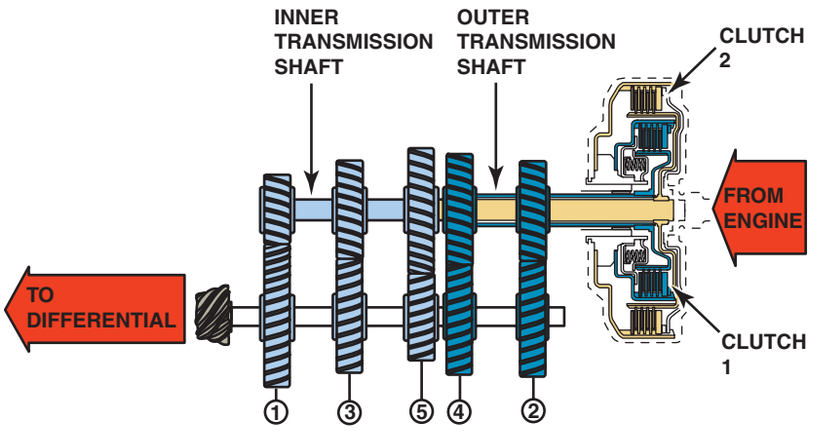

FIGURE 127–31 A dual clutch automatic uses the best features of an automatic transmission without the power loss of a torque converter.

Fluid level checks are performed with the vehicle sitting level, transmission up to the operating temperature, but with the *engine turned off.* A dipstick is used to check the level, and fluid may be poured into the dipstick pipe to bring the level up if it is low. Be sure to use only manufacturer-specified fluids when topping up or replacing transmission fluids.

DUAL CLUTCH AUTOMATIC TRANSMISSIONS

PURPOSE AND FUNCTION A dual clutch automatic transmission or transaxle uses a manual-type transmission and two clutches that engage either the main input shaft or the counter shaft to achieve the following goals, compared to a conventional automatic transmission or transaxle equipped with a torque converter and planetary gear sets.

1. Improve the fuel economy.
2. Reduce the cost of the assembly by using manual transmission components.
3. Improve the speed of the gear changes.
4. Provide smoother operation.

PARTS AND OPERATION

- A dual clutch automatic transmission uses two clutches that are mounted together concentrically. The larger clutch drives the odd number gears (first, third, fifth, and seventh).
- The smaller clutch drives the even number gears (second, fourth, and sixth). ● **SEE FIGURE 127–31.**

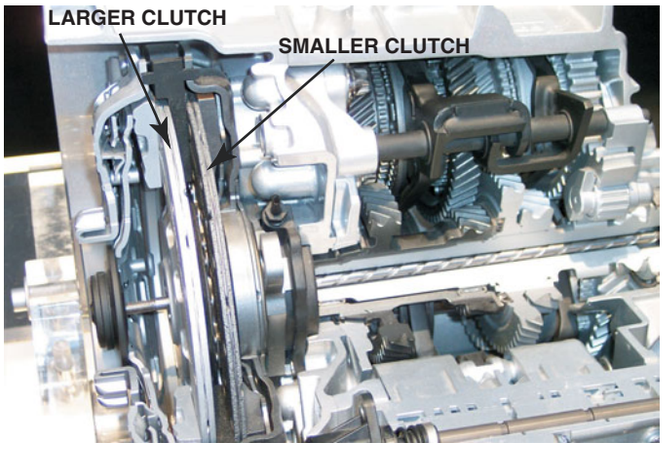

FIGURE 127–32 Dual clutch automatic transaxles that use two dry clutches. The larger clutch drives the odd number gear ratios (first, third, and fifth) and the smaller clutch drives the even numbered gear ratios (second, fourth, and sixth).

The shifts occur without interrupting the torque from the engine by applying torque to the clutch while at the same time disconnecting the other clutch. These actions result in a rapid shift without the slight delay usually associated with an automatic transmission.

There are two types of clutches used depending on application.

1. Dual dry clutches are used in low powered vehicles such as small front-wheel-drive vehicles. ● **SEE FIGURE 127–32**.
2. Dual wet clutches are often used in higher powered vehicles.

Vehicles that use a dual clutch automatic-type transmission include certain models of Audi, Nissan, Mercedes, BMW, Porsche, Ford, Ferrari, VW, and Mitsubishi.

ADVANTAGES The advantages of a dual clutch automatic transmission compared to a conventional automatic transmission include:

1. Quicker throttle response
2. No drop in engine speed when the driver releases the throttle
3. Instant gear changes
4. Improved fuel economy

DISADVANTAGES The disadvantages of a dual clutch automatic transmission compared to a conventional or continuously variable automatic transmissions include:

1. No torque multiplication advantage of a torque converter
2. Not as fuel efficient as a continuously variable (CV) transmission or transaxle

REVIEW QUESTIONS

1. How can torque converters double engine torque?
2. What are the three members of a planetary gear set?
3. How can various gear ratios and reverse be obtained by using a compound planetary gear set?
4. How does a continuously variable transmission provide variable ratios?
5. How does a dual clutch automatic transmission shift gears?

CHAPTER QUIZ

1. Two technicians are discussing automatic transmissions/transaxles. Technician A says that it is normal for a vehicle to move slightly when the gear selector is in the drive position with the brakes released. Technician B says that the stator may be defective if the vehicle moves while in gear when the engine is at idle speed. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. Technician A says that a five-speed automatic transmission will often use a compound planetary gear set. Technician B says that the torque converter clutch is often pulsed on and off to provide smooth engagement. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Technician A says that a held member is also called the reaction member. Technician B says that if any two elements are locked together then the output will be 1:1. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. Technician A says that all dual clutch automatic transmissions use two dry clutches. Technician B says that some automatic transmissions do not use planetary gear sets. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. Technician A says that when an automatic transmission/transaxle shifts into overdrive, the output shaft is rotating faster (higher RPM) than the engine crankshaft. Technician B says that an overdrive ratio is a ratio where the first number is less than 1. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
6. Technician A says that one planetary gear set can provide gear reduction, overdrive, and reverse. Technician B says that most transmissions today use compound (multiple) planetary gear sets. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B

7. Using a torque converter smaller than stock size could result in _____.
   a. Slower than normal acceleration
   b. Faster than normal acceleration
   c. Reduced fuel economy
   d. Both b and c
8. Which compound planetary gear set is commonly used in six-speed transmissions?
   a. Simple gear set
   b. Simpson gear set
   c. Ravigneaux gear set
   d. Lapelletier gear set
9. Which compound gear set uses a planetary gear set in front of a Ravigneaux gear set?
   a. Simple gear set
   b. Simpson gear set
   c. Ravigneaux gear set
   d. Lapelletier gear set
10. How much is engine torque increased or multiplied when a typical torque converter is at stall speed?
   a. Double
   b. Four times
   c. Eight times
   d. Ten times

chapter 128

HYDRAULIC COMPONENTS AND CONTROL SYSTEMS

OBJECTIVES: **After studying Chapter 128, the reader will be able to:** • List the various types of automatic transmission fluids. • Explain how automatic transmission fluid is circulated through the system and how it is cooled. • Describe how a transmission cooler works. • Describe how clutch packs and bands work. • Discuss one-way clutches and how they are used. • Explain how shifts are controlled in an electronically controlled automatic transmission/transaxle. • Discuss how accumulators work. • Explain the difference between on and off solenoids compared to linear solenoids. • Explain the power flow through a typical automatic transmission.

KEY TERMS: Apply devices 1571 • Automatic transmission fluid (ATF) 1567 • Balance valve 1570 • Check balls 1577 • Clutch drum 1573 • Clutch pack 1572 • Default gear 1581 • Electronic pressure control 1570 • Force motors 1570 • Governor valve 1578 • Holding devices 1571 • Integral accumulator 1575 • Limp-in gear 1581 • Lube oil 1569 • Manual valve 1577 • Multiple-plate clutch 1572 • One-way clutch 1575 • One-way clutch 1575 • One-way valve 1576 • Pressure control 1570 • Pressure control solenoids 1570 • Pressure plate 1573 • Pressure regulator valve 1569 • Reaction member 1577 • Separator plate 1576 • Servo 1572 • Shift valve 1579 • Sprags 1575 • Transmission band 1571 • Valve body 1576 • Variable force solenoids (VFS) 1570 • Worm holes 1576 • Worm tracks 1576

AUTOMATIC TRANSMISSION FLUID

PURPOSE AND FUNCTION

Automatic transmission fluid (ATF) is highly refined oil with a viscosity similar to SAE 20W-20 oil, and is specially designed for use in an automatic transmission. Newer ATFs are lower in viscosity and are similar to SAE 0W-10 oil. Purposes and functions of ATF are as follows:

- Transfers power in torque converter
- Provides hydraulic pressure in clutches and servos
- Lubricates bearings, bushings, and gears
- Transfers heat to cool transmission parts
- Provides the correct friction for clutch and band application
- Acts as the medium to control transmission shifting by traveling through passageways, acting on valves, and being directed by solenoids

TYPES

The three basic types of ATF include:

1. **Non-friction modified.** The first ATF did not have friction reducing additives. This type of fluid was used in early band-type automatics (all first generation). Type F ATF is an example of a non-friction-modified ATF.
2. **Friction modified.** Friction-modified ATF types include Dexron.
3. **Highly friction modified.** All current original equipment manufacturers use automatic transmission fluids that are highly friction modified. These include Dexron VI, Mercon V, ATF + 4, and ATF WS. Friction modifiers add to the ATF, and along with hydraulic (orifices and accumulators) devices and electronic controls help produce "proper shift quality."

TYPICAL ATF APPLICATIONS

Automatic transmission fluid is formulated to work in specific transmissions. Using the specified fluid is the key to proper operation. ● **SEE CHART 128–1** for examples of the types and applications of selected vehicles and fluids.

GENERAL MOTORS	DESCRIPTION
Type A	1949
Type A, Suffice A	1957 (friction modified)
Dexron	1967 (lower viscosity)
Dexron II	1978 (lower viscosity)
Dexron II-E	1990 (improved low temperature fluidity)
Dexron III	1993–2005 (improved low temperature fluidity)
Dexron VI	2005 (improved viscosity stability)

FORD/JAGUAR	DESCRIPTION
Type F	1967 (non-friction modified; designed for older band-type automatic transmissions)
Mercon	1987 (friction modified)
Mercon V	1997 (highly friction modified)
Mercon SP	Used in the Ford six speeds such as the 6R60 6HP 26 and also the 2003 and up Torque Shift
Idemitsu K-17	Jaguar X-type

CHRYSLER	DESCRIPTION
Chrysler 7176	Designed for front-wheel-drive transaxles
ATF + 2	1997 (improved cold temperature flow)
ATF + 3	1997 (designed for four-speed automatics)
ATF + 4	Used in most 20000 and newer Chrysler vehicles

HONDA/TOYOTA	DESCRIPTION
Honda Z-1	For use in all Honda automatic transaxles
Toyota Type III	Specific vehicles and years
Toyota Type IV	Specific vehicles and years
Toyota WS	Lower viscosity than Type IV; used in specific vehicles and years

MAZDA/NISSAN/SUBARU	DESCRIPTION
Mazda ATF-III	Specific vehicles and years
Mazda ATF-MV	Specific vehicles and years
Nissan Matic D	Specific vehicles and years
Nissan Matic J	Specific vehicles and years
Nissan Matic K	Specific vehicles and years
Subaru ATF	Specific vehicles and years
Subaru ATF-HP	Specific vehicles and years

AUDI/BMW/MERCEDES/ VOLVO	DESCRIPTION
Audi G-052-025-A2	Specific vehicles and years
Audi G-052-162-A1	Specific vehicles and years
BMW LA2634	Specific vehicles and years
BMW LT1141	Lifetime fill (BMW warns to not use any other type of fluid)
Mercedes 236.1	Specific vehicles and years
Mercedes 236.2	Specific vehicles and years
Mercedes 236.5	Specific vehicles and years
Mercedes 236.6	Specific vehicles and years
Mercedes 236.7	Specific vehicles and years
Mercedes 236.9	Specific vehicles and years
Mercedes 236.10	Specific vehicles and years
Volvo 97340	Specific vehicles and years
Volvo JWS 3309	Specific vehicles and years

MITSUBISHI/HYUNDAI/KIA	DESCRIPTION
Diamond SP II	Specific vehicles and years
Diamond SP III	Specific vehicles and years

CHART 128–1

Selected samples of automatic transmission fluid and some applications. Always check service information for proper specified fluid when servicing any automatic transmissions/transaxles.

AUTOMATIC TRANSMISSION FLUID COOLER

PURPOSE AND FUNCTION The torque converter generates a great amount of heat because of fluid shear as its internal elements spin at different speeds in relation to each other. The greatest amount of heat is generated when the vehicle is operating under a heavy load and the torque converter clutch is disengaged. The ATF can reach high temperatures (over 250°F [120°C]) very quickly, which is why an automatic transmission fluid cooler is used. Most vehicles use a small section of the engine cooling system radiator to transfer heat from the ATF to the coolant, which cools the ATF.

PARTS AND OPERATION Automatic transmissions/transaxles use a pump to circulate ATF and to provide the necessary hydraulic flow to operate the hydraulic components of the unit. The ATF is pumped (directed) from the torque converter (greatest source of heat) to the cooler when the torque converter clutch is not applied. The ATF flows through the cooler which has the following characteristics.

- It is a separate section of the radiator tank.
- The hotter transmission fluid gives up heat to the cooler engine coolant.
- Some manufacturers use a *cooler bypass valve* that will allow fluid to bypass the cooler if restricted. Some vehicles also use a temperature controlled valve to block the flow of fluid during low temperature operation such as is used in Dodge (Ram) trucks.
- Many vehicles with towing packages use a larger cooler or a combination of a liquid-to-liquid and a liquid-to-air cooler in series with each other to handle the extra heat load of towing.

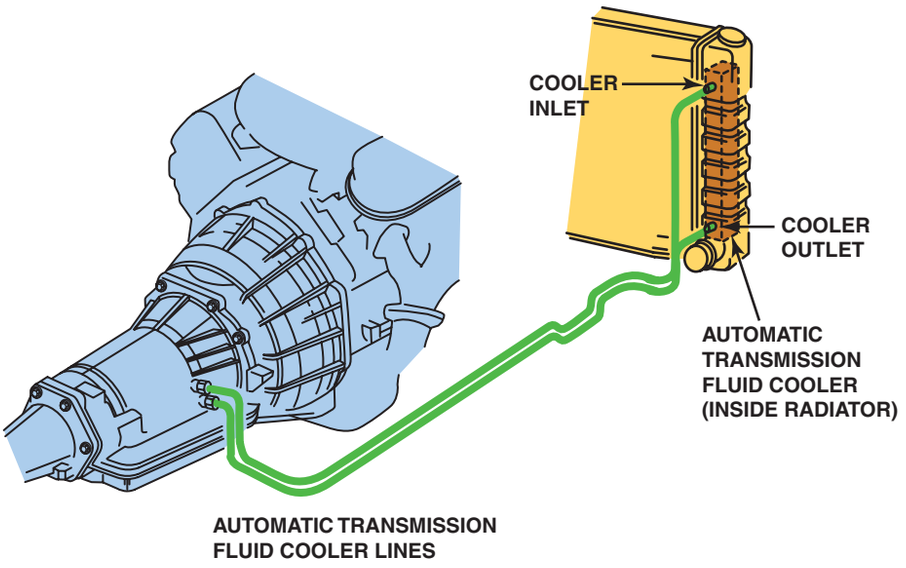

FIGURE 128–1 Automatic transmission fluid is routed from the torque converter, where most of the heat is generated, to the radiator where it is cooled. The fluid then returns to the transmission/transaxle to lubricate the bearings and bushings.

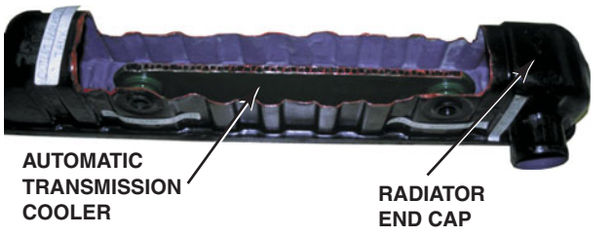

FIGURE 128–2 A cutaway of a typical radiator showing the automatic transmission cooler. The heat from the automatic transmission fluid is released to the engine coolant. The engine coolant also warms the fluid as soon as the coolant flows through the radiator.

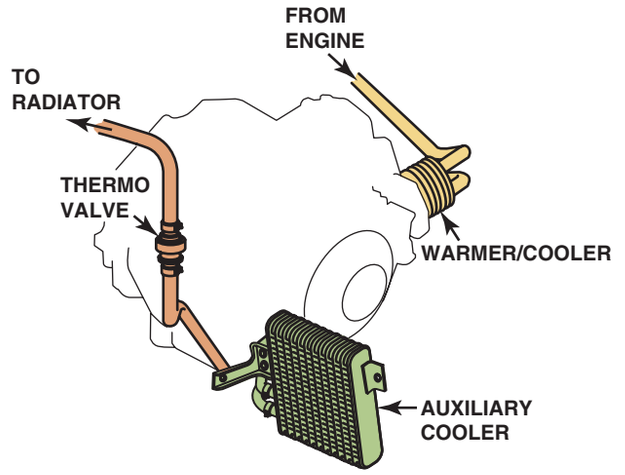
The ATF returns to the transmission/transaxle to passages that lubricate the internal moving parts. This returned fluid is called **lube oil.** ● **SEE FIGURES 128–1 AND 128–2.**

CAUTION: Because the lube oil uses the ATF flowing from the cooler, if there is a blockage in the cooler, the transmission/transaxle may not have enough fluid flow to properly cool or lubricate the bearings and bushings inside the unit, leading to wear and eventually premature failure.

TRANSMISSION FLUID HEATER The cooler is located in the radiator in most vehicles and, as a result, the coolant will also warm the ATF when the temperatures are cold. Some vehicles are equipped with a transmission fluid heater that uses the coolant to warm the fluid when it is cold. Warm fluid works better than cold fluid to lubricate moving parts inside the unit. ● **SEE FIGURE 128–3.**



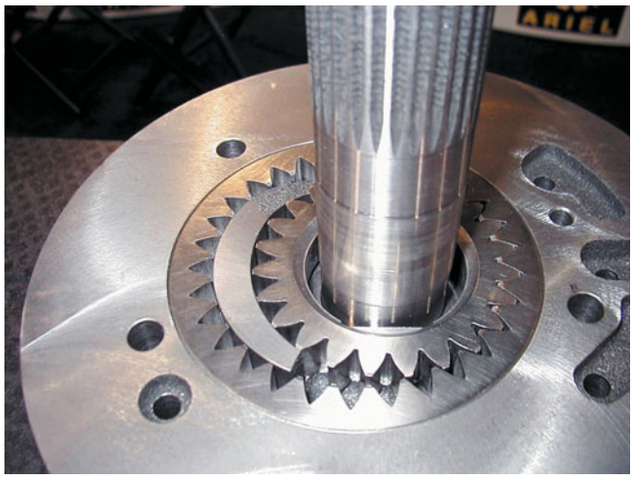


FIGURE 128–3 Engine coolant from the engine block flows through the passages in the cooler /warmer, and then out through the thermo valve to the upper radiator tank. The thermo valve uses a wax element–type valve to control the flow of engine coolant through the case-mounted cooler/warmer. The thermo valve improves the ATF warm-up times and maintains ATF temperature within the optimum operating range between 170° and 190°F (77° and 88°C).

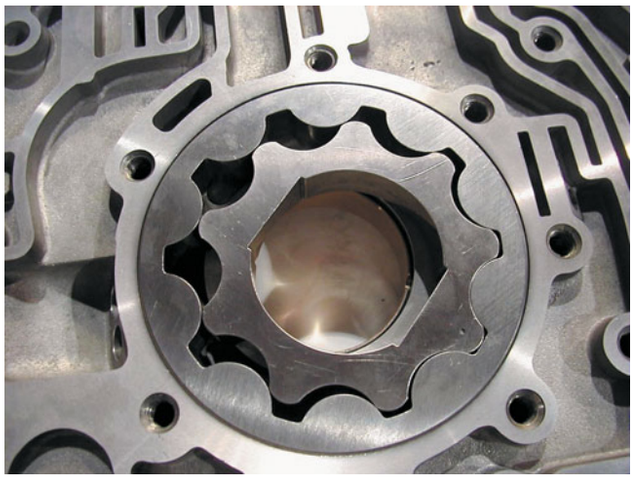
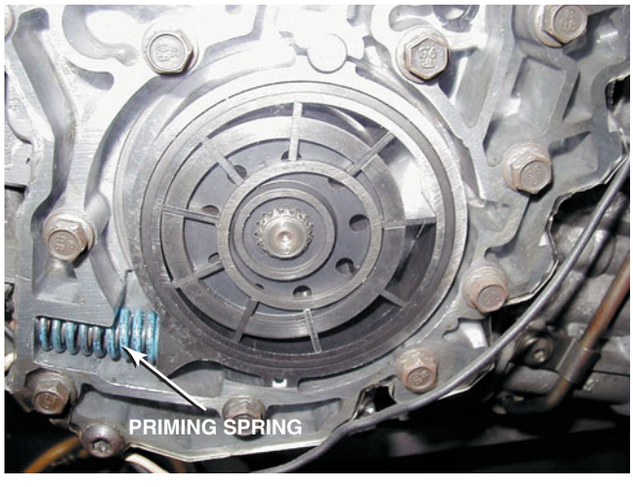
PUMP



PURPOSE AND FUNCTION Every hydraulic system requires a *pump* to supply fluid flow and to pressurize the system. However, the pump itself does not develop pressure but instead pressure occurs when there is a resistance to flow. Initially, fluid flows freely when a hydraulic circuit is empty or partially filled. Once the circuit is completely full, there is a resistance to further flow. At this point, pressure begins to build up in the circuit as the pump continues to create flow.

PARTS AND OPERATION Most oil pumps mount directly behind the torque converter and are usually driven by the converter drive hub. This connects the pump to the engine and allows it to respond quickly to engine demand. This type of oil pump operates whenever the engine is running. ● **SEE FIGURE 128–4.**



PRESSURE REGULATION Transmission oil pumps are capable of creating an excessive amount of pressure quickly; therefore, every transmission uses a **pressure regulator valve,** or *pressure control valve,* to control hydraulic pressure. This is usually a spool

(a)

(b)

(c)

FIGURE 128–4 (a) Gear-type pump. (b) Geroter-type pump. (c) Vane-type pump.

valve and spring combination. This regulated pressure, commonly known as *mainline pressure,* is the working pressure for the entire hydraulic system. Most pressure regulator valves balance pump pressure on one side of the valve against a preset spring force acting on the other side of the valve.

When hydraulic pressure is greater than the spring force, the valve moves in its bore far enough to uncover an exhaust port. ● **SEE FIGURE 128–5.**

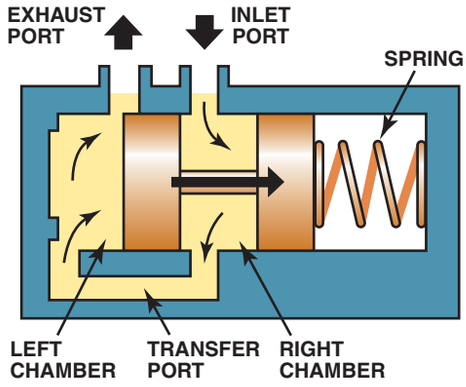


FIGURE 128–5 When pressure on the face of the pressure regulator valve overcomes spring force, the valve moves to open the exhaust port.

The exhaust port provides a low-pressure path to the transmission oil pan (sump) where excess ATF is stored. Excess pressurized fluid flowing through this port reduces system pressure. When hydraulic pressure drops below spring pressure, the regulator valve closes the port and pressure begins to build up again.

In operation, the opening and closing of the exhaust port occurs many times per second. This sequence of events achieves a steady pressure as the valve balances both the spring pressure and the hydraulic pressure. Because of this action, this type of valve is sometimes called a **balance valve.**

VARIABLE DISPLACEMENT PUMP

Many newer automatic transmissions and transaxles use a variable displacement pump to reduce the power needed to achieve fluid pressure to the amount required instead of being based on pressure alone. The use of a variable displacement pump helps improve fuel economy and reduce exhaust emissions. ● **SEE FIGURE 128–6.**

ELECTRONIC PRESSURE REGULATION

Electronic automatic transmissions/transaxles often regulate hydraulic system pressure using computer-controlled solenoids called any of the following:

- **Pressure control solenoids (PCS)**
- **Electronic pressure control (EPC)**
- **Pressure control (PC)**
- **Variable force solenoids (VFS)**
- **Force motors**

An onboard computer switches the solenoids on and off very quickly using pulse-width modulation (PWM). The solenoid pushes against an internal valve which opens and closes the hydraulic circuit it regulates. Electronic pressure control allows precise hydraulic system pressure regulation and can also be used to modify the timing and feel of transmission shifting. ● **SEE FIGURE 128–7.**

TYPICAL PRESSURES

Line pressure is controlled by the powertrain control module (PCM) or the transmission control module (TCM) to provide the specific pressure needed by the system based on input from the sensors such as vehicle speed and engine load. Line pressure is reduced to improve fuel economy because lowering pressure reduces draw on the engine which is driving the pump.

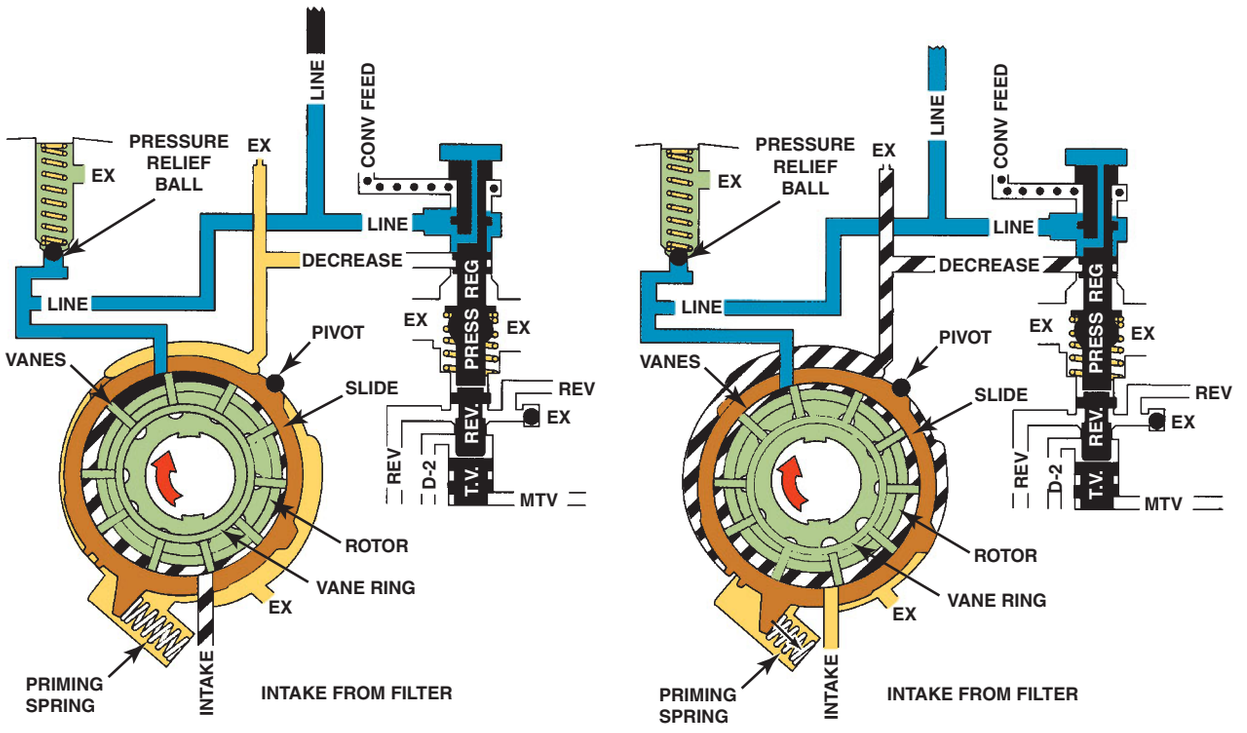

FIGURE 128–6 The variable pump is at the maximum output position until the regulator valve moves enough to decrease volume by rotating the slide against the force of the priming spring. The position of the pump constantly varies depending on the needs of the transmission/transaxle and the driving conditions.

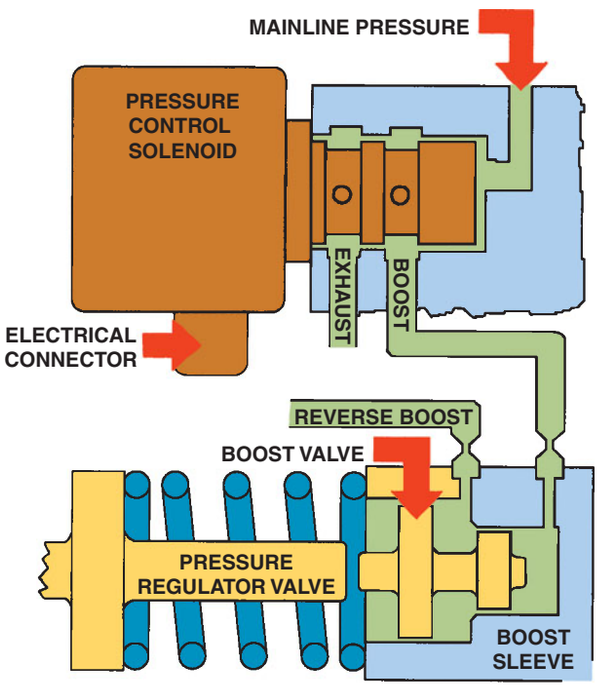

FIGURE 128–7 The pressure control solenoid controls the mainline pressure, which is in turn controlled by the powertrain control module (PCM) or the transmission control module (TCM), by applying pressure to the spring side of the pressure regulator valve.

Typical line pressures include:

- Normal line pressure = 60 to 120 PSI (414 to 830 kPa)
- The accelerator pedal pressed to wide open throttle (WOT) = 90 to 150 PSI (620 to 1,034 kPa)
- The gear selector in reverse or manual low (1) = 150 to 300 PSI (1,034 to 2,068 kPa)

Higher pressures are necessary in reverse because these apply devices are usually smaller and or have fewer clutch plates to ensure that the clutches are firmly applied, in order to avoid slippage when the engine is producing maximum torque.

APPLY OR HOLDING DEVICES

PURPOSE AND FUNCTION **Apply devices** or **holding devices** are the mechanical or hydraulic assemblies that provide the force to hold or drive members of a planetary gear set. Automatic transmissions typically use the following as apply devices.

- Transmission bands
- Multiple-plate clutches
- One-way clutches

BANDS

TERMINOLOGY Transmission bands are holding (braking) devices. The planetary gear set member held is known as a **reaction member.** A **transmission band** stops and holds one planetary gear set member so that another member can react against the held member and develop output motion. The reaction member has a control surface for the band to ride on, known as a drum. The band directly affects the drum, and the drum directly affects the planetary gear set member. ● **SEE FIGURE 128–8.**

The band provides a holding force around the outside of the drum, closing tightly to keep it from turning. To repeat, a transmission

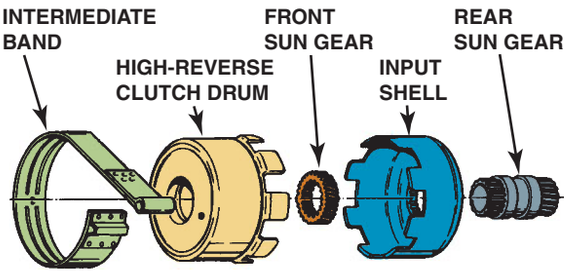

FIGURE 128–8 Gear set members are attached to a drum and are held stationary when the band applies.

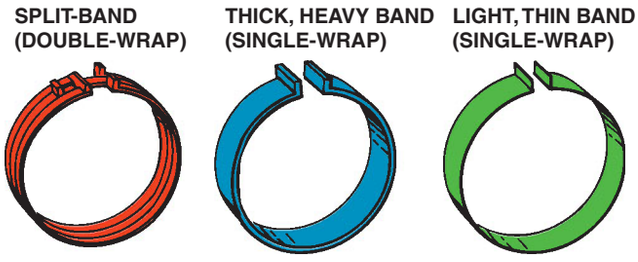

FIGURE 128–9 Transmission bands come in several designs and thicknesses.

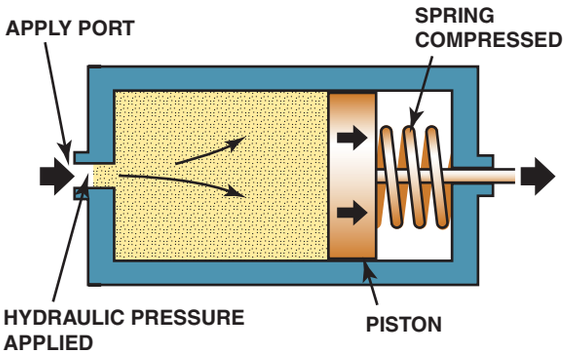

FIGURE 128–10 A servo uses hydraulic pressure to move a piston, which applies a band.

band is a holding device and is not capable of driving any member of the planetary gear set.

Transmission bands are made of cast iron or steel with friction material lining on the inside surface. Transmission design and component size dictate the type and size of band used. Bands fall into one of two categories:

- Single wrap
- Double wrap

The single-wrap band is a simple one-piece design, while the double-wrap band is a split band with overlapping ends. Bands may also be classified as either flexible or fixed, depending on how well they hold their shape when they are off the drum. ● **SEE FIGURE 128–9.**

HYDRAULIC SERVOS

A band is applied by using a hydraulically operated piston that travels inside a machined cylinder bore. This piston and cylinder assembly is known as a **servo.** ● **SEE FIGURE 128–10.**

A piston return spring normally holds the servo piston in its unapplied position. To apply the band, hydraulic fluid, under pressure,

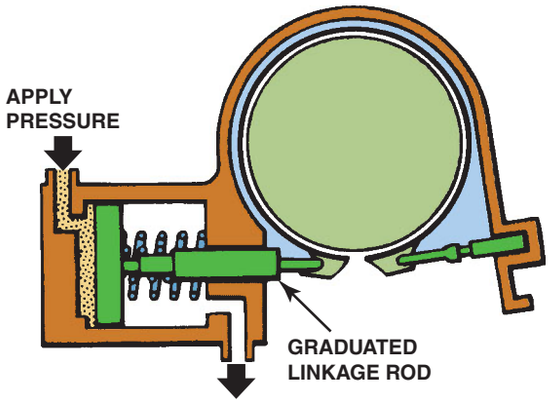

FIGURE 128–11 One end of a band is held stationary and the other end is attached to the servo.

enters the servo cylinder and acts on the piston. The piston begins moving once hydraulic pressure overcomes spring force.

SERVO LINKAGES

A mechanical rod, called a *strut,* and linkage attaches to the piston and connects it to the band. As the piston moves, the linkage applies the band by tightening it around the drum. Servo *rods* and *struts* transfer the servo apply force to the transmission band. Rods are round metal bars and struts are flat metal plates. These may be used at either or both ends of the band. Linkages connect the band to the servo or an anchor. One end of a band is often anchored to the transmission case and whenever the band is applied, the drum that the band wraps around is held from rotating. ● **SEE FIGURE 128–11.**

NOTE: Some bands have a provision for adjustment and may be adjusted in vehicle while others are adjusted or set during transmission assembly.

MULTIPLE-PLATE CLUTCHES

TERMINOLOGY

Like a transmission band, a multiple-plate hydraulic clutch is a type of apply device. Clutches have more friction area so they can develop more force and handle more torque than a band, and they are self-adjusting.

PARTS

The **multiple-plate clutch** consists of plates, a piston, drum (retainer), and snap ring. Hydraulic pressure acts upon the clutch piston which moves in the drum. The piston movement compresses the plates together to provide either a holding or driving function. When the pressure is released, the piston returns to an unapplied position via a return spring assembly. The entire assembly is commonly known as a **clutch pack.** ● **SEE FIGURE 128–12.**

The plates of a multiple-plate clutch assembly consist of a friction plate alternated with steel plates.

- A friction plate, also called simply a *friction,* has a rough surface friction material applied to both faces. The friction (clutch lining) material is made from a mixture of natural and man-made fiber. Natural fibers include cotton or wood (paper), and man-made fibers are aramid (Kevlar®) or carbon. The exact mixture is determined by the transmission engineer to provide the desired heat resistance and durability standards.

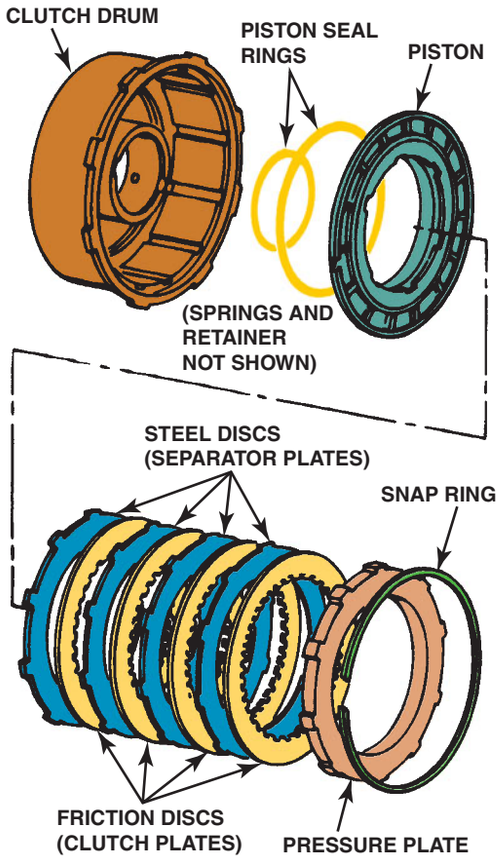

FIGURE 128–12 An exploded view of a multiple-plate clutch pack assembly.

- A steel plate, also called simply a *separator plate* or *steel,* has a smooth, flat surface finish with no friction material.
- Some transmissions may not have separate frictions and steels but rather combine them. One side of the plate will be coated with the frictional surface while the other side is flat metal like the steels.
- Collectively, the friction and steel plates are called clutch plates.

Generally, the steel plates have splines on their outer edge, while the friction plates have splines on their inner edge. Each set of splines engages matching splines on a:

- Shaft
- Drum
- Planetary gear set member or
- Transmission case

The piston compresses the clutch plates against a thicker reaction plate known as the **pressure plate.** Pressure plates may be used at one or both ends of the clutch pack and are available in selective (specific) sizes for adjusting clutch pack clearance. The pressure plate and clutch assembly components fit into either a **clutch drum** (retainer) or a machined bore in the transmission case. Snap rings retain all the clutch assembly components and are available in selective (specific) sizes for adjusting clearance. ● **SEE FIGURE 128–13.**

Some transmissions use a special wave-type spring to return the piston and cushion clutch applications. The piston returns to an unapplied position via a return spring assembly. These springs are designed to return the piston to the released position when apply fluid pressure is removed from the clutch pack. The two types of springs commonly used are the coil spring and the Belleville spring.

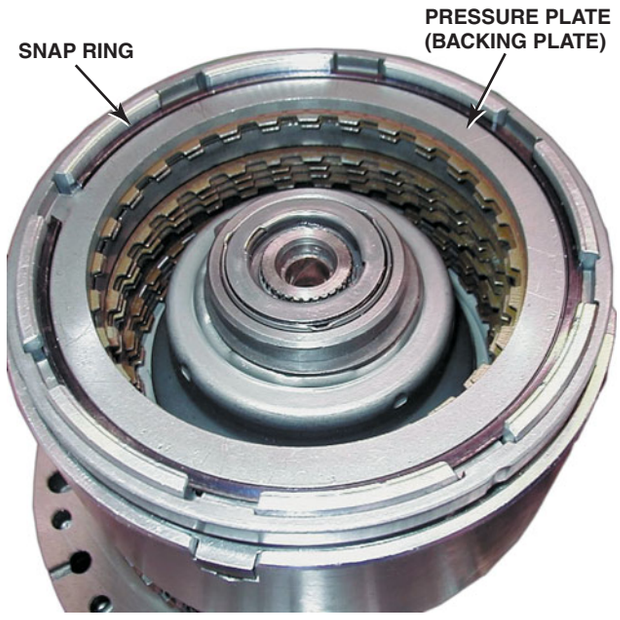

FIGURE 128–13 A typical clutch pack assembly.

CLUTCH OPERATION

To apply the clutch, pressurized fluid enters the drum through an internal passage in the input shaft. When the clutch applies, hydraulic pressure acting on the piston squeezes the two sets of plates together to mechanically connect the two components that engage the splines of the plates.

The fluid acts on the piston and moves it against return spring force to clamp the clutch plates together and hold them against the pressure plate. ● **SEE FIGURE 128–14.**

The friction between the plates then locks the clutch drum to the hub, causing them to turn as one unit.

To release the clutch, hydraulic fluid to the apply side of the piston is cut off and exhausted through an exhaust port. The piston return springs, which were compressed when the clutch was applied, are now free to expand and move the piston back, allowing the clutch plates to disengage.

TWO TYPES OF CLUTCHES

Although a multiple-plate clutch is an apply device similar to a transmission band, it differs from a band because it can also be used to drive members of planetary gear sets as well as hold them. There are two types of multiple-plate clutches.

1. **Holding (braking) clutches.** A clutch contains frictions discs which are splined to one member and the steel disc are splined to another member of a planetary gearset. When the clutch is applied, the friction surfaces are clamped or held together keeping whatever the clutch plates are splined to from rotating.

   ● **SEE FIGURE 128–15.**

2. **Driving clutches.** There are two types of multiple-plate driving clutches, and both types are commonly used in automatic transmissions. In one configuration, splines connect a set of friction plates to the transmission input shaft so that these plates function as the driving member. The alternating set of steel plates is splined to the inside of the clutch drum and serves as the driven member. When the clutch is released, the drive plate rotates with the input shaft, but they do not drive the driven plate that splines to the drum.

   When the clutch applies, the piston takes up clearance and forces both sets of plates firmly together. Now, the input

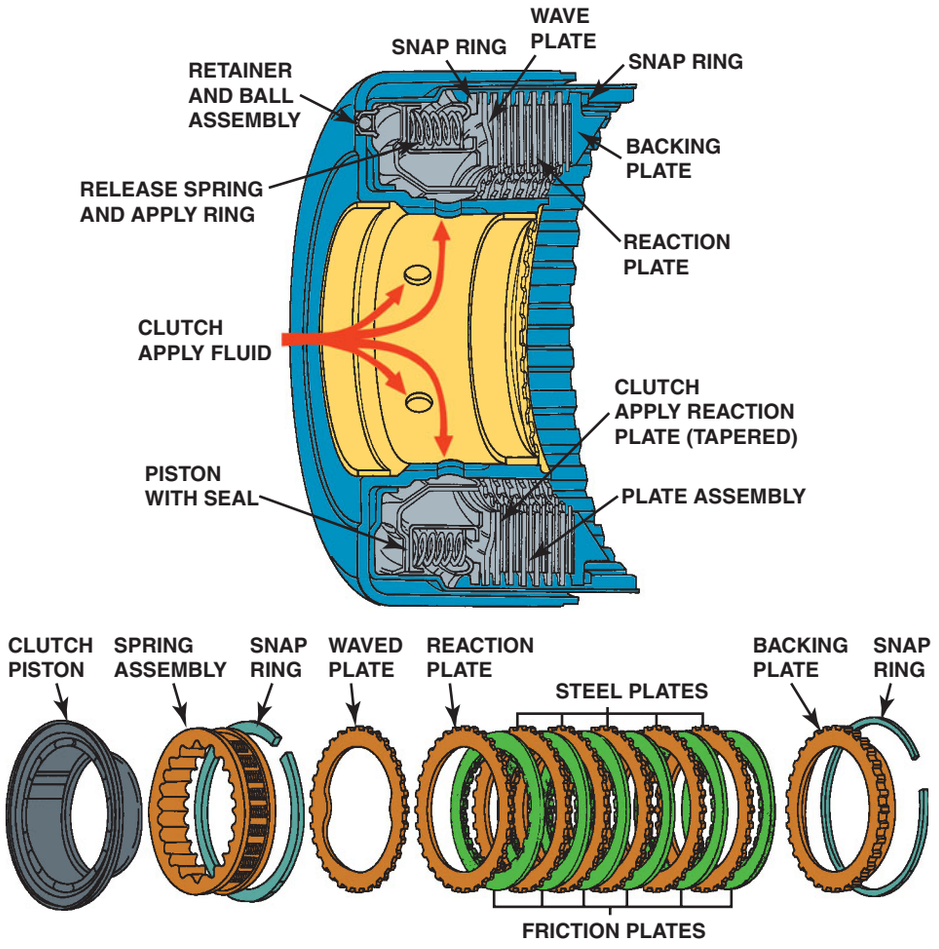

FIGURE 128–14 Hydraulic fluid under pressure enters the clutch housing and exerts a force on the clutch piston. The clutch piston forces the steel plates and the friction plates together, creating a shift.

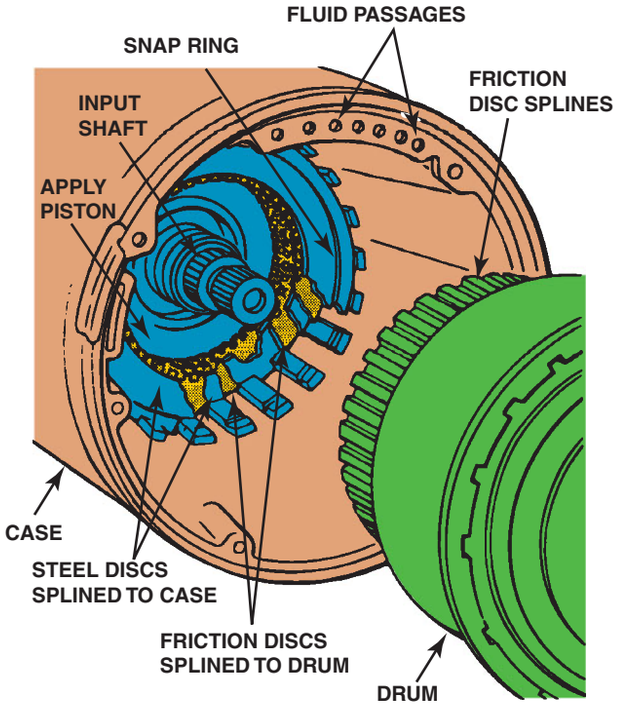

FIGURE 128–15 In a holding clutch, one set of discs engages splines on the transmission case and the other set engages splines on the drum.By applying the clutch, the drum is locked to the case.

shaft and drum rotate together at the same speed and torque transfers from one gear set member to another. A passageway carries fluid to the clutch apply piston.

With the second driving clutch configuration, the drum connects directly to the input shaft so the drum always rotates with the shaft. Splines connect the steel plate to the inside of the drum and the friction plate to the outside of a clutch hub. When the clutch applies, hydraulic pressure compresses the clutch pack to lock the drum and clutch hub together. The input shaft then drives the output shaft and both turn at the same speed.

ACCUMULATORS

PURPOSE AND FUNCTION An accumulator cushions or dampens the apply force during a shift. An accumulator reduces hydraulic pressure surges by temporarily diverting part of the fluid flow in a hydraulic circuit into a parallel circuit or chamber. Accumulators can be described as “hydraulic shock absorbers” because they absorb or reduce the shock of engagement of the clutch or band. The diversion allows pressure in the main apply circuit to increase gradually and provides a smooth engagement of the band or clutch.

Piston-type accumulators look and function much like servo pistons. In fact, some piston-type accumulators share a bore with

one of the transmission servos. This common bore design is known as an **integral accumulator.** ● **SEE FIGURE 128–16.**

OPERATION As hydraulic pressure enters both circuits, the clutch piston or band servo piston starts to move first. Once the clearance is taken up and resistance increases, the circuit pressure increases. This is when the accumulator piston starts to dampen the clamping force and time of the apply device. The accumulator piston area and spring are designed to absorb fluid during the clutch circuit pressure rise when the clutch piston stops moving. The result of this dampening action results in a slight increase in the clutch application. When the time is increased between the initial clutch application and complete application of the clutch, the result is a smoother shift.

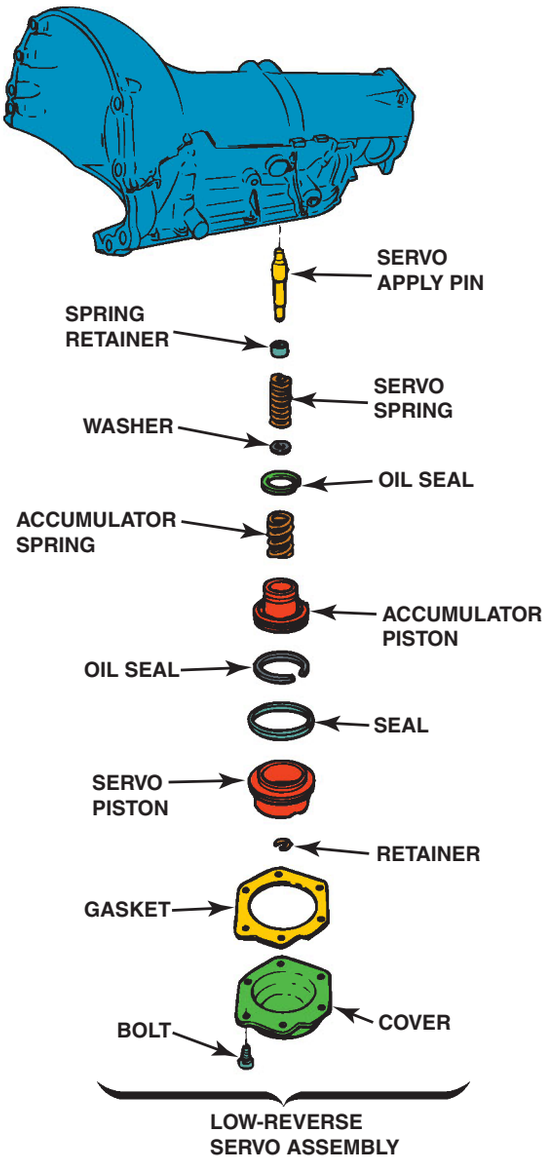

FIGURE 128–16 An integral accumulator is combined with a servo in a single bore in the transmission housing.

NOTE: Accumulators are disappearing in modern, electronic transmissions due to adaptive learning. The PCM or TCM measures the shift time and if it is too long or too short, it will raise or lower line pressure so shift time matches the programming.

ONE-WAY CLUTCHES

TERMINOLOGY Another common type of automatic transmission device is the **one-way clutch** (OWC), or overrunning clutch. Like a transmission band, a one-way clutch is always a holding device. One-way clutches are either roller or sprag clutches, although the roller clutch is more common.

ONE-WAY ROLLER CLUTCH A one-way roller clutch consists of a hub, rollers, and springs that fit inside a drum. The inner circumference of the drum has a series of machined ramps, or cam cuts, to accommodate the rollers and springs. Each ramp is narrower at one end than at the other.

If the drum is held while rotating the hub clockwise, the rollers will compress their springs and move toward the larger end of the ramps. This unlocks the clutch because there is enough clearance between the rollers and the drum for the hub to freewheel.

Rotate the hub counterclockwise while holding the drum. The rollers move toward the narrow end of the ramp, wedging themselves between the hub and drum to lock the clutch. With the rollers at the narrow end of the ramp there is no roller-to-drum clearance. Therefore, the hub cannot turn counterclockwise because the drum is being held. ● **SEE FIGURE 128–17.**

ONE-WAY SPRAG CLUTCH A **one-way sprag clutch** that consists of a hub and a drum separated by a number of figure-eight-shaped metal pieces called **sprags.** ● **SEE FIGURE 128–18.**

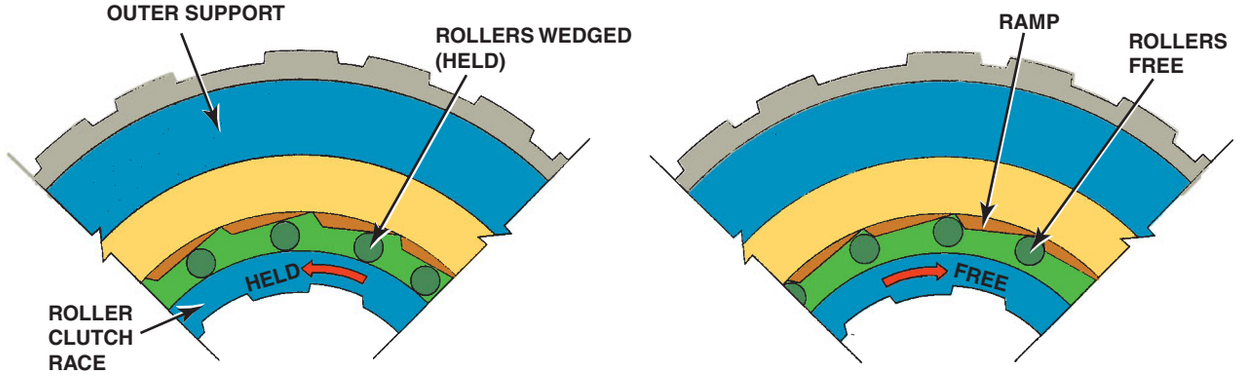

FIGURE 128–17 (a) Roller one-way clutch in the locked (held) position. Note how the rollers are wedged into the ramp that is machined into the outer support. (b) Roller one-way clutch in released (free) position. When the inner roller clutch race rotates faster than the outer support, the rollers move out of the wedge and are free to rotate, thereby unlocking the one-way clutch.

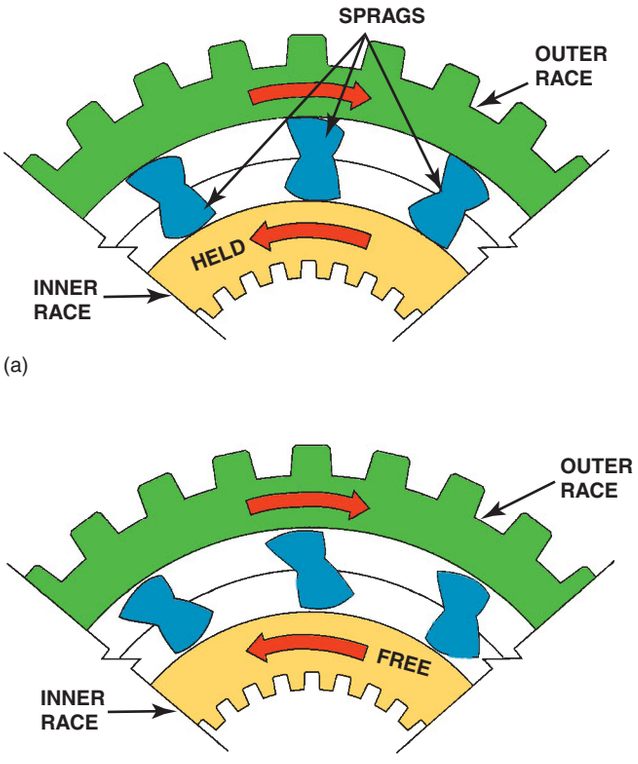

FIGURE 128–18 (a) The sprag in the holding (locked) position. Note how the long portion of the sprag is wedged between the inner and outer race. (b) The sprag in the released position. The inner race is free to rotate faster than the outer race.

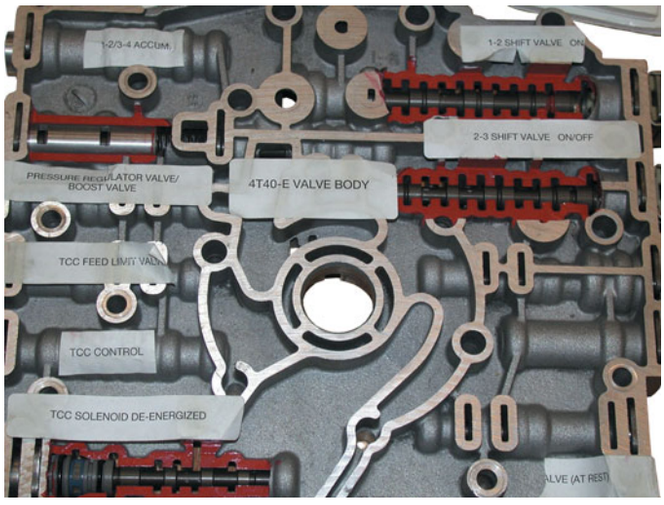

FIGURE 128–19 A partially cutaway valve body from a General Motors 4T40-E transaxle.

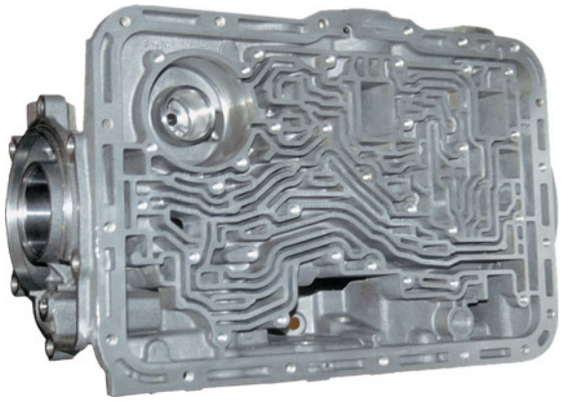

FIGURE 128–20 A typical upper valve body showing the fluid passages ("worm holes").

Sprags lock and unlock the clutch in a manner similar to the rollers in a one-way roller clutch. The shape of a sprag provides two effective working lengths. The direction the sprag tilts determines if working length is short or long.

NOTE: Some one-way clutches, either roller or sprag types, can be installed in a transmission or transaxle upside down by mistake. The transmission will not work correctly and will require that the unit be removed and disassembled again. Also check service information on how the one-way clutches should be installed.

VALVE BODY

PURPOSE AND FUNCTION A **valve body** is where most of the valves in a transmission are located, and is attached to the case with bolts. Valve bodies can be either cast aluminum or cast iron. The valve body in most rear-wheel-drive transmissions is located inside the oil pan at the bottom of the case. A transaxle valve body may be at the bottom of the case, on the backside of the torque converter housing, or on the top or side of the transaxle housing depending on the specific application. ● **SEE FIGURE 128–19.**

PARTS Valve bodies have many fluid passages for the various transmission hydraulic circuits cast into them. These are sometimes called **worm holes** or **worm tracks.** ● **SEE FIGURE 128–20.**

Some of these passages may be widened to form pockets that contain steel, nylon, or rubber check balls. Most valve bodies consist of two or more cast sections that bolt together with a flat metal separator plate between them. The upper section of the valve body is part of the transmission case casting. The **separator plate,** also called a *spacer plate,* provides rigidity and contains calibrated holes and openings that help manage fluid flow. Valve bodies contain specialized valves and circuits that are particular to a specific transmission. Electronic solenoids are used in place of some valves on electronically controlled transmissions/transaxles. Some transmissions/transaxles incorporate the TCM right on the valve body. This eliminates the wire harness between the TCM and the solenoids which in turn eliminates connector problems. ● **SEE FIGURE 128–21.**

FLOW DIRECTING VALVES Flow directing valves, or switching valves, control the direction and distribution of fluid flow in the hydraulic system. These valves may open or close passages, fill hydraulic circuits, apply or release clutches and bands, and control the direction of fluid flow from one passage or circuit to another.

ONE-WAY VALVES A **one-way valve** allows fluid to flow in one direction. The spring-loaded ball check valve is an example of a one-way valve. Valve operation is similar to that of a poppet valve. The spring holds the ball against its seat at the inlet port until fluid pressure overcomes spring force to push the ball from its seat. Fluid flows through the valve as long as hydraulic pressure exceeds the force of the spring.

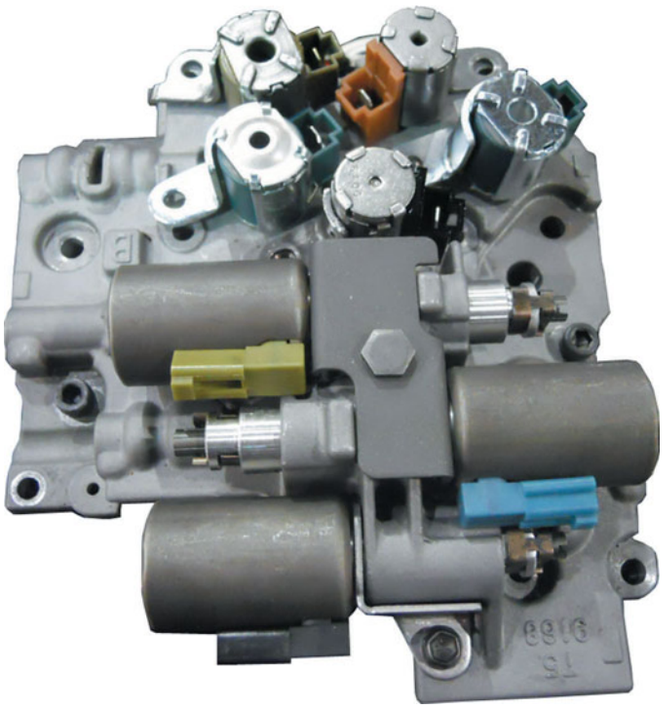

FIGURE 128–21 Electronically controlled automatic transmissions/transaxles use solenoids located in the valve body to control line pressure and to open and close passages in the valve body to control shifts.

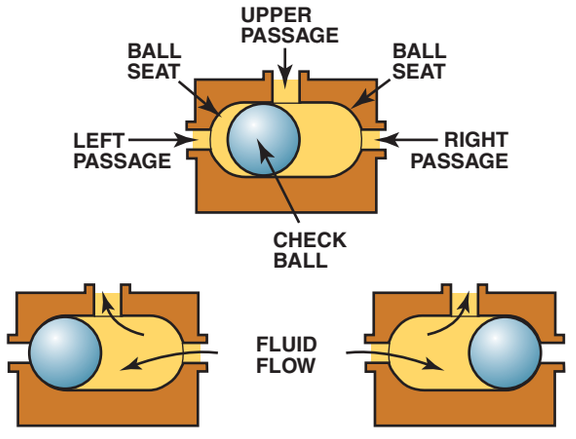

FIGURE 128–22 Check balls are used in the valve body to allow hydraulic circuits to share a common passage.

Spring-loaded ball check valves are used as pressure-relief valves, and work well on bypass circuits because they provide a fast apply rate with a slow release. A second type of one-way valve is a simple gravity valve, as commonly used in transmission valve bodies.

CHECK BALLS The **check balls** in these valves are usually made of steel, but they can be nylon, rubber, or some composite material as well. The type of material used depends on the manufacturer and application. Steel balls generally hold up better, but cause greater seat wear because of their hardness. The softer composite balls are easier on seats and they cannot be magnetized. ● **SEE FIGURE 128–22.**

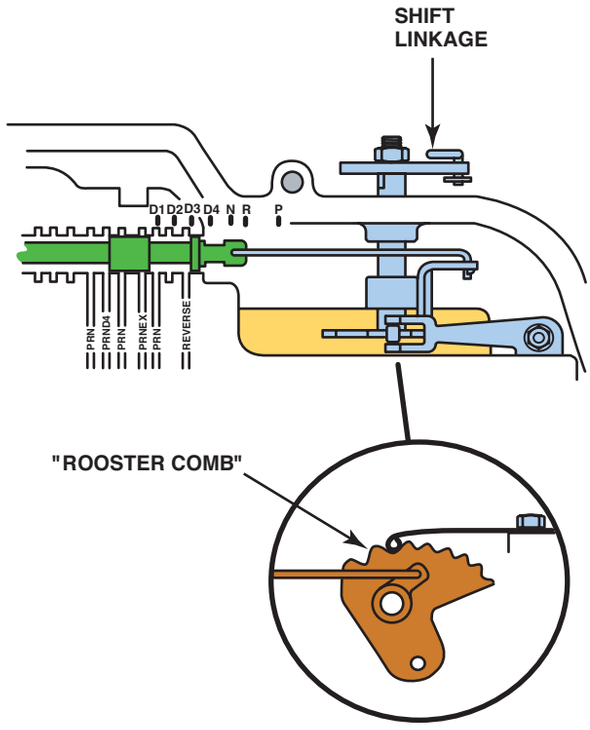

FIGURE 128–23 A rooster comb is the detent that helps retain the manual valve in the various positions in the valve body.

ORIFICES Orifices are holes in the separator plate and are used for several reasons, including:

- To control the rate of fluid movement and timing of clutch/accumulator application (shift feel)
- To separate hydraulic circuits inside the transmission, so a big leak in one circuit will not cause pressures to drop in the rest of the transmission as well

MANUAL VALVE The **manual valve** is the primary flow-directing valve in an automatic transmission. This valve connects to a shift lever in the transmission, which in turn connects to the gear selector lever through a mechanical linkage. The driver controls manual valve position through the gear selector and shift linkage.

Mechanical linkage physically positions the manual valve in its bore for the particular gear range selected. The part used to position the manual valve is commonly called the “rooster comb” because of its shape. ● **SEE FIGURE 128–23.**

The manual valve receives mainline pressure from the regulated pump output and distributes it to the hydraulic circuits uncovered by the valve lands.

HYDRAULICALLY CONTROLLED TRANSMISSION VALVES

PURPOSE AND FUNCTION Hydraulically controlled automatic transmissions/transaxles use valves to control when to shift instead of sensors that are used in electronically controlled transmissions/transaxles. These valves use mainline pressure to develop other hydraulic circuit pressures within the transmission. Pressure or control valves are normally spool valves that link to external components.

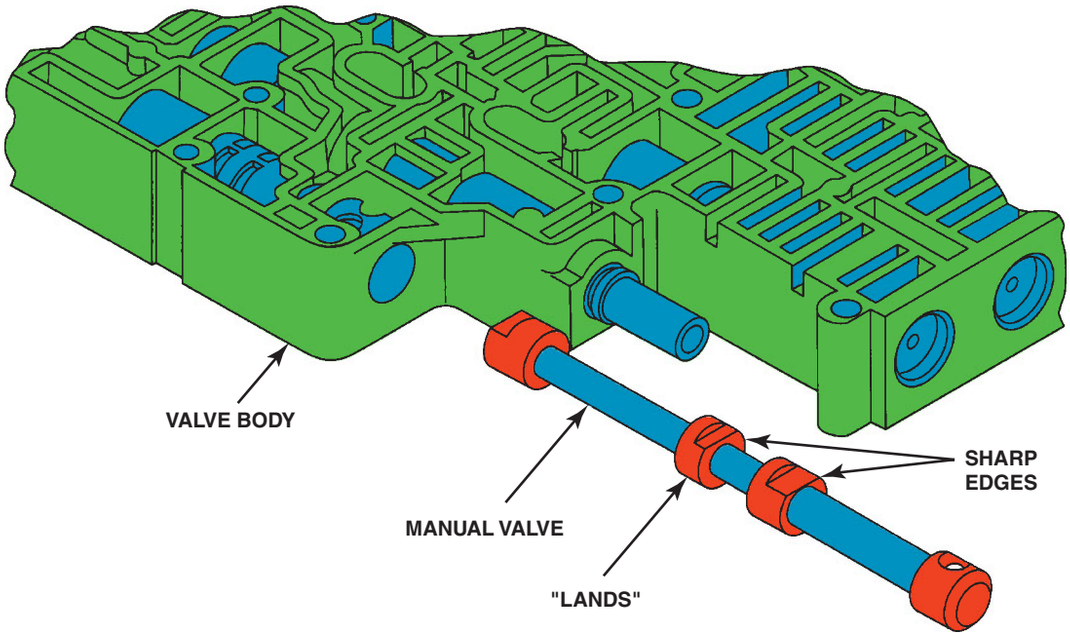

FIGURE 128–24 The manual valve is a spool valve that is moved by the shift linkage. All valves in the valve body have sharp edges on the lands. Any dirt in the valve body area can cause shifting problems due to the close tolerances between the valves and the bores in the valve body.

FREQUENTLY ASKED QUESTION

What Is a Spool Valve?

A spool valve is named after a spool of thread. A spool of thread is wooden and a spool valve used in an automatic transmission/transaxle is aluminum or steel. The ridges (larger diameter) of the spool valve fit closely into a smooth bore in the valve body and are used to direct the flow of automatic transmission fluid.

- The larger diameter sections of the spool valve are called *lands.*
- The smaller diameter sections of the valve are called *grooves* or *valleys.*
- The fluid is blocked by the lands and flows through the grooves or valleys.

● **SEE FIGURE 128–24.**

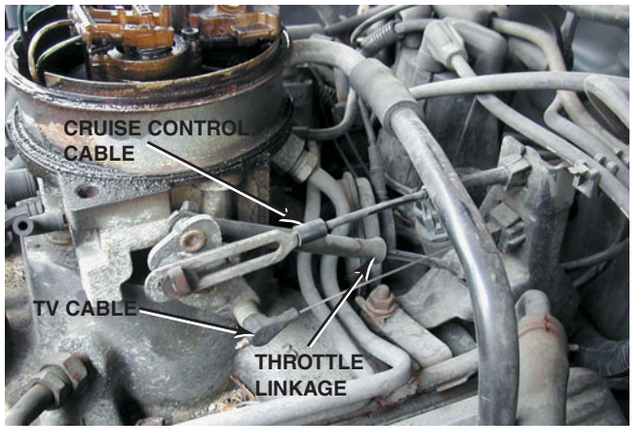

FIGURE 128–25 The throttle valve (TV) cable on a 4T-60.

THROTTLE VALVE The transmission throttle valve senses engine load and uses that operating signal to develop throttle pressure on hydraulically controlled automatic transmissions. Throttle valves have linkage that connects them mechanically to the throttle plates, and the throttle valve responds directly to engine load. ● **SEE FIGURE 128–25.**

Throttle valves are responsible for delaying the upshift points of the transmission based on the amount of load on the engine. A low engine load develops low throttle pressure while a higher load develops higher throttle pressure. The throttle position (TP) sensor has replaced the need for these valves in electronically controlled automatic transmissions/transaxles.

VACUUM MODULATOR VALVE A vacuum modulator is used to convert engine manifold vacuum into a signal pressure that increases as engine vacuum decreases. The modulator is connected to the intake manifold vacuum with a rubber hose or steel line. A vacuum modulator is used on hydraulically controlled transmissions/transaxles to help determine the shift point based on engine load. The purpose of the vacuum modulator is to delay the upshifting of the transmission based on the engine load. ● **SEE FIGURE 128–26.**

Consider, for example, the following:

- **Light engine load.** Manifold vacuum is high, shifts occur at lower speeds.
- **Heavy engine load.** Manifold vacuum is low, shifts occur at higher speeds.

The manifold absolute pressure (MAP) sensor or mass airflow (MAF) sensor and throttle position (TP) sensor serve in place of the vacuum modulator valve in measuring engine load on electronically controlled automatic transmissions/transaxles.

GOVERNOR VALVE The **governor valve** monitors vehicle road speed and uses that operating signal to develop governor pressure. The governor valve normally follows transmission output shaft rotation speed, which increases with vehicle speed. Mechanical governors contain "flyweights" that move in relation to centrifugal forces

caused by the speed of the output shaft. As the output shaft speed flyweights move outward, this in turn moves an internal valve which controls the output pressure. As the speed increases, governor pressure also increases. Governor pressure opposes throttle pressure at the shift valves to control upshifts and downshifts in relation to vehicle speed. ● **SEE FIGURE 128–27.**

Some electronic transmissions use the speed sensor signal to control a solenoid which produces a governor pressure and some do not use a governor pressure. Instead the speed signal is processed to control the shift valve solenoid directly.

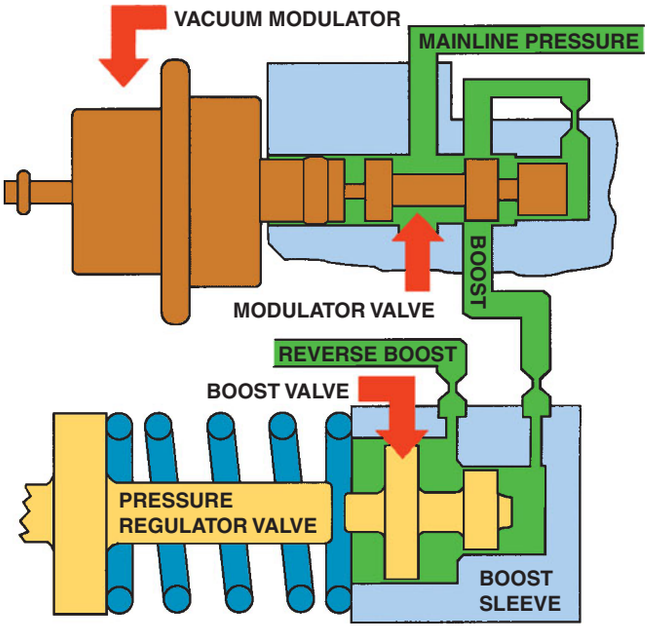

FIGURE 128–26 A vacuum modulator moves the modulator valve depending on the vacuum of the engine. A heavy load on the engine causes the vacuum to be lower than when the engine is operating under a light load. The spool valve applies mainline pressure to the boost sleeve of the pressure regulator valve which causes the mainline pressure to increase.

SHIFT VALVES

A **shift valve** is a spring-loaded spool valve that controls the transmission upshift and downshift circuits. Throttle pressure works against one side of the valve, while governor pressure works against the other side. When one pressure is greater than the other, the valve moves to the upshift or downshift position and the valve lands uncover the ports to the relative circuits. Transmission shift valves may be referred to as "snap valves" or "relay valves" because they shift almost instantly in response to pressure differential changes. Since these valves cause upshifts and downshifts, they are also known as "event-causing valves." There are only two positions for a shift valve:

- One end of the stroke or
- the other end of the stroke

Otherwise, hydraulic pressure could apply control devices for two gears at once and damage the transmission. ● **SEE FIGURE 128–28.**

In an electronically controlled automotive transmission/transaxle, solenoids control the pressure force which in turn controls the position of the shift valve.

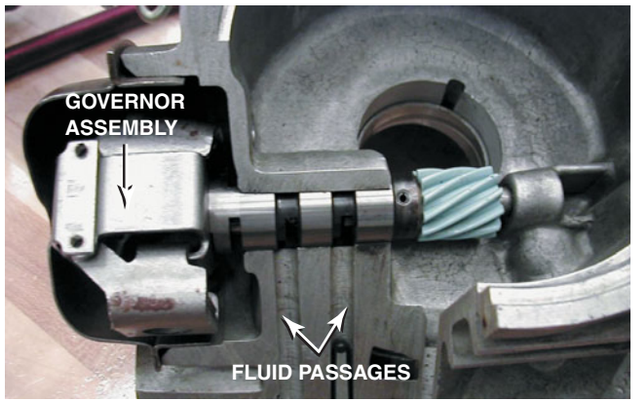

FIGURE 128–27 A governor assembly is used on older hydraulically controlled automatic transmissions/transaxles to control shift points based on vehicle speed.

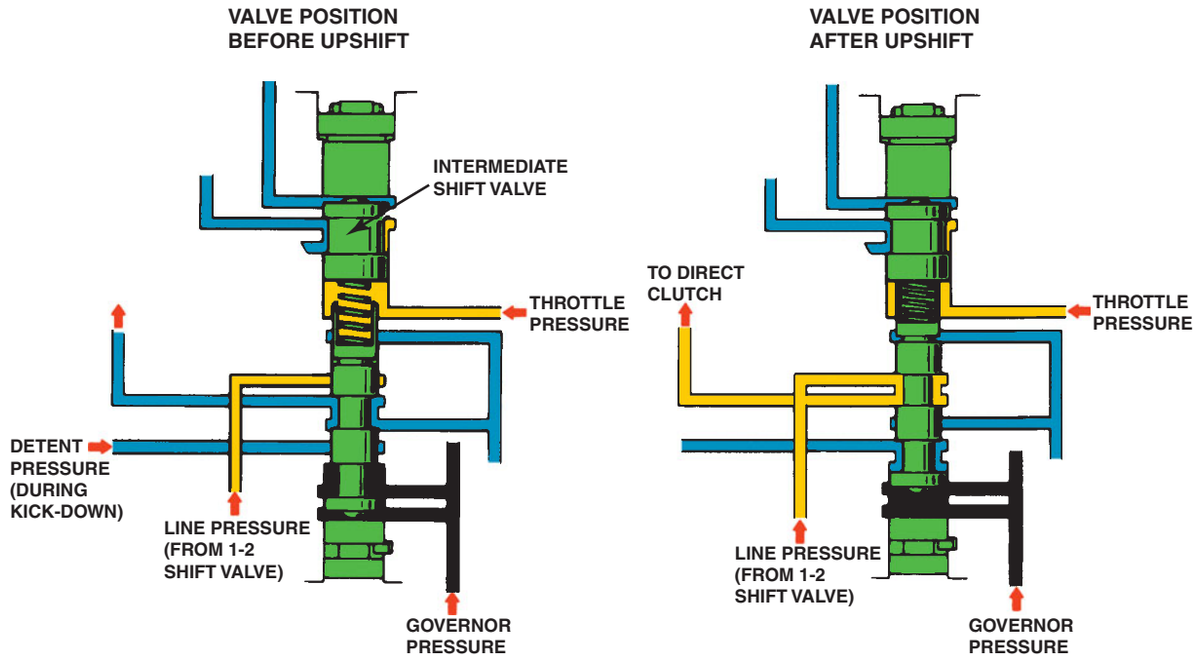

FIGURE 128–28 Shift valves move when there is a difference in pressure. In a hydraulically controlled automatic transmission/transaxle, the shift valves compare governor pressure force against throttle valve (TV) pressure force to determine when to upshift or downshift.

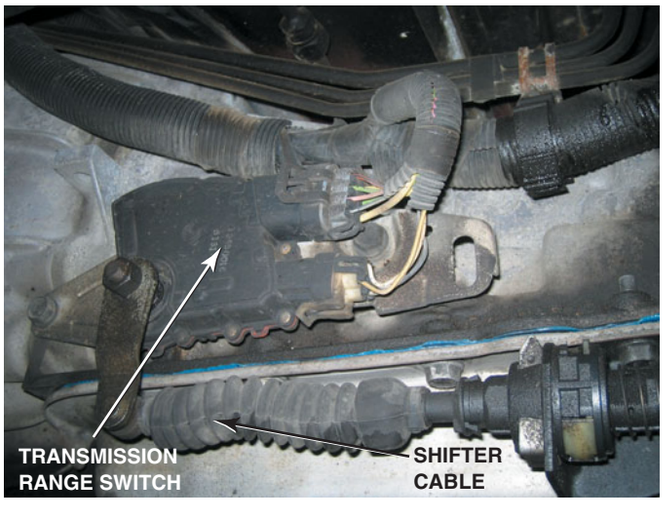

FIGURE 128–29 A transmission range switch on a rear-wheel-drive automatic transmission mounted directly to the side of the case of the unit and accessible from underneath the vehicle.

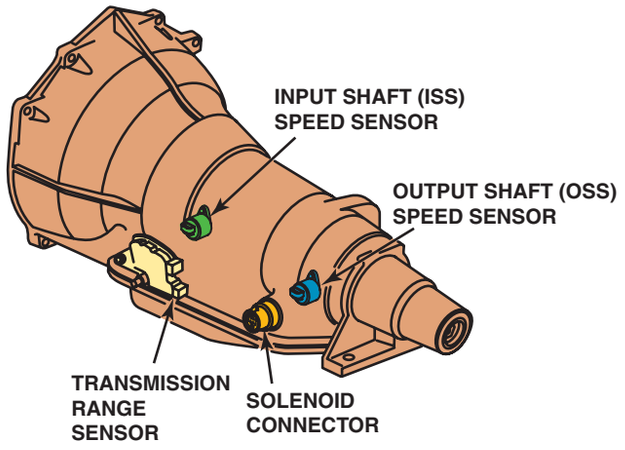

FIGURE 128–30 Speed sensors are used by the powertrain control module (PCM) or the transmission control module (TCM) to control shifts and detect faults such as slippage when the two speeds do not match the predetermined ratio for each gear commanded.

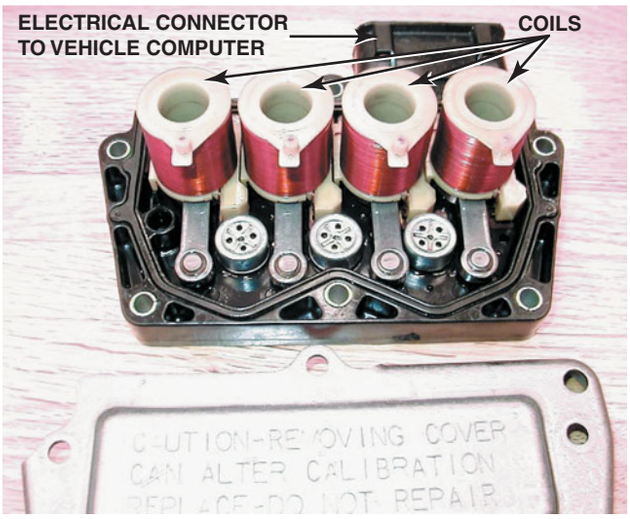
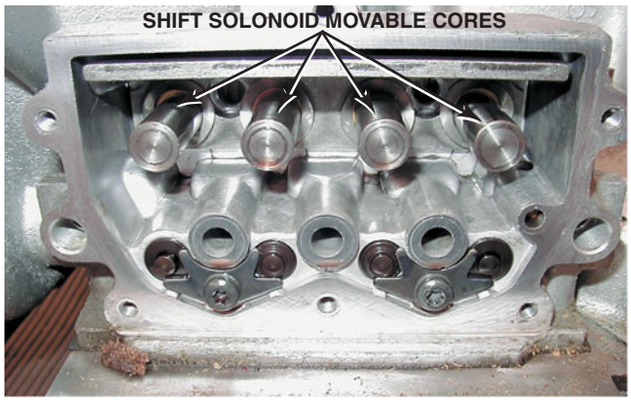
ELECTRONICALLY CONTROLLED TRANSMISSIONS

BACKGROUND Electronically controlled transmissions and transaxles have been used by most vehicle manufacturers since the early 1990s. Compared to hydraulically controlled units, using the powertrain control module (PCM) or the transmission control module (TCM) to operate and control shifting results in smoother operation. Also, the PCM or TCM can monitor the circuits and set a diagnostic trouble code if a fault is detected.



NOTE: All transmissions use hydraulic pressure and automatic transmission fluid to do the actual shifting. The difference between hydraulically controlled and electronically controlled automatic transmissions is the way that the shift points are controlled.

INPUTS Following are inputs to the powertrain control module (PCM) and their purposes.



- **Transmission range switch.** This sensor is used by the PCM to detect the gear being commanded by the driver. If reverse or a manual forward gear is selected, then higher line pressure will be needed and the shifts will be delayed to provide more power being delivered to the drive wheels. ● **SEE FIGURE 128–29.**
- **Engine speed.** The speed of the engine has a direct relation to the amount of power the engine is developing. The engine speed information is taken from the crankshaft position (CKP) sensor and is used by the PCM or TCM to control shift points and to regulate line pressure.
- **Throttle position (TP) sensor.** This sensor is used by the PCM to detect the throttle opening being commanded by the driver. A higher throttle opening means that higher line pressure will be needed and the shifts will be delayed to provide more power being delivered to the drive wheels.
- **Manifold absolute pressure (MAP) sensor.** This sensor is used by the PCM to detect the amount of load on the engine. The greater the load, the more fuel that needs to be supplied, and the greater the amount of power the engine will create. This signal is used to determine the best shift points and to regulate line pressure.
- **Mass airflow (MAF) sensor.** This sensor is used by the PCM to detect the amount of air entering the engine. The greater the amount of air, the more fuel that needs to be supplied and, therefore, the greater the amount of power the engine will create. This signal is used to determine the best shift points and to regulate line pressure.
- **Speed sensors.** These sensors measure the speed of the input shaft and output shaft or sometimes other shaft speeds in the automatic transmission or transaxle. The output shaft speed sensor is often used to provide vehicle speed information to the PCM and for adaptive learning and self-diagnosis. ● **SEE FIGURE 128–30.**
- **Transmission fluid temperature (TFT) sensor.** This sensor is used by the PCM or TCM to detect the temperature of the automatic transmission fluid. This signal is used to determine the best shift points and to regulate line pressure. It will cause the PCM or the TCM to engage the torque converter clutch (TCC) sooner and disable overdrive, to help reduce the fluid temperature if it reaches higher than normal.

OUTPUTS Outputs to the powertrain control module (PCM) or transmission control module (TCM) and their purposes include the following:

- **Pressure control.** The PCM or TCM controls the line pressure by changing the signal to the pressure control solenoid. Using the input signal to detect the conditions that the vehicle is being driven, the specified line pressure is commanded to provide smooth shifts without slippage.
- **Shift control solenoids.** The PCM or TCM controls the shifting by applying power or ground to the correct control solenoid(s) at the right time.

(a)

(b)

FIGURE 128–31 An example of a solenoid valve installed in a valve body assembly.

- **Torque converter clutch (TCC).** The PCM or TCM controls the application of the torque converter clutch (TCC) by applying power or ground to the correct control solenoid at the right time.

  ● **SEE FIGURE 128–31.**

ADAPTIVE LEARNING Most late model electronically controlled automatic transmissions/transaxles use the PCM or TCM to monitor the time it takes to complete a shift. The PCM can determine this from the comparison between the engine speed and the output speed sensor data. When a shift is commanded, there should be a change in the speed of the output shaft. If the change in speed is longer than normal, which could indicate normal wear in the clutch pack, the PCM can learn from this and start the shift sooner to allow time for the clutch to be fully engaged.

SHIFT SOLENOIDS Solenoids used in electronically controlled automatic transmissions/transaxles are:

- **On-off solenoids.** These are can be normally open to fluid flow or normally closed to block fluid flow. They are commanded on or off by the PCM or TCM. The resistance of most on-off shift solenoids is 10 to 15 ohms.
- **Linear solenoids.** This type of solenoid can be varied by changing the amount of on time to precisely control the fluid flow through the solenoid valve. The variable power or ground applied to the linear solenoids is pulse-width modulated (PWM) and allows the PCM precise control over the shifting and the fluid pressure. The resistance of most linear (PWM) shift solenoids is about half of the on-off type and range from 4 to 6 ohms.

GENERAL MOTORS 4T60-E (FRONT-WHEEL-DRIVE TRANSAXLE)

TECH TIP

Parking Brake Before Parking Pawl

To prevent possible damage to the transmission/transaxle case or other internal components, most experts agree that the parking brake should be applied *before* placing the gear selector into the park position, especially when parking on a hill. This procedure keeps the weight of the vehicle from being exerted entirely on the parking pawl and makes it easier to move the gear selector out of the park position.

Shift solenoids control the pressure force which in turn controls the position of the shift valve. Shift solenoids may be labeled 1 and 2 or A and B. Using a combination of the two shift solenoids prevents the actuation of four forward gears.

A **default** (or **limp-in**) **gear** is the forward speed that is used if there is a failure in the electronic or computer system. If neither solenoid is engaged, then either second or third gear is actuated, depending on the exact make and model of the transmission or transaxle. ● **SEE CHARTS 128–2 AND 128–3** for examples of two General Motors transmissions.

CHART 128–4

The General Motors 4L60-E electronically controlled rear-wheel-drive transmission clutch, band, and solenoid application chart.

TYPICAL TORQUE FLOW

The General Motors 4L60-E can provide an example of how a typical electronically controlled rear-wheel-drive automatic transmission works. ● **SEE CHART 128–4.**

PARK AND NEUTRAL With the gear selector level in P or N, there is no torque flow through the gear set, even though the low-reverse clutch is applied in the 4L60-E. The clutch holds the reaction carrier stationary, but torque input to the gear set stops at the input housing.

The torque converter housing and impeller rotate clockwise at engine speed to hydraulically drive the turbine and mechanically drive the oil pump. The transmission input drum assembly rotates clockwise at turbine speed to drive the gear set. Turbine speed is slightly less than engine crankshaft speed. However, there is nothing connecting the input drum assembly to drive the gear sets and transfer torque at this time.

In neutral, the output shaft is free to rotate in either direction, and the vehicle can be pushed or towed. However, use caution because if the engine is not running, the pump is not providing lube fluid to components. In park, a mechanical pawl or finger engages one of many large notches cut into a gear mounted on the output shaft. In park to the transmission case, preventing the vehicle from moving in either direction.

OVERDRIVE FIRST With the gear selector lever in overdrive, the transmission starts off in first gear, and then upshifts into second, third, and fourth gears as the vehicle continues to accelerate. To engage first gear, the forward clutch applies, transferring engine torque from the input shaft to the input sun gear through the forward sprag clutch, driving the sun gear clockwise.

With the input sun gear turning clockwise, the input pinion gears spin counterclockwise in the stationary carrier and attempt to drive the input ring (internal) gear and reaction carrier counterclockwise. However, the forward sprag clutch is holding, so the pinions walk clockwise inside the ring (internal) gear, turning the input carrier clockwise. Then, the input carrier drives the output shaft clockwise in gear reduction. ● **SEE FIGURE 128–32.**

The reaction ring (internal) gear turns clockwise along with the output shaft and drives the reaction pinions clockwise on the stationary reaction carrier assembly. Pinion action drives the reaction sun gear counterclockwise. However, the reaction sun gear is not connected to a gear set member, so the reaction gear set simply freewheels. The low roller clutch prevents the reaction carrier from turning counterclockwise.

As long as the vehicle continues to accelerate in overdrive first, torque transfers through the gear set to the output shaft. During closed-throttle coasting, the clockwise torque load on the forward sprag clutch and the counterclockwise torque load on the low roller clutch are released. Both one-way clutches overrun so the gear sets freewheel on deceleration, and engine braking is not available.

OVERDRIVE SECOND As the vehicle continues to accelerate in the overdrive range, the transmission upshifts to second gear by applying the 2-4 band. The band holds the reverse drum, input shell, and reaction sun gear stationary. The forward clutch remains applied, while the input shaft drives the input sun gear clockwise through the forward sprag clutch. ● **SEE FIGURE 128–33.**

As in first gear, the input sun gear rotates clockwise and drives the input pinions counterclockwise. Since the 2-4 band is holding, the input pinions walk inside the internal gear, driving the input carrier and output shaft clockwise in gear reduction.

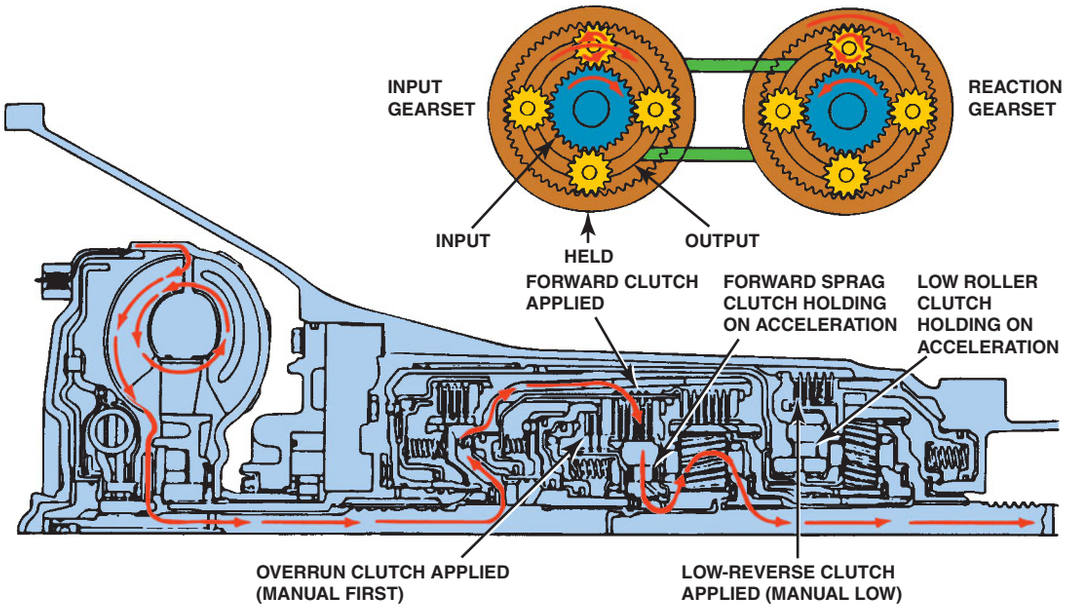

FIGURE 128–32 A GM 4L60-E torque (power) flow in overdrive first gear.

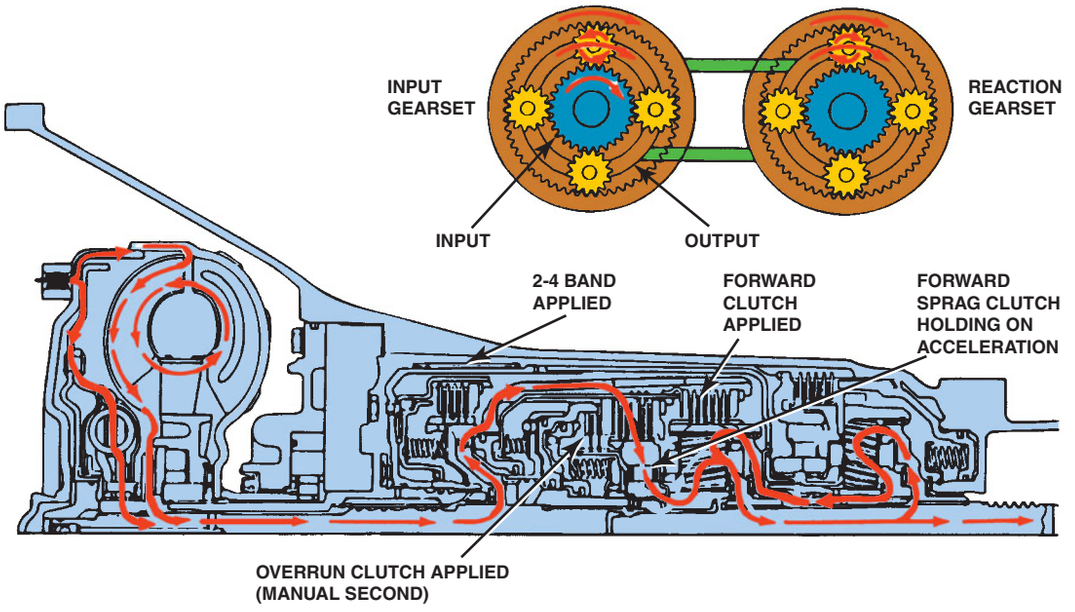

FIGURE 128–33 A GM 4L60-E torque (power) flow in overdrive second gear.

At the same time, the output shaft drives the reaction internal ring gear and pinion gears clockwise. With the reaction sun gear held, the pinion gears walk clockwise and drive the reaction carrier clockwise with them.

Clockwise rotation of the reaction carrier transfers to the input ring (internal) gear through the reaction carrier shaft. With the input ring (internal) gear turning clockwise, the input pinions spin counterclockwise and drive the input carrier clockwise. This removes the counterclockwise torque load from the low roller clutch so that it overruns at this time. There is no engine compression braking available in overdrive second because the forward sprag clutch overruns.

OVERDRIVE THIRD To automatically upshift into third gear as the vehicle continues to accelerate, the transmission releases the 2-4 band and applies the 3-4 clutch. Also, the forward clutch remains applied so the input shaft drives the input sun gear clockwise through the forward sprag clutch. ● **SEE FIGURE 128–34.**

Applying the 3-4 clutch connects the input shaft to the input ring (internal) gear, which drives the ring (internal) gear clockwise at turbine speed. Now that two members of the input gear set—the sun and ring (internal)—are being driven at turbine speed, the gear set provides direct drive as it locks up and turns as a unit.

As long as the vehicle is accelerating in overdrive third, torque transfers through the planetary gear set to the output shaft. There is no engine braking because the forward one-way clutch overruns and allows the input sun gear to freewheel.

OVERDRIVE FOURTH The transmission upshifts into fourth gear by applying the 2-4 band as the vehicle continues to accelerate in overdrive range. The 2-4 band holds the reverse drum and reaction sun gear stationary. Both the 3-4 and forward clutches remain applied, and the input drum continues to drive the input ring (internal) gear clockwise. ● **SEE FIGURE 128–35.**

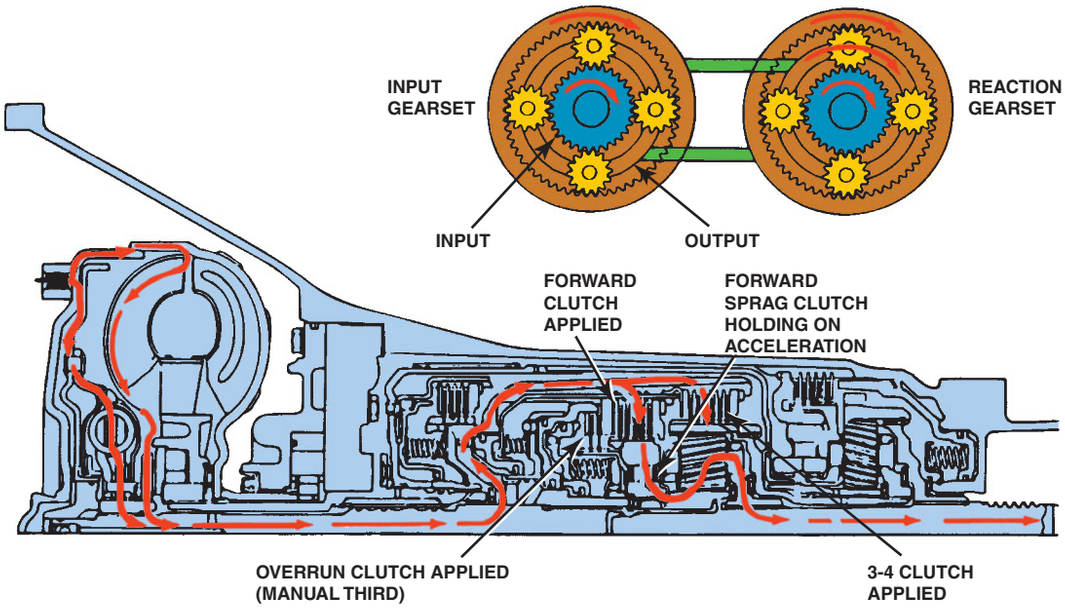

FIGURE 128–34 A GM 4L60-E torque (power) flow in overdrive third gear.

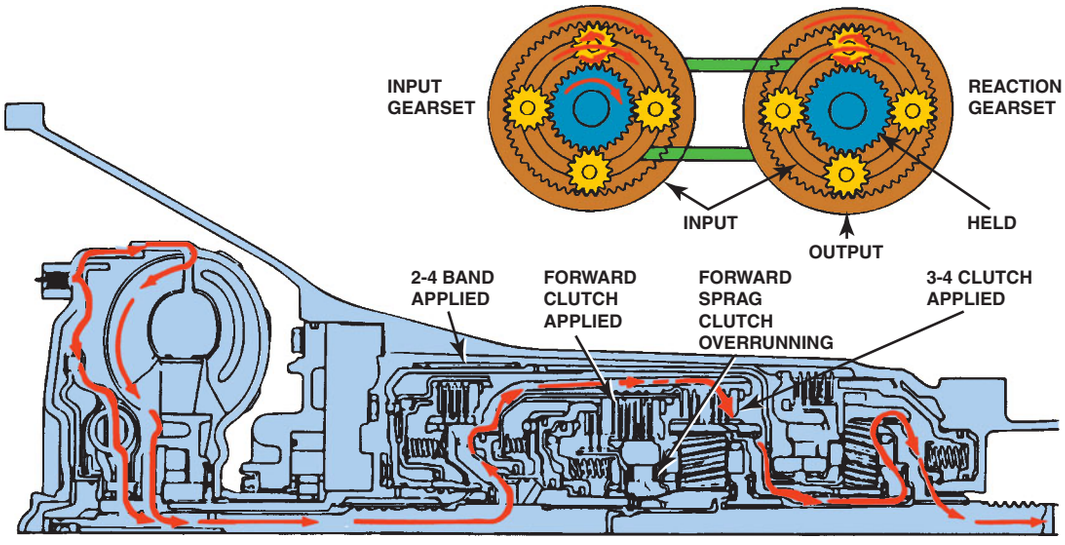

FIGURE 128–35 A GM 4L60-E torque (power) flow in overdrive fourth gear.

This drives the reaction carrier clockwise as well, since it is in common with the input ring (internal) gear. As the carrier turns, the reaction pinions walk clockwise around the stationary reaction sun gear. This drives the reaction ring (internal) gear and output shaft clockwise at an overdrive ratio.

In fourth gear, the input ring (internal) gear turns at input shaft speed, while the input carrier turns at a faster output shaft speed; both gears turn clockwise. As a result, the input pinions turn counterclockwise and drive the sun gear clockwise faster than input speed. This causes the forward sprag clutch to overrun and renders the forward friction clutch, which remains applied, ineffective.

When the transmission is operating in fourth gear, the input member, the reaction carrier, is being driven by a multiple-plate clutch, while a band prevents the held member, the reaction sun gear, from turning in either direction. Therefore, engine compression braking is available. However, due to the overdrive gear ratio, the braking effect is not noticeable to the driver.

REVERSE With the gear selector lever in reverse, the low-reverse clutch applies to drive the reaction sun gear clockwise with the input shaft. The reaction carrier and input ring (internal) gear are held stationary by the applied reverse input clutch. This turns the reaction pinions counterclockwise and drives the carrier counterclockwise in gear reduction. ● **SEE FIGURE 128–36.**

In reverse gear, the input ring (internal) gear is held, while the input carrier is driven counterclockwise. This causes the input pinions to rotate clockwise and drive the input sun gear counterclockwise.

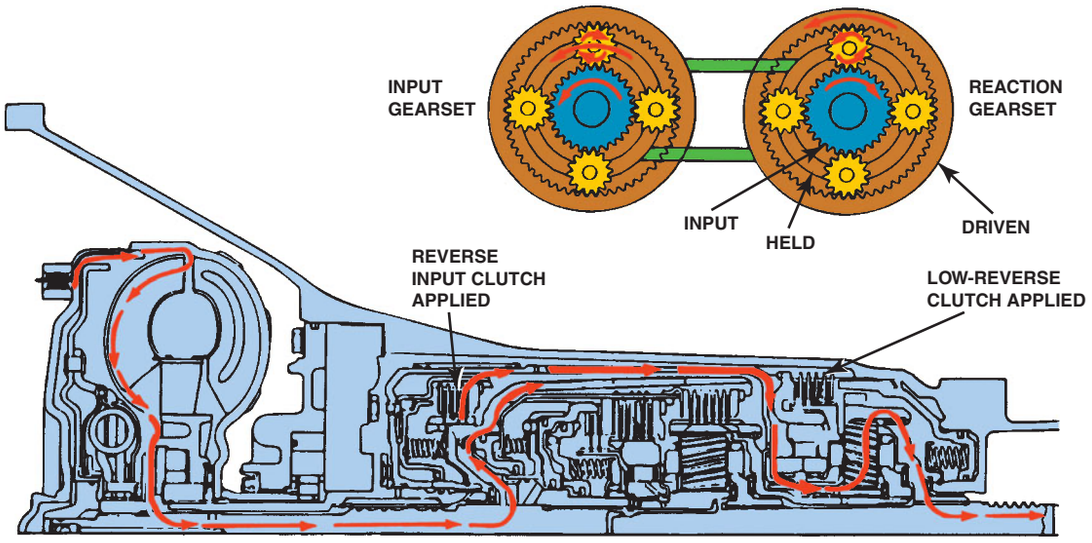

FIGURE 128–36 A GM 4L60-E torque (power) flow in reverse.

REVIEW QUESTIONS

1. What are three planetary gear set holding devices?
2. How are shift points achieved with a hydraulically controlled automatic transmission/transaxle?
3. How are solenoids used to control the shifting on electronically controlled automatic transmissions/transaxles?
4. What are the parts of a typical clutch pack assembly?
5. What are the solenoids used in a typical electronically controlled automatic transmission/transaxle?

CHAPTER QUIZ

1. Two technicians are discussing one-way clutches. Technician A says that a sprag and a roller are two types of one-way clutches. Technician B says that a one-way clutch could be installed upside down and cause the automatic transmission/transaxle to not function correctly. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. Two technicians are discussing automatic transmission/transaxle oil pumps. Technician A says that a vane-type pump is a positive displacement pump. Technician B says that the pump is driven by the torque converter. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Which part controls mainline pressure in an electronically controlled automatic transmission/transaxle?
   a. Pressure control solenoid (force motor)
   b. Spool valve
   c. Boost valve
   d. Modulator valve
4. Technician A says that the automatic transmission/transaxle fluid (ATF) cooler is designed to cool the automatic transmission fluid.Technician B says that the cooler also warms the ATF when the fluid is cold. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. Technician A says that the mainline pressure is usually higher in manual first or manual second gear than it is when the gear selector is in the drive position. Technician B says that mainline pressure is higher in reverse than when the gear selector is in the drive position. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
6. What is the part of the planetary gear set called that is being held by a band?
   a. Reaction member **c.** Simple gear set
   b. Compound gear set **d.** Held member
7. What is the purpose and function of an accumulator?
   a. To apply a clutch
   b. To apply a band
   c. To cushion or dampen pressure surges
   d. Either a or b
8. The steel plates in a clutch pack are commonly called _____.
   a. Friction disks **c.** Friction members
   b. Reaction members **d.** Steels
9. Force motors are controlled by the computer by _____.
   a. Increasing/decreasing current (amperes)
   b. PWM
   c. Increasing/decreasing voltage
   d. Changing the resistance in the circuit
10. Check balls used in the valve body are constructed of _____.
    a. Steel **c.** Rubber
    b. Nylon **d.** All of the above

chapter 129

AUTOMATIC TRANSMISSION/ TRANSAXLE DIAGNOSIS AND IN-VEHICLE SERVICE

OBJECTIVES: **After studying Chapter 129, the reader will be able to:** • Prepare for ASE Automatic Transmission/Transaxle (A2) certification test content area "A" (General Transmission/Transaxle Diagnosis), content area "B" (Transmission/Transaxle Maintenance and Adjustment), content area "C" (In-Vehicle Transmission/Transaxle Repair), and content area "D" (Off-Vehicle Transmission/Transaxle Repair). • Describe what to look for regarding the operation of an automatic transmission or transaxle during a test drive. • Explain how to test an automatic transmission/transaxle using a scan tool. • Discuss how to locate automatic transmission fluid leaks. • Explain how to perform a system pressure test. • Describe how to replace or flush automatic transmission fluid. • Describe how to perform on-vehicle transmission adjustments.

KEY TERMS: Diagnostic trouble codes (DTCs) 1588 • Technical service bulletins (TSBs) 1590

TRANSMISSION PROBLEM DIAGNOSIS

VERIFY THE CUSTOMER CONCERN The first step is to verify the customer concern. The customer should be asked the following questions in an effort to determine as much about the problem as possible.

- What exactly seems to be the concern? (Ask the customer to be as detailed as possible.)
- When did the problem first appear?
- Under what conditions do the symptoms occur? (Do they occur first thing in the morning? After the vehicle has been driven for a while?)
- Describe under what driving conditions the problem is noticed, such as when accelerating or while coasting to a stop or some other condition.
- Has the vehicle been serviced recently, such as a fluid change?

FLUID CHECK The first step in diagnosing any problem is to test drive the vehicle and verify the customer complaint (concern). Before test driving the vehicle, check the level and condition of the automatic transmission/transaxle fluid. Follow the procedure for checking the level as published in the owner's manual or factory information. **SEE FIGURES 129–1 AND 129–2.**

The typical procedure for checking automatic transmission fluid level includes the following steps. (Check service information for the exact procedure to follow.)

STEP 1 Start the engine, except for Honda/Acura vehicles which specify that the ATF be checked with the engine off.

STEP 2 Be sure that the ATF is at normal operating temperature. This may require that the vehicle be driven for several miles.

STEP 3 Park the vehicle on a level surface. Start the engine and shift the transmission through each gear, allowing engagement in each gear.

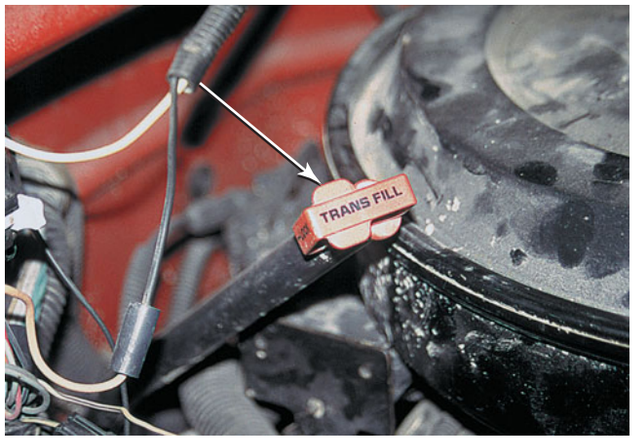

FIGURE 129–1 A typical automatic transmission dipstick (fluid level indicator). Many use a clip to keep it from being forced upward due to pressure changes inside the automatic transmission. A firm seal also helps keep water from getting into the fluid, which can cause severe damage to the clutches and bands.

FIGURE 129–2 The "add" mark on most automatic transmission dipsticks indicates the level is down 0.5 quart (0.5 liter). Always follow the instructions stamped or printed on the dipstick.

STEP 4 Clean the area around the dipstick to help prevent dirt from falling into the filler tube when the dipstick is removed.

CAUTION: Be sure any transmission filler cap, plug, or dipstick is installed tightly. Water contamination of the transmission fluid will eventually destroy frictional linings of apply devices.

STEP 5 Remove the dipstick and wipe it off with a shop cloth.

STEP 6 Reinsert the dipstick and then remove it again. Check the level. The "add" mark indicates that the level is a half quart (liter) low.

TECH TIP

Quick-and-Easy Automatic Transmission/ Transaxle Diagnosis

An experienced technician told the beginning technician that automatic transmission/transaxle diagnosis is often very easy. For example:

- **If the vehicle does not move in drive or reverse,** remove the transmission/transaxle for service because the problem is likely mechanical rather than hydraulic (valve body) or electrical (computer, solenoids, or sensors). If the unit will not power the vehicle, the unit will more than likely require removal for a thorough mechanical inspection and repair.
- **If the vehicle moves, but does not shift correctly,** the problem is likely electrical (computer, solenoid, or sensor) or hydraulic (valve body) rather than mechanical. This is usually true because if the vehicle is able to move forward and backward, the major mechanical components, though not in like-new condition, are at least able to function. Therefore, correcting the non-mechanical problem should be the technician's first consideration.

Results and possible causes include:

- If the fluid level is low, add the specified fluid until the proper level is achieved before test driving the vehicle.
- If the level is too high, this can cause the fluid to become aerated, meaning that the fluid becomes filled with air bubbles. When the fluid is aerated, the transmission or transaxle cannot shift properly. The fluid should be red, although some highly friction-modified ATFs are normally light brown which is normal and not a cause for alarm.
- If the color of the fluid is dark brown or black, then the fluid has been overheated.
- Smell the fluid. It should have a "clean petroleum" smell. If it smells "burned" or rancid, then this indicates that the fluid has been overheated and will require replacement.
- If the fluid is milky, this usually means that coolant has entered the fluid usually through a fault with the ATF cooler located in the radiator.

STEP 7 Insert the dipstick into the transmission/transaxle and remove. Allow a few drops to fall onto a paper towel. Then take the end of the dipstick and place it into a container of new ATF and allow the same number of drips to fall onto another section of the paper towel. Allow to sit for 10 minutes.

- If the fluid expands to the same size as the new fluid, then it has maintained it lubricity and viscosity.
- If the fluid fails to expand to the same diameter as the new fluid, this means that the fluid has lost some of its lubricity and has increased in viscosity. A fluid change would then be indicated.
- If a dark stain shows on the white paper towel, this means that it is contaminated with clutch material or varnish from oxidized fluid and requires further diagnosis.
- If the stain is a foamy pink, then this may indicate coolant in the transmission/transaxle.

FIGURE 129–3 Use all shift modes when diagnosing automatic transmission/transaxle concerns to help pinpoint the area where the fault is located.

STEP 8 Rub the fluid between your fingers. It should feel slick. If it feels gritty, then it is contaminated with friction material or other solid particles.

NOTE: Many newer transmissions/transaxles do not use a dipstick. The fluid level is usually checked similar to how the fluid in a manual transmission/transaxle is checked by removing a plug in the side of the case. In some vehicles the fluid level can be checked using a scan tool. Check service information for the exact methods to use to check ATF level.

TEST DRIVE

When test driving the vehicle, try to drive the vehicle under the same conditions that the owner noticed the problem.

To ensure a thorough diagnosis, the vehicle should be driven under a variety of conditions to see if it functions correctly, including the following:

1. **From a stop, and accelerated slowly until at highway speed.** This will check if all shifts are occurring and at the correct speeds.
2. **Note how the shifts feel.** The shifts may be too harsh or too soft. This could indicate a fluid pressure problem, or a worn clutch, bands, or accumulator.
3. **Note when the shifts occur.** The shifts may occur too early or too late.
4. **Use all gear selections.** Often a different element of clutch is used for manual gears compared to the same gear when the gear selector is in drive (D). Note any differences that may help in identifying the source of the problem. ● **SEE FIGURE 129–3.**

COMMANDING SHIFTS

Many automatic transmission test tools or scan tools can be used to actually cause the automatic transmission/transaxle to shift electrically. The tester is connected to the electrical connector at the automatic transmission/transaxle after disconnecting the factory connector. To perform this simple test, perform the following steps.

STEP 1 Safely hoist the vehicle.

STEP 2 Start the engine.

STEP 3 Place the gear selector in the drive position and use the tester or scan tool to command the various shift solenoids to actuate.

CHART 129–1

Transmission/transaxle-related diagnostic trouble codes (DTCs). For transmission-related diagnostic trouble codes for vehicles older than 1996, check service information on how to retrieve and read the codes.

RESULTS: If the shift occurs when commanded, the hydraulic system is functioning. If the tester commands a shift to occur and a shift does not occur, the service technician knows that the problem is either in the solenoid itself or the hydraulic system that actuates the clutch or band to accomplish the shift. ● **SEE FIGURE 129–4**.

CAUTION: A scan tool or special tester can be used to command shift while an assistant is driving the vehicle instead of on a hoist as stated above. If commanding a shift when driving, use extreme care as some shift may be harsh and damage to the vehicle could occur if the commanded shift occurs at too high a vehicle speed.

CHECK DIAGNOSTIC TROUBLE CODES

If there are any **diagnostic trouble codes (DTCs)** stored in the memory of the vehicle computer, then a problem has been detected that should be corrected before further testing. ● **SEE CHART 129–1** for transmission-related diagnostic trouble codes.

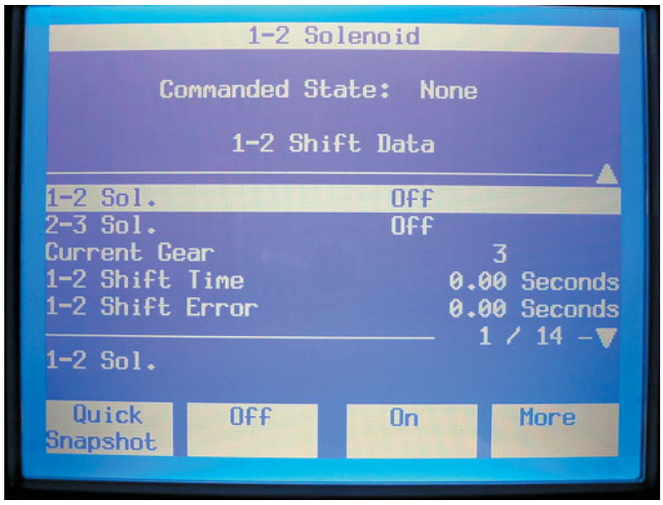

FIGURE 129–4 Most factory or factory-level scan tools are capable of bidirectional control of the automatic transmission or transaxle.

A weak or missing engine cylinder can cause the vehicle to lack power, jerk, and hesitate. These symptoms are often blamed on an incorrectly shifting or slipping automatic transmission/transaxle. If a P0300 diagnostic code (random engine misfire code) is set, repair the cause of the misfire before trying to diagnose the transmission. Other misfire codes include:

P0301	Cylinder 1 misfire detected
P0302	Cylinder 2 misfire detected
P0303	Cylinder 3 misfire detected
P0304	Cylinder 4 misfire detected
P0305	Cylinder 5 misfire detected
P0306	Cylinder 6 misfire detected
P0307	Cylinder 7 misfire detected
P0308	Cylinder 8 misfire detected
P0309	Cylinder 9 misfire detected
P0310	Cylinder 10 misfire detected
P0311	Cylinder 11 misfire detected
P0312	Cylinder 12 misfire detected

SCAN DATA A scan tool can display information about the various sensors and components that can assist the service technician in determining the cause of many automatic transmission/transaxle problems.

A properly operating engine should display the following readings with the engine at idle and operating in closed loop.

- **Engine coolant temperature (ECT)**—between 180°F and 215°F (82°C and 102°C)
- **Throttle position (TP) sensor**—usually between 0.5 volt and 4.5 volts and varying directly with throttle movement
- **Accelerator pedal position sensor (APPS)**—usually two or more sensors on differing scales (0.4 volt to 4.6 volts) and varying with accelerator pedal movement
- **Fuel injector pulse width**—1.5 to 3.5 ms
- **Upstream oxygen sensor (O2S)**—voltage varying between 200 and 800 mV
- **Air-fuel ratio sensor(s) (if equipped)**—scan tool to read fairly low and steady
- **Transmission fluid temperature**—less than 275°F (135°C)
- **Brake switch**—scan data to show a change when brake pedal is pressed and released
- **Manifold absolute pressure (MAP) sensor**—with the engine idling in park or neutral, the voltage should be within 0.88 volt and 1.62 volts or between 102 and 109 Hz for a Ford MAP sensor.
- **Mass airflow sensor (MAF)**—warm engine in park with no load typically reads grams per second within 20% of the engine's liters of displacement, a 3.5 liter engine will show fairly close to 3.5 g/s of airflow at idle
- **Vehicle speed (VS) sensor**—source can vary: derived from ABS wheel speed sensors, output speed sensor of transmission, or a dedicated sensor on transmission or transfer case
- **Idle speed**—check for normal idle speed; vehicles with electronic throttle control are usually 2% to 3% open at warm idle in park and vehicles with IAC (idle air control) valves are typically 10 to 30 steps if stepper motor type or 250 to 400 milliamps if linear
- **Shift solenoids**—check for the proper voltage and current of the shift solenoids using a factory or factory-level scan tool.

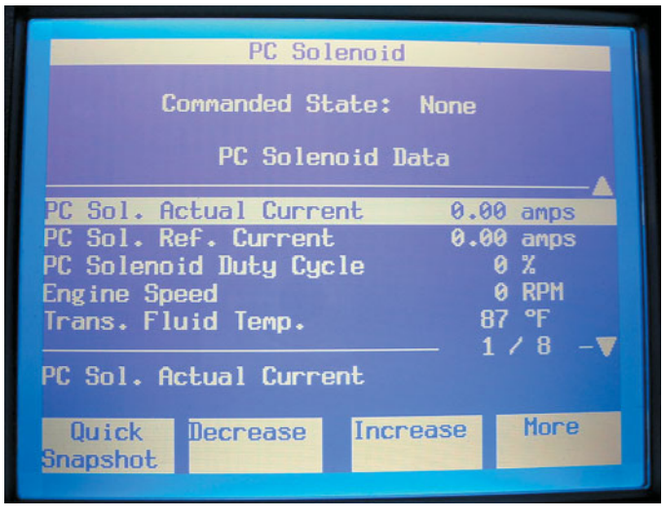

FIGURE 129–5 A Tech 2 scan tool is able to display shift solenoid current. Use this information and check service information for the specified current to help diagnose shift solenoid-related faults.

INPUT SENSOR	TYPICAL VALUE
Throttle position (TP) sensor	0.5 to 4.5 volts (0% to 100%)
Mass airflow (MAF) sensor	3 to 7 grams per second at idle
Oxygen sensor (O2S)	200 to 800 mV and changing rapidly
Turbine shaft speed (TSS) sensor	Should be the same as the engine speed
Transmission fluid temperature (TFT) sensor	−40°F to 300°F (−40°C to 150°C)
Transmission range (TR) sensor	P, N, R, D, L (or 2, 1)
Overdrive switch (if equipped)	On or Off
Barometric pressure (BARO) sensor	Varies with weather and altitude
Accelerator pedal position (APP) sensor	0% to 100%
Brake pedal position (BPP) switch	On or Off

CHART 129–2

Typical automatic transmission/transaxle sensor values as displayed on a scan tool.

Observe the operation of the command for the shift solenoids and the TCC solenoid while driving the vehicle. This information confirms that the computer is commanding the operation; it does not mean that the solenoids are working correctly. Therefore, if the scan data indicates that a particular solenoid is being commanded on and nothing occurs, then the problem could be caused by a defect with the following:

1. Hydraulic component (clutch, band, etc.)
2. Solenoid
3. Fault in the wiring to the solenoid or from the solenoid to the PCM or TCM

● **SEE FIGURE 129–5.**

Use a scan tool to check the engine operation values and inputs that could affect transmission operation. ● **SEE CHART 129–2.**

TECH TIP

You'd Ask a Friend, Wouldn't You?

If you were stuck on a difficult transmission problem, you would probably ask a technician friend for ideas. Think of the service information as a friend with some inside information. It is written by the people who know how the system works in detail.

Such advice is available in service information. If the technician follows the recommended steps, chances are excellent of finding the problem—just like getting the advice of an experienced technician. ● **SEE FIGURE 129–6.**

FIGURE 129–6 Checking service information for how to perform diagnosis on an automatic transmission fault is a wise step.

TECH TIP

Quick-and-Easy Automatic Transmission/Transaxle Diagnosis

An experienced technician told the beginning technician that automatic transmission/transaxle diagnosis is often very easy. Assuming that the fluid level has been checked and is at the specified level, consider the following examples.

- **If the vehicle does not move in drive or reverse,** then remove the transmission/transaxle for service because the problem is likely mechanical rather than valve body or electrical (computer, solenoids, or sensors). If the unit will not power the vehicle, the unit will more than likely require removal for a thorough mechanical inspection and repair.
- **If the vehicle moves, but does not shift correctly,** then the problem is likely electrical (computer, solenoid, or sensor) or hydraulic (valve body) rather than mechanical. This is usually true because if the vehicle is able to move forward and backward, the major mechanical components, though not in like-new condition, are at least able to function. Therefore, correcting the nonmechanical problem should be the technician's first consideration.

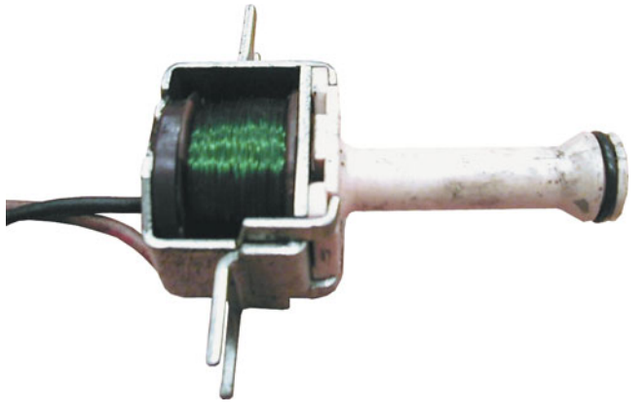

FIGURE 129–7 A torque converter clutch (TCC) solenoid. This TCC can be replaced on a General Motors vehicle without having to remove the transmission/transaxle from the vehicle.

REAL WORLD FIX

The Stalling Impala

The owner of a Chevrolet Impala complained that the vehicle would occasionally stall when slowing to a stop. The problem only occurred after at least 20 miles and occurred more frequently in warm weather. The owner also indicated even though this vehicle was equipped with an automatic transmission it felt like the clutch not being depressed on a manual transmission. Thankfully, the service technician was aware of this common problem and installed a new torque converter clutch solenoid.

When the original solenoid got hot, it became stuck in the applied position. Even though the voltage was removed from the solenoid when the brakes were applied, the solenoid and the torque converter clutch (TCC) remained applied. ● **SEE FIGURE 129–7.**

CHECK TECHNICAL SERVICE BULLETINS

According to studies performed by automobile manufacturers, as many as 30% of the vehicles can be repaired following the information, suggestions, or instructions concerning replacement parts found in a **technical service bulletin (TSB).** Before an accurate search of a TSB can be performed, the technician must know the following information about the vehicle under service.

- Make, model, and year of the vehicle
- Engine size and VIN
- Transmission type
- Federal, high-altitude, or California emissions
- Build date (sometimes)
- Current hard codes
- History or soft codes
- PCM/TCM part number for applicable module flash

Diagnostic trouble codes must be known before searching for TSBs because bulletins often include information on solving problems that involve a stored code.

TRANSMISSION/TRANSAXLE IDENTIFICATION

The identification of the transmission/transaxle can sometimes be a

REAL WORLD FIX

The Rough Idle Story

The owner of a Chevrolet pickup truck equipped with a V-6 engine complained of a rough idle. The idle was smooth when the transmission was in park or neutral, but became rough when the gear selector was placed in any drive gear position. The service technician could not find the cause of the problem but did notice that the engine seemed to be under a heavy load at idle speed due to the MAP sensor reading. The customer was questioned again about the possibility of a previous repair that may have had an effect on the idle. The customer said that the automatic transmission had been replaced recently but didn't think that could have an effect on the rough idle problem. A quick check of the stall speed indicated a much lower stall speed than normal—1400 RPM versus 1850 RPM normal stall speed. Obviously, either the torque converter was defective or a torque converter for a V-8 was installed in the V-6 truck. After returning to the transmission shop and getting a replacement torque converter installed, the rough idle problem was solved.

challenge. Check service information to determine the identification of the unit based on one or more of the following:

- Vehicle identification number
- Engine (transmissions can vary internally based on engine size)
- Regular production option (RPO) code
- Transmission/transaxle identification plate information
- Pan shape and/or number of bolts used on the pan

STALL TESTING THE TORQUE CONVERTER A stall test is often performed to verify the proper operation of the torque converter.

CAUTION: Some vehicle manufacturers do not recommend performing a stall test because it can be dangerous if the brakes were to fail during the test and it places stress on the engine. Always follow the manufacturer's recommended service procedures.

Performing a stall test includes the following steps.

STEP 1 Drive the vehicle until normal operating temperature is achieved.

STEP 2 Check the stall speed specifications for the vehicle being serviced and connect a tachometer to the engine.

STEP 3 With your left foot firmly applied to the brake pedal, move the shift selector in the drive position and depress the accelerator pedal to the floor. Observe the maximum engine speed. This engine speed is the stall speed.

● **SEE FIGURE 129–8.**

STEP 4 Release the accelerator as soon as possible to avoid the possibility of overheating the automatic transmission fluid. Repeat the test with the gear selector in reverse.

NOTE: Checking the stall speed in reverse is just a double check. This is done because the line pressure is higher in reverse and as a result, the higher pressure will hold clutches better and keep them from slipping. A slipping forward clutch could cause the engine speed to be higher than normal and would affect the recorded stall speed.

FIGURE 129–8 This 4-cylinder General Motors vehicle has a stall speed of about 2350 RPM. Notice that the gear selector is in drive and the speedometer is reading zero.

STEP 5 Compare results with the specifications.

- *If the engine speed is higher than specifications,* then a holding clutch or band is slipping.
- *If the engine speed is lower than specifications,* then the torque converter is defective (one-way clutch or stator is slipping) or the engine is not producing normal power output.

Both conditions can result in reduced vehicle performance and slow acceleration.

NOTE: There are many other possible causes of poor performance or sluggish acceleration besides a fault with the automatic transmission/transaxle. The stall test is just one test that can be performed to help narrow the problem to the root cause.

FLUID LEAK DIAGNOSIS

VISUAL INSPECTION To locate a leak from an automatic transmission/transaxle, the first step is to perform a thorough visual inspection. Start by checking the fluid level.

- If too high, then the fluid loss could be caused by it being overfilled and forced out of the vent opening located at the top of the unit.
- If too low, a fluid leak is the most likely cause and should be corrected as soon as possible to prevent damage, wear, or harm to the transmission/transaxle parts due to low fluid level.

Perform a visual inspection using the following steps.

STEP 1 Use a trouble light and start the visual inspection under the hood and look for signs of fluid leakage on the top of the unit. Because fluids flow downward due to gravity, the fluid will be most likely seen from underneath the vehicle; however, the source could be at or the near the top.

STEP 2 Hoist the vehicle safely and look for the highest and most forward place where fluid is seen. Due to gravity and the forward movement of the vehicle, leaking fluid will travel downward and toward the rear. ● **SEE FIGURE 129–9.**

DYE TESTING Often the exact location of a fluid leak is difficult to locate. Using a dye designed for ATF and a black light is an

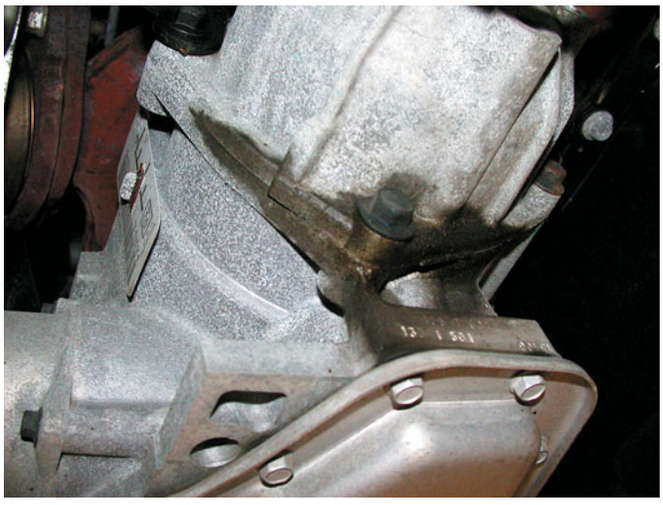

FIGURE 129–9 Sometimes the location of a transmission fluid leak is easy to see, but with others it can be difficult to find the exact location. Look closely at places where O-rings or gaskets are used, as these are the most common areas where fluid leaks occur.

FIGURE 129–10 A black light being used to locate the source of an automatic transmission fluid leak.

TECH TIP

Vibration—Engine or Transmission?

A vibration is often difficult to diagnose. One method is to separate (unbolt) the torque converter from the engine drive flex plate. Push the torque converter as far toward the transmission/transaxle as possible, then start the engine. If the vibration is gone, the problem is due to a fault in the torque converter, pump assembly, or other component that is constantly rotating with the engine running. If the vibration is still present, then the cause is due to an engine or accessory problem.

TECH TIP

Look at the Command and the Engine Speed

Using a scan tool is very helpful when diagnosing automatic transmission problems. However the display often shows when the shift has been commanded and may not show if the shift or the TCC engagement actually occurred. To help ensure that the shifts have in fact occurred, also watch the engine speed. Many factory or enhanced scan tools can also display the engagement speed. A slow engagement is usually caused by worn clutches. Check service information for the exact parameters and range of proper operation for the vehicle being diagnosed.

effective method to locate ATF leaks. To check for leaks using a dye, perform the following steps.

STEP 1 Add a small bottle of dye that is designed for use in ATF into the dipstick tube using a transmission funnel.

CAUTION: Do not use dye designed for use in coolant or air-conditioning systems or severe harm can occur to the automatic transmission/transaxle.

STEP 2 Drive the vehicle until the fluid has reached normal operating temperature.

STEP 3 Safely hoist the vehicle.

STEP 4 Using a black light, look for the highest and most forward place where a greenish stain appears. This is the source of the leak.

SEE FIGURE 129–10.

TORQUE CONVERTER CLUTCH DIAGNOSIS

The torque converter clutch is usually applied above 30 MPH (48 km/h) when the automatic transmission/transaxle is in second, third, or overdrive gear, depending on the vehicle speed and the throttle position. It is often difficult to distinguish between a normal shift and the application of the torque converter clutch. The torque converter clutch (TCC) may not even be applying due to a fault in the computer sensors, wiring, or the TCC solenoid.

NOTE: If the torque converter clutch does not apply, a drop in fuel economy of 3 to 4 miles per gallon is commonly reported. If the TCC fails to apply on an automatic transmission/transaxle, the automatic transmission fluid is likely to become overheated due to the torque converter slip. The higher fluid temperature can cause the automatic transmission/transaxle to fail.

To test for proper operation of the torque converter clutch, simply drive the vehicle and watch either the tachometer on the dash or connect a scan tool to observe the engine RPM.

STEP 1 Drive the vehicle until the engine has reached normal operating temperature.

STEP 2 Drive the vehicle on a flat, level road away from any traffic about 50 MPH (80 km/h).

STEP 3 While maintaining constant speed with your right foot on the accelerator, gently apply the brake pedal with your left foot to open the electrical circuit for the torque converter clutch through the brake switch. The TCC will disengage and the RPM should increase about 150 to 250 RPM and then drop back when the brake pedal is released. This RPM change is evidence that the TCC is, in fact, working. If the torque converter clutch is not operating, consult the factory information for the exact procedures to follow.

RANGE	GEAR	2-4 BAND	REVERSE INPUT CLUTCH	OVERRUN CLUTCH	FORWARD CLUTCH	FORWARD SPRAG CL. ASSEMBLY	3-4 CLUTCH	LO-ROLLER CLUTCH	LO-REV. CLUTCH
Park-Neutral

	Second Gear	Applied		Applied		Holding			
Manual 1St	First Gear			Applied		Holding		Holding	Applied
Reverse	Reverse		Applied						Applied

CHART 129–3

This typical range chart shows the forward clutch is applied in all forward gears. Notice that if the low-reverse clutch were to fail, it would prevent the vehicle from moving in both reverse and forward.

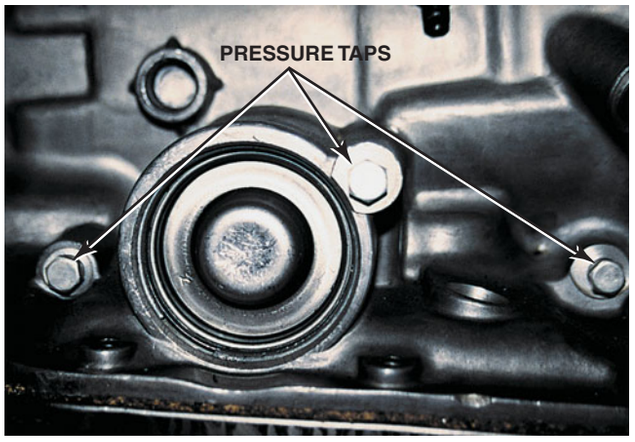

FIGURE 129–11 The locations (taps) for connecting a pressure gauge to measure the pressure of the various hydraulic circuits are usually found on the side of the automatic transmission/transaxle. Check service information for the exact locations for the vehicle being tested.

GEAR SELECTION	IDLE (PSI)	WIDE OPEN THROTTLE (WOT) (PSI)
Park (P)	54–60	54–60
Reverse (R)	100–105	250–300
Neutral (N)	54–60	54–60
Drive (D)	54–87	240–250
Low (L)	84–87	240–250

CHART 129–4

A pressure chart for the Ford 6F50N/GM 6T70 transaxle.

NOTE: If the temperature of the automatic transmission fluid (ATF) is too high, the computer will modify the shift pattern (usually disabling overdrive) and engage the TCC at slower speeds in an attempt to drop the temperature of the ATF to less harmful temperatures. Also if the temperature is too low, the PCM may not allow lockup and may limit the number of forward gears available until the transmission fluid warms up. This computer control of the shifting may be noticeable to the driver as a fault.

RANGE CHARTS

All vehicle manufacturers publish range charts that indicate which holding device is used for each gear selection. Knowing which component is being used for each gear helps the service technician determine the cause of a failure or problem. ● **SEE CHART 129–3.**

PRESSURE TESTING

Pressure testing involves connecting a pressure gauge to pressure taps located on the outside of the automatic transmission/transaxle. ● **SEE FIGURE 129–11.**

After connecting the pressure gauge(s) to the transmission/transaxle, start the engine and select the gear being monitored. Check service information for the specified pressures.

● **SEE CHART 129–4** for a typical pressure chart.

If the pressure is not within specifications, then the technician knows that the fault is internal and usually involves either removing the valve body, or in many cases, removing the automatic transmission/transaxle from the vehicle. ● **SEE FIGURE 129–12.**

TRANSDUCERS

Pressure switches are used to verify that solenoids and/or valves have done their job. They do not read actual pressure as they are usually controlled by a spring rated at a certain number of pounds. A transducer-equipped vehicle will usually provide an actual pressure reading on a scan tool. Many vehicles with variable line pressure will have a transducer.

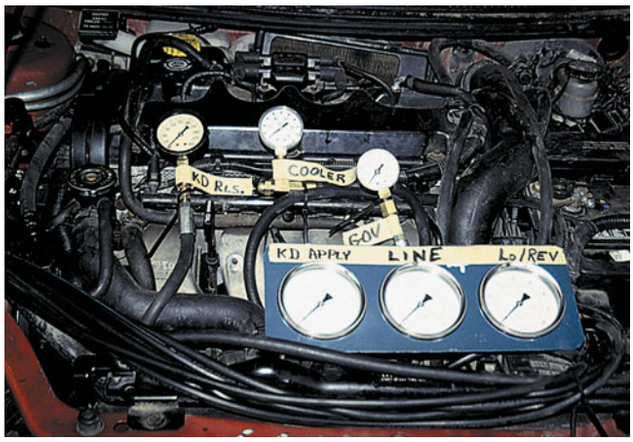

FIGURE 129–12 Six pressure gauges are installed on this vehicle to show students how the pressures vary and how the gauges can be used to find faults or possible problem areas before the unit is removed and disassembled.

FIGURE 129–13 Draining the fluid from an automatic transaxle by allowing the fluid to flow into a container after most of the retaining bolts have been removed.

REAL WORLD FIX

The Customized Van Story

The owner of a customized General Motors van equipped with an electronically controlled automatic transmission (4L80-E) complained that the automatic transmission downshifted into second gear and stayed in second gear whenever the headlights were turned on. The transmission shifted okay when the headlights were turned off. After hours of troubleshooting, including the replacement of the vehicle computer (which did not help), the technician discovered that 4 volts DC were on the one wire leading from the vehicle speed (VS) sensor to the vehicle computer whenever the headlights were turned on. Obviously, there was a short to voltage between a light wire and the sensor wire. Instead of totally disassembling the van, the technician decided to replace the wire with a new one, and the problem was solved. The 4 volts DC apparently shut down the computer. When the computer stopped controlling the shifts, both A and B solenoids were shut off. With both solenoids A and B off, the transmission was in second gear. This is the default gear or the limp-in-mode gear for this transmission. After replacing the wire, the automatic transmission returned to manual operation, allowing the driver to drive at night and in the daytime.

FREQUENTLY ASKED QUESTION

What Is Wrong When My Automatic Transmission Does Not Upshift?

The following examples can cause the automatic transmission/transaxle to fail to upshift.

- A *defective governor* (if so equipped) will often not allow any automatic transmission/transaxle to shift out of first gear or stuck in high gear.
- A *defective vacuum modulator* (if so equipped) or misadjusted *throttle valve* will often delay the shift until a very high speed is achieved.
- A *fault in the PCM, TCM, or a speed sensor* on electronically controlled automatic transmissions/transaxles will occur when one gear, usually second or third, is selected and the unit will not shift out of that gear.

IN-VEHICLE SERVICE

PAN REMOVAL Check service information for the exact procedure to follow when removing the pan. Some transaxles are equipped with a side pan that either may nor may not be needed to be removed when serving the assembly. The usual procedure includes the following steps.

STEP 1 Hoist the vehicle safely.

STEP 2 Place a large drain pan under the transmission/transaxle pan.

STEP 3 Loosen all of the fasteners except for those at one end. Allow the pan to drop down slightly at one end allowing fluid to drain into the drain pan.

● **SEE FIGURE 129–13.**

STEP 4 After the fluid has stopped flowing from the pan, carefully remove the last retaining bolts, slowly lower the pan, and allow any remaining fluid to flow into the drain pan.

STEP 5 Dispose of or recycle the used automatic transmission fluid according to state or local laws.

STEP 6 Remove all of the oil pan bolts except for two at one end. This will allow the pan to drop and empty most of the ATF into the drain container without falling. After most of the ATF has drained, remove the remaining bolts and remove the pan.

STEP 7 Inspect the inside of the pan for excessive friction material and wear metals (such as lead and copper from bushings). Use a magnet to check for steel particles, which would indicate serious wear to major components. ● **SEE FIGURE 129–14.**

FIGURE 129–14 This is a normal amount of wear material in the bottom of an automatic transmission pan.

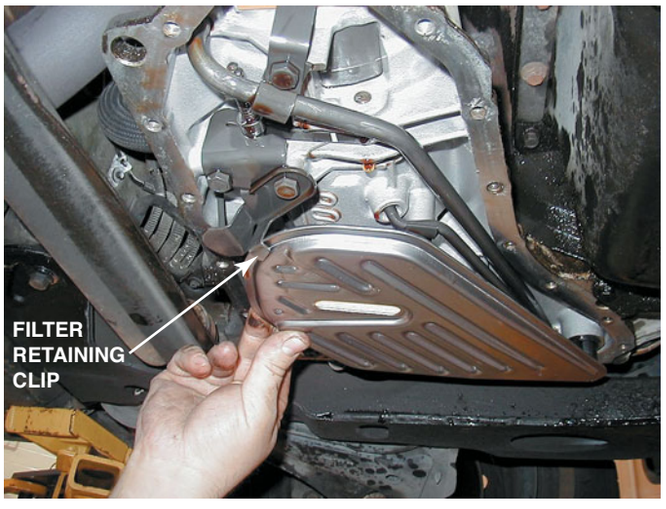

FIGURE 129–15 Always check that the filter is secured by a clip or other fastener to keep it from dropping out of location.

NOTE: The presence of metal particles in the pan of an automatic transmission/transaxle does not necessarily mean that a part(s) has failed or needs to be replaced. Some wear is normal. If there are a lot of metallic particles in the pan, then this may be an indication of severe gear failure that may require replacement. Use a magnet to check for steel particles. Ask the advice of an experienced transmission expert, if in doubt, about whether the wear should be considered "normal."

WARNING

The automatic transmission fluid may be hot enough to cause personal injury. Wear protective clothing and avoid contact with the hot fluid.

FILTER REPLACEMENT

Check service information for the exact procedure to follow when replacing the filter. Most are retained by a clip or a bolt. ● **SEE FIGURE 129–15.**

CAUTION: Extra or missing O-rings on filter necks and/or cracked or mispositioned filter filler necks cause many problems. The pump may intermittently ingest air, leading to transmission or driveability complaints such as rough idle or an engine stalling condition.

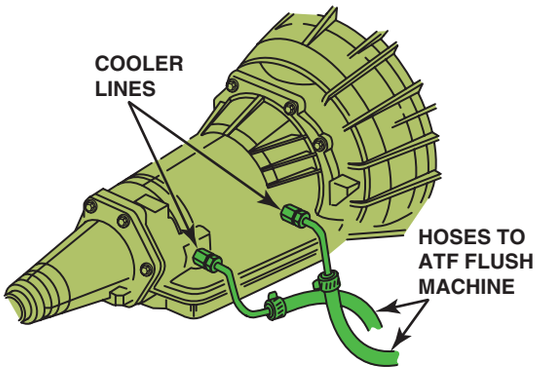

FIGURE 129–16 A fluid exchange machine uses the engine and the transmission pump to force the fluid into the machine where the old fluid is used to push against a diaphragm, which then forces new fluid back through the transmission. A sight glass is used to show the technician the fluid, so the process can be stopped when only clean, new fluid is seen flowing through the cooler line.

FIGURE 129–17 In this case, the cork-rubber gasket is glued to the pan and is ready to be installed. The retaining bolts need to be tightened in sequence, but be aware that overtightening will cause a leak. Also, some manufacturers recommend using only an RTV sealer, but never use an RTV sealer and a gasket together.

FLUSHING ATF

The following are ways to flush automatic transmission fluid.

1. Connect the cooler lines to a machine that exchanges the old fluid with new fluid. ● **SEE FIGURE 129–16.**
2. Use a machine to draw out the old fluid though the filler tube and then refill it with clean fluid.
3. Use a machine that attaches to the pump inlet after the pan and filter have been removed. The machine uses its own pump to force all of the old fluid from the transmission or transaxle.
4. Drain and refill. Using this method, recommended by Honda and Acura, means that about 3 quarts are being replaced. The vehicle should be driven and the drain and refill formed another two times.

Most experts recommend that the filter be replaced, so the pan should be removed (except for Honda and Acura) and the filter replaced after any of the above methods are used. ● **SEE FIGURE 129–17.**

FREQUENTLY ASKED QUESTION

How Is a Vacuum Modulator Tested?

A vacuum modulator is used on many hydraulically controlled automatic transmissions/transaxles. Most vacuum modulators affect shift points, so if shift timing is delayed on most units that have a vacuum modulator, then it should be tested. Higher engine loads (lower vacuum to the vacuum modulator) result in a firmer shift occurring later than normal; and at light engine loads, the shift is softened and will occur earlier.

To check for proper operation of the vacuum modulator, follow these steps:

STEP 1 Hoist the vehicle safely and locate the vacuum modulator (if equipped).

STEP 2 Remove the vacuum hose from the vacuum modulator. If automatic transmission fluid drips out when the hose is removed, the vacuum modulator is defective and must be replaced.

STEP 3 Use a hand-operated vacuum pump to apply vacuum to the vacuum modulator. If the modulator is okay, the vacuum reading will hold steady and not drop. If the vacuum modulator will not hold vacuum, the modulator should be replaced.

STEP 4 Connect a vacuum gauge to the vacuum line from the intake manifold and have an assistant start the engine. The vacuum reading at the vacuum modulator should be 17 to 21 in. Hg with a minimum vacuum reading of 15 in. Hg to assure proper shifting of the automatic transmission/transaxle.

NOTE: A defective vacuum modulator can cause automatic transmission fluid (ATF) to be drawn by engine vacuum into the intake manifold. When ATF burns, it produces white smoke. The white smoke is often confused with steam. Therefore, the smart technician should check if the vehicle is equipped with a properly functioning vacuum modulator before continuing the diagnosis for steam coming from the tailpipe.

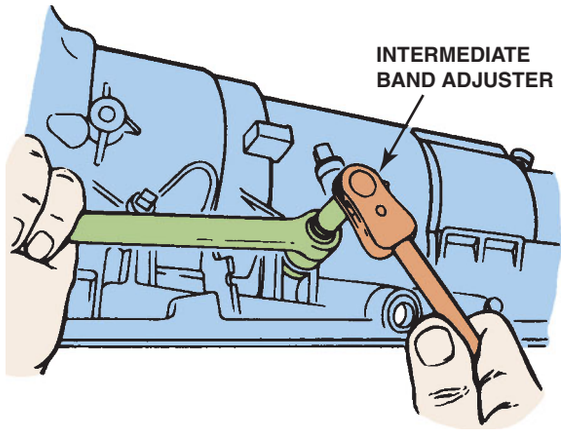

FIGURE 129–18 Adjusting the intermediate band on a Ford A4LD transmission.

BAND ADJUSTMENT Some automatic transmissions/transaxles allow the technician to adjust the clearance between the band and the drum inside the unit. The procedure usually involves tightening the adjustment nut or bolts to a specified torque reading and then backing off the adjustment nut or bolts a specified number of times. Some bands are adjustable external to the transmission and others require dropping the pan. ● **SEE FIGURE 129–18.**

TECH TIP

Use Old Headlights to Check Wiring

The proper operation of any electronically controlled automatic transmission/transaxle depends on having electrical power available to operate the solenoids. Before removing the unit from the vehicle, use a headlight to check if there is enough current being sent to the unit. Unplug the electrical connection that supplies 12 volts, usually from the ignition switch. Use a headlight and attach wires to the ground and the bright filament terminals.

Attach one test lead from a headlight to the terminal that supplies 12 volts to the unit. Attach the other lead from the headlight to a good clean chassis or transmission ground such as the case. Turn ignition key on, engine off (KOEO) and observe the headlight.

- If the headlight is dim, there is a voltage drop between the source (battery) and the transmission feed. Check the wires directly leaving the ignition switch or transmission control relay. If the headlight is still dim, replace the ignition switch or transmission feed relay. ● **SEE FIGURE 129–19.**
- If the headlight is off, then there is an open circuit between the battery and the transmission/transaxle. Follow electrical troubleshooting procedures to find and repair the open circuit.
- If the headlight is bright, there is enough voltage and current being supplied to the transmission/transaxle to correctly operate all of the solenoids. ● **SEE FIGURE 129–20.**

FIGURE 129–19 A dim headlight indicates excessive resistance between the battery and the electrical connector to the automatic transmission/transaxle.

FIGURE 129–20 A bright headlight indicates that there should be sufficient current flow available at the automatic transmission/transaxle to operate all the solenoids correctly.

Some bands are adjusted using selective length push rods and some bands are not adjustable at all. The band(s) should be adjusted whenever the fluid is changed or when recommended by the vehicle manufacturer.

LINKAGE ADJUSTMENT The linkage between the shift selector and the automatic transmission should be checked for proper adjustment whenever there is a transmission-related problem. The linkage may need to be adjusted to compensate for worn linkage components. Before adjusting the linkage, check the engine and transmission/transaxle mounts carefully, because a defective mount is a common reason for needing a linkage adjustment.

REVIEW QUESTIONS

1. What tests can be performed on an automatic transmission/transaxle to determine any faults while the unit is still in the vehicle?
2. How does a defective torque converter clutch solenoid cause the vehicle to stall when the vehicle is slowing to a stop?
3. How does automatic transmission fluid reach the intake manifold of the engine and be burned in the engine?
4. How do you perform a test of the mainline and other pressures of an automatic transmission/transaxle?

CHAPTER QUIZ

1. Technician A says that the apply and hold units are usually the same as for first gear when the gear selector is in manual first. Technician B says that a defective vacuum modulator could cause the automatic transmission to delay shifting until a higher-than-normal speed is achieved. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
2. Two technicians are discussing what could be wrong with a hydraulically controlled automatic transmission/transaxle that does not shift out of first gear regardless of vehicle speed. Technician A says that a defective governor could be the cause. Technician B says that a weak pump could be the cause. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
3. Two technicians are discussing an automatic transmission that will not go into any forward gear or reverse. Technician A says that a defective PCM or TCM could be the cause. Technician B says that a defective or worn pump could be the cause. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
4. A General Motors vehicle is being tested using a scan tool. The input speed and the output speed sensor read the same when at highway speed. Technician A says that the transmission/transaxle is in a gear where the ratio is 1:1. Technician B says that the torque converter clutch must be defective and not working. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
5. An electronically controlled overdrive automatic transmission is equipped with a transmission fluid temperature sensor. Technician A says that the shifts may be changed if the fluid temperature is too high. Technician B says that overdrive may be disabled if the transmission fluid temperature is too high. Which technician is correct?
   a. Technician A only **c.** Both Technicians A and B
   b. Technician B only **d.** Neither Technician A nor B
6. A scan tool can be used to _____.
   a. Check for stored diagnostic trouble codes
   b. Command a shift
   c. Check for transmission-related sensor information
   d. All of the above
7. Fluid exchange can be performed using _____.
   a. Drain and refill three times
   b. A machine that replaces the ATF through the cooler lines
   c. A machine that forces the old fluid out, using a pump inside the machine that is attached to the fluid inlet after removing the transmission pan and filter
   d. All of the above
8. Caution should be used when performing a stall test because _____.
   a. It could increase the temperature of the ATF
   b. It could be hazardous if the brakes fail
   c. It puts a strain on the engine
   d. All of the above

9. An electronically controlled automatic transmission operates okay in reverse, but the vehicle does not shift at all when moving forward. Technician A says that a defective torque converter is the likely cause. Technician B says that a defective shift solenoid could be the cause. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

10. Two technicians are discussing inspection of the transmission pan. Technician A says that some friction material at the bottom of the pan is normal. Technician B says that if any metal parts stick to a magnet then further investigation is needed to determine the cause. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

chapter 130 AUTOMATIC TRANSMISSION/ TRANSAXLE UNIT REPAIR

OBJECTIVES: **After studying Chapter 130, the reader will be able to:** • Explain how to identify the transmission/transaxle. • Discuss how to disassemble an automatic transmission/transaxle. • Describe what repairs can be done with the transaxle in the vehicle. • Explain how to properly install and check clutch packs. • Describe how to flush the cooler. • Explain how to properly reassemble an automatic transmission/transaxle. • List the steps necessary to follow when removing an automatic transmission/transaxle assembly. • Describe how to properly remove and install an aluminum pump in an automatic transmission/transaxle. • Discuss how to assemble an automatic transmission/transaxle. • Explain how to flush an automatic transmission fluid cooler. • Describe how to install an automatic transmission into a vehicle.

KEY TERMS: Air pressure check 1604 • Holding fixture 1600 • Tag number 1599

VERIFY THE NEED FOR UNIT REPAIR

VERIFY THE FAULT It is not unusual for a transmission or transaxle to be removed from the vehicle when the fault could have been repaired with the unit still in the vehicle. Or the fault could be due to an electrical or engine-related fault outside the transmission/transaxle. Check with all of the following to be sure that the unit needs to be removed from the vehicle.

- A knowledgeable technician
- The archives at www.iatn.net
- A hotline service provider, such as Identifix (www.identifix.com)

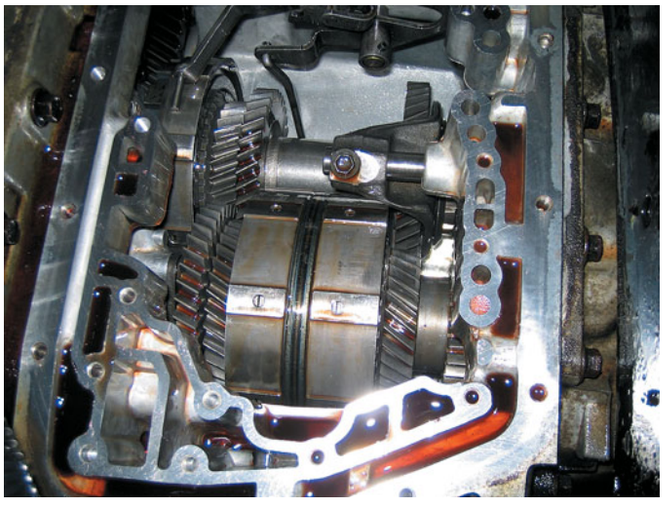
Use these resources to verify that the fault is inside, not outside, the unit.

IN-VEHICLE REPAIRS Not all mechanical faults require that the automatic transmission/transaxle be removed from the vehicle. Faults that can usually be repaired with the unit still in the vehicle include any valve-body-related concerns.

● **SEE FIGURE 130–1.**

Depending on the transmission/transaxle, it may be possible to disassemble and repair many mechanical components of the unit while it remains in the vehicle. Parts and components that may be replaced with the transmission/transaxle still in the vehicle include:

- Pressure switches
- Transmission range switch
- Turbine and output speed sensors
- Extension housing gasket
- Drive axle seals
- Valve body replacement



Check service information for details on what can be replaced with the unit in the vehicle.

IDENTIFY THE UNIT Before removing the transmission/transaxle for replacement or repair, be sure that the unit is properly identified. This identification is critical because of the following:

1. The final drive ratio in transaxles can vary depending on the application; and using the wrong unit can cause shifting and other issues such as gear ratio–related diagnostic trouble codes.
2. The internal gear ratios can vary depending on exact application of the unit.

(a)

(b)

(c)

FIGURE 130–1 (a) This Saturn did not shift correctly and one technician was ready to replace the unit; however, another technician thought that the problem could be due to a fault in the valve body. (b) Removing the valve body shows the nonplanetary gears used in the Saturn automatic transaxle. (c) The valve body was disassembled and a broken pressure regulator spring was found to be the cause of the customer concern.

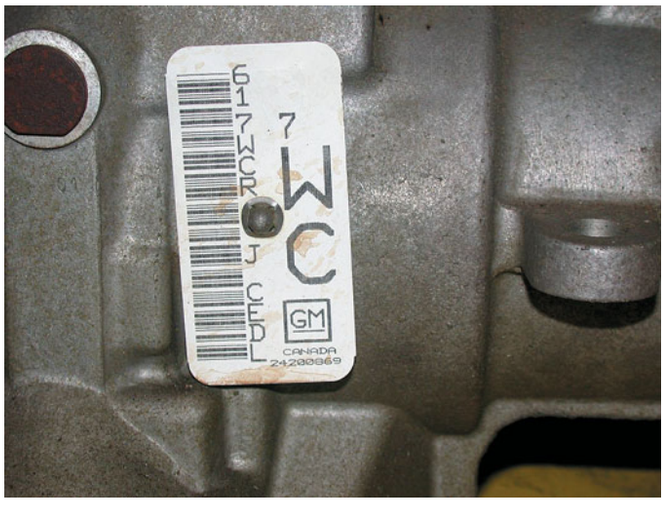


FIGURE 130–2 A transmission identification number on the side of the unit. The information on this tag is needed when ordering parts, as there are often several versions of the same transmission used in similar vehicles and the differences could affect the parts needed.

3. Sometimes the vehicle identification number (VIN) is needed to obtain the correct parts, but more often the transmission/transaxle identification number, also called the **tag number,** is the identification needed to be assured of ordering and receiving the proper parts.

   ● **SEE FIGURE 130–2.**

REMOVING THE AUTOMATIC TRANSMISSION/TRANSAXLE FOR SERVICE

STEPS INVOLVED Removing an automatic transmission/transaxle from a vehicle includes many steps to avoid doing damage to the vehicle or personal harm. Always follow the vehicle manufacturer's recommended procedures. Most procedures include the following steps.

STEP 1 Disconnect the negative (−) battery cable from the battery. This prevents the possibility of an accidental short circuit that could damage the vehicle or cause a spark that could start a fire.

STEP 2 Hoist the vehicle safely and drain the fluid from the unit.

STEP 3 Disconnect the driveshaft or drive axle shafts.

STEP 4 Disconnect all cooler lines, linkage, and electrical connections. Be sure to label each to ensure proper reinstallation. Also be sure to label all electrical connectors so that they can be reinstalled in the proper location.

STEP 5 Disconnect the torque converter from the flex (drive) plate of the engine.

STEP 6 Support the engine before disconnecting the automatic transmission/transaxle. ● **SEE FIGURE 130–3.**

STEP 7 Remove the transmission/transaxle mounting fasteners.

FIGURE 130–3 A chain and holding fixture being used on this front-wheel-drive vehicle to support the engine when the transaxle is removed.

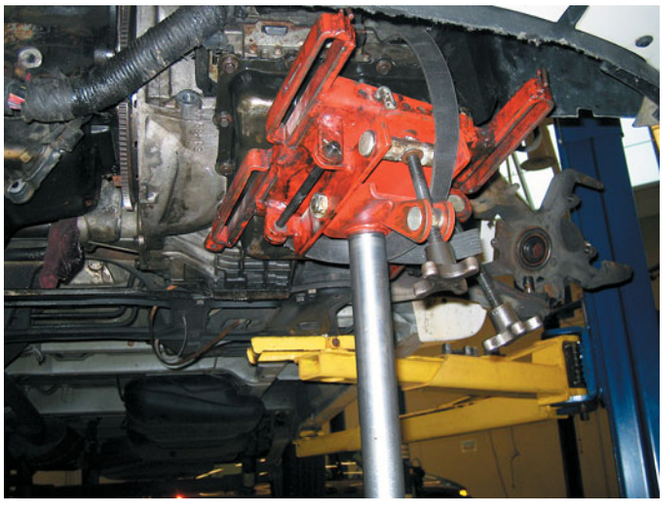

FIGURE 130–4 A transaxle being supported by a transmission jack prior to removal of the unit from underneath the vehicle.

STEP 8 Support the transmission/transaxle on a jack and remove the attaching bolts at the bell housing of the engine. ● **SEE FIGURE 130–4.**

STEP 9 Remove the transmission/transaxle from the vehicle.

AUTOMATIC TRANSMISSION/ TRANSAXLE DISASSEMBLY

MOUNT TO HOLDING FIXTURE For best results, the automatic transmission/transaxle should be attached to a **holding fixture** that allows the unit to be rotated yet properly supported during disassembly and reassembly. ● **SEE FIGURE 130–5.**

TORQUE CONVERTER CHECKS Remove the torque converter and drain the fluid by tipping it so the fluid runs out into a suitable container. Check the torque converter for the following:

- Visually check for wetness that could indicate a leak such as at the welded seam.
- Check for damage to the pump drive tags.

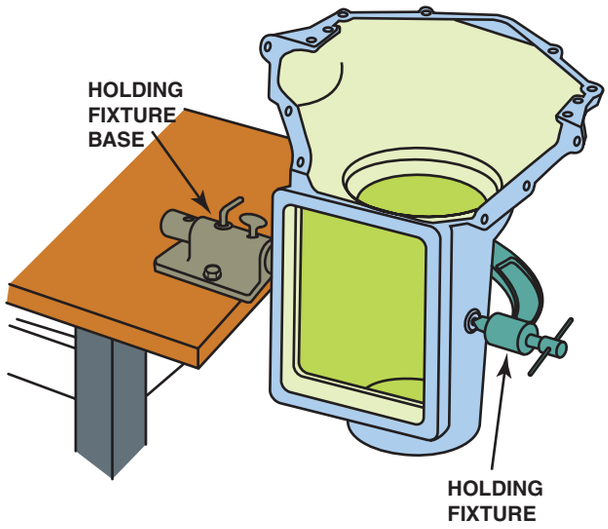

FIGURE 130–5 A holding fixture makes working on a transmission easier.

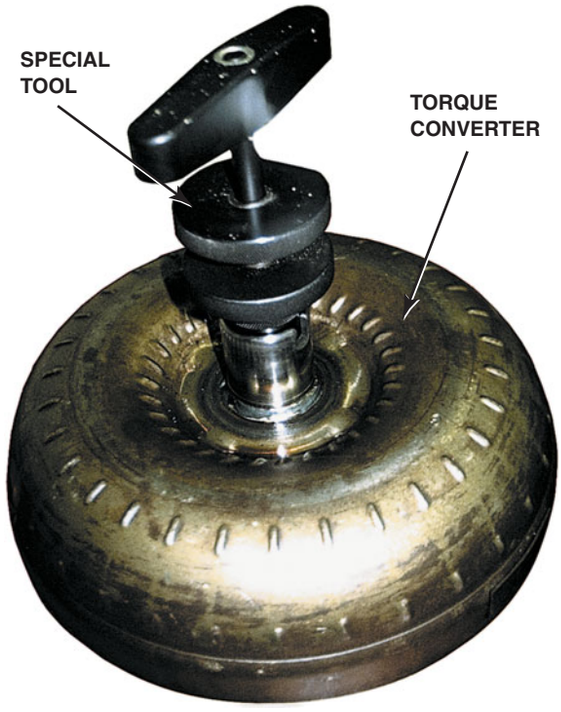

FIGURE 130–6 A special tool being used to check the end play of the stator inside the torque converter.

TECH TIP

Check the Flex Plate

After removing the transmission or transaxle, carefully inspect the flexplate for the following faults.

1. Cracks
2. Warpage
3. Stripped starter ring gear teeth

- Inspect the hub for seal and wear.
- Check that the one-way clutch of the stator is working.
- Check for end play of the stator. ● **SEE FIGURE 130–6.**

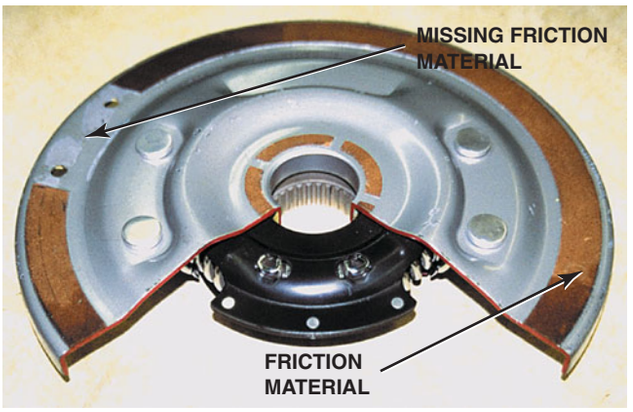

FIGURE 130–7 A cutaway of the torque converter clutch showing the paper-thin friction material.

FIGURE 130–8 A typical separator plate. Check holes over check balls to make sure that the metal balls have not caused damage to the separator plate during operation.

TECH TIP

Replace the Torque Converter

Many automotive transmission/transaxle experts recommend that the torque converter be replaced when the automatic transmission is rebuilt or replaced. This is because the torque converter is generally considered to be the "garbage pit" of the entire unit in that it often collects wear particles from the clutches and bands that can cause future problems. According to remanufacturers of torque converters, the majority of the torque converters being returned as cores have little, if any, friction material remaining for the torque converter clutch. ● **SEE FIGURE 130–7.**

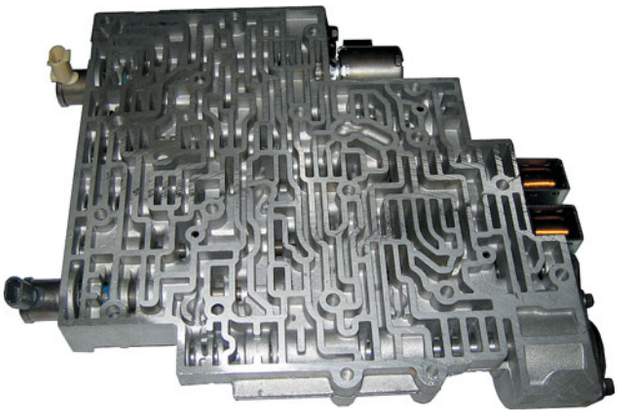

FIGURE 130–9 Check that all valves are free to move, and look for signs that the valves have caused wear to the valve bore. This causes fluid to leak around the valves, which can also cause shifting problems. If the bore is found to be worn, then the valve body will require repair using specialized tools or replacement.

TECH TIP

The Valve Body Cardboard Trick

To help remember where each bolt goes in the valve body, draw an outline of the valve body on cardboard and then stick the bolts through the cardboard in the position where they were removed. Often the lengths of the bolts are different, so this method saves time and helps prevent possible harm to the valve body of the case of the transmission/transaxle when reassembling the unit.

VALVE BODY Remove the valve body and the internal electronic components found in many units. Before the valve body fasteners are removed, the following items need to be performed or checked.

1. Disconnect the manual valve linkage and "rooster comb."
2. Carefully loosen the valve body bolts starting from the outside and working toward the center or help prevent distortion.
3. Remove the lower part of the valve body.
4. Remove the separator plate. ● **SEE FIGURE 130–8.**
5. Check and note the location of all check balls in the upper valve body.
6. Carefully check the operation of all shift valves by using a plastic tool or compressed air to move the valves in their bores. All valves should be free to move and should return to the home position by spring pressure.

● **SEE FIGURE 130–9.**

To service a valve body, disassemble all the parts, identify them for reassembly, and check the valve body with a precision straightedge.

PUMP ASSEMBLY Remove the pump assembly using the proper removal tool to avoid damaging it. ● **SEE FIGURES 130–10 AND 130–11.**

Check the pump for wear by checking service information for the recommended procedure and specifications. ● **SEE FIGURE 130–12.**

UNIT DISASSEMBLY Before disassembly, measure input shaft end play. Some transmissions require the measurement of output shaft end play. Always check service information for the specified procedures to follow.

The usual disassembly procedure includes:

1. Removal of snap rings
2. Compressing of clutch pistons most often using special tools

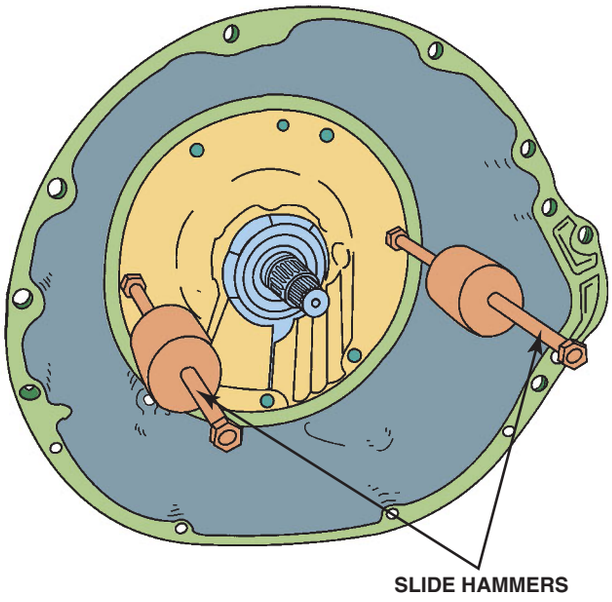

FIGURE 130–10 Two slide hammers are often used to remove a pump from older automatic transmissions.

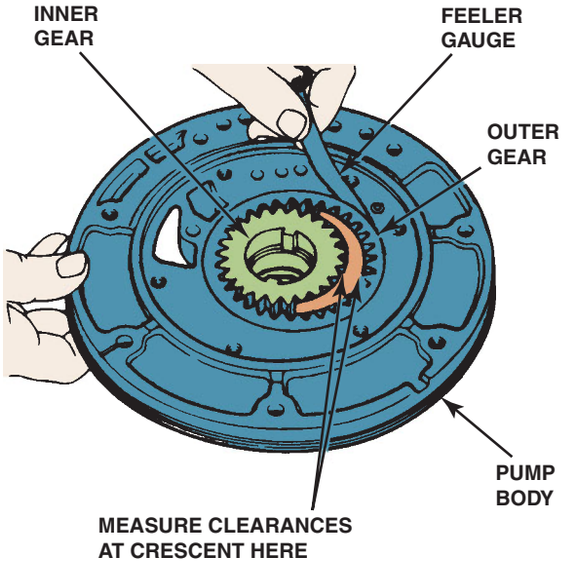

FIGURE 130–12 Checking a transmission pump assembly for wear using a feeler gauge. Compare the reading to factory specifications.

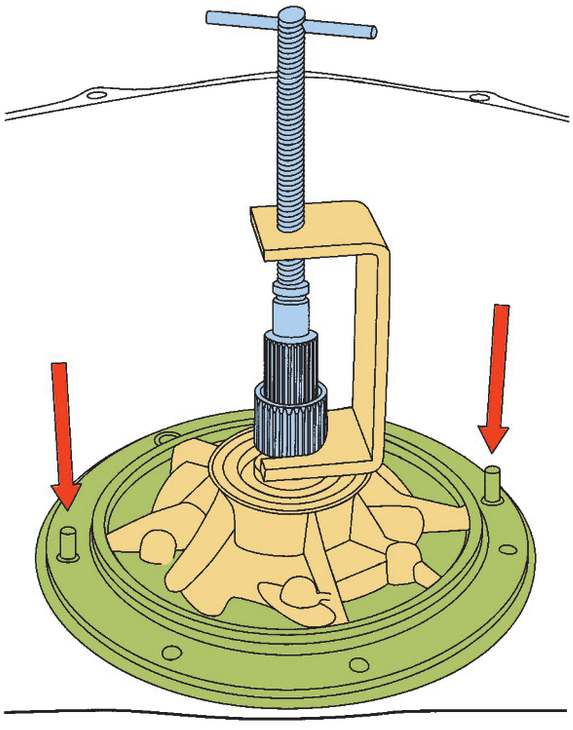

FIGURE 130–11 A special puller is usually specified to remove aluminum pumps from automatic transmission/transaxles. Alignment pins (arrows) are used to properly align the gasket and pump on the case during reassembly.

3. Removal of bands (if equipped)
4. Removal of solenoids
5. Disconnecting and labeling of all interior wiring

Note the condition of all of the following so that any parts needed can be ordered.

- One-way clutches
- Clutches and bands (if used)
- Accumulators and springs

TECH TIP

A Picture Is Worth a Thousand Words

During disassembly, note items such as direction of snap rings front and back and clock position of the snap ring openings. Instead of taking numerous detailed notes, use a digital or phone camera and take pictures as the unit is being disassembled. Then the photos can be reviewed during reassembly to be sure that everything is installed in the same position as it was when it was disassembled.

- Trust washers
- Snap rings
- Servos and springs
- Planetary gear sets
- Final drive assembly on transaxles
- Shift and pressure control solenoids

Save the old gaskets to match with the new ones. Clean all parts in a solvent that removes all gum, varnish, dirt, and grease. Rinse clean parts in hot, running water, and then immerse them in clean mineral spirits or a similar solvent to separate water from the parts. Finish cleaning by blow drying with low-pressure, filtered, compressed air. Once clean, inspect the valve body and its components for the following:

- Scored, cracked, or burred plugs and valves
- Broken, bent, or worn springs
- Scored or rusted bores
- Plugged or restricted fluid passages
- Bent or rusted separator plates
- Stuck check valves
- Bent manual valves
- Cracked castings and distorted or nicked mating surfaces.

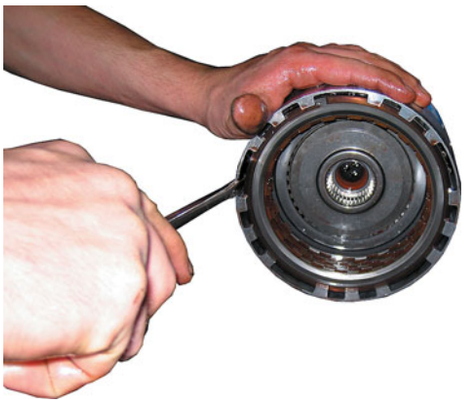

FIGURE 130–13 A straight-blade screwdriver can help remove the snap ring that is used to retain the frictions and steels in the clutch pack.

Shiny areas on valve lands indicate friction between the spool valve and body. On steel valves, these areas can be polished carefully with 400- to 600-grit wet or dry sandpaper, crocus cloth, or polishing stone. Take care not to round off the edges of the valve lands while polishing. Aluminum valves cannot be polished. If a valve needs polishing, the bore it rides in also requires servicing. Polish the valve bore by inserting and turning loosely rolled wet or dry sandpaper or crocus cloth. Attach a piece of crocus cloth to a slotted dowel rod or bent welding rod to reach the bottom of a deep bore. Rewash and dry any valves and bores that are polished.

After polishing and washing, lubricate the spool valve with ATF and slide it into its bore to check fit and operation. The valve should slide back and forth freely of its own weight.

CAUTION: Do not use cloth shop cloth as lint can cause a sticking shift valve.

CLUTCH PACKS Begin disassembling a clutch pack by removing the snap ring that holds the discs in the housing. Remove the snap ring from most clutches by prying one end of it free from its groove with a small screwdriver. Then, slide the screwdriver around the drum and the snap ring removes easily. ● **SEE FIGURE 130–13.**

FRICTION DISC INSPECTION Wipe each friction disc with a dry, lint-free cloth and inspect for the following:

- Excessive wear
- Cracks in the lining material
- Charred, burned, or glazed lining surface
- Pitting, flaking, or scoring
- Chips or particles embedded in the lining
- Scoring or burns on disc serrations
- Distortion and/or warping

Friction discs tend to discolor in use, which is normal. However, if any friction disc shows signs of one or more of the defects above, replace the entire set. Replace the set of friction discs if they do not fit freely in the clutch hub serrations (grooves) or if there is wear or damage to their splines.

STEEL DISC INSPECTION Clean steel discs by wiping with a dry, lint-free cloth and, once clean, inspect each disc for the following:

- Uneven heat discoloration
- Surface scuffing or scoring
- Drive lug damage
- Distortion and/or warping

Replace the entire set of steels if you note a rough surface or there is uneven or spotty discoloration on any of the discs. Also replace steel discs if they do not fit freely into the clutch drum tang notches.

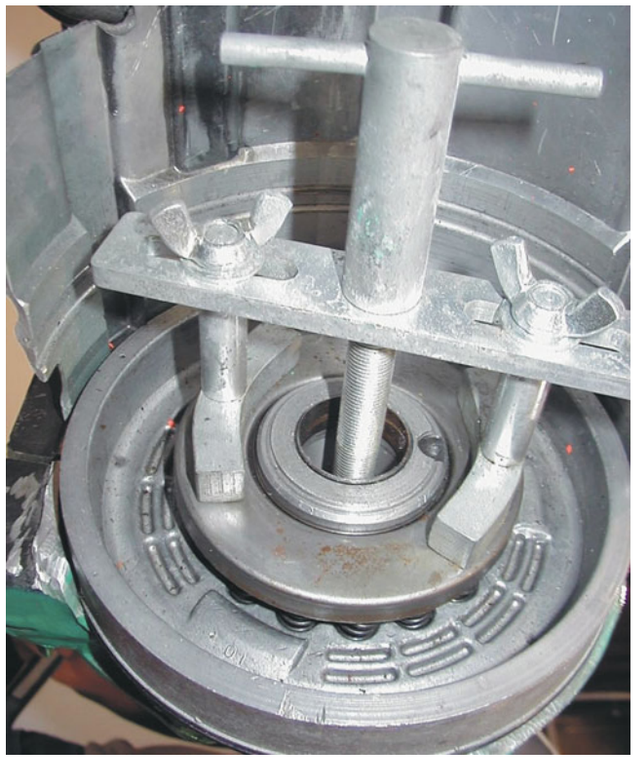

FIGURE 130–14 A compressor tool is usually necessary to compress the springs of the clutch piston to remove the snap ring.

TECH TIP

Smooth Is In; Rough Is Out

It used to be common practice in the automatic transmission business for the rebuilder to use sandpaper to "roughen up" the surface of the steel discs to achieve a good clutch apply. This is not true now. Sanding creates grooves and sharp peaks that decrease the oil film between the paper on the friction plate and the steel plates. There should be a thin oil film between the paper and the steel to create a holding bond and make it possible for a clutch pack to apply and release thousands of times without wear. Therefore, for consistent shifts and a long-lasting transmission/transaxle, do not sand the steel discs. Steels are often replaced with new steels along with new friction discs during an overhaul.

CLUTCH PISTON REMOVAL AND INSPECTION To remove the snap ring holding the clutch piston in place, compress the piston return springs using the proper compressor tool. Always check service information for proper procedure. ● **SEE FIGURE 130–14.**

Tightening a nut onto the shaft draws the fingers of the tool down, compressing the spring, and allowing the snap ring to be removed. After removing the snap ring, release and remove the spring compressor, then remove and inspect the return springs.

RETURN SPRING INSPECTION Coil springs should be straight and provide proper pressure. Check for broken, distorted, or collapsed springs. If one or more of the springs requires replacement, discard them all and install a complete set of new springs.

NOTE: Individual return springs are often colored coded as to their location. Make note of the color and number of return springs for ease of reassembly.

Some coil springs are permanently attached to their retaining collar and can only be serviced as a set. There will be vacant spring seats in some applications. This allows the manufacturer to use the same piston but vary the number and location of springs to precisely match spring return rate to the requirements of a particular vehicle. In these cases, reinstall return springs in exactly the same location.

CLUTCH PISTON INSPECTION Remove the clutch piston from the hub. The drag of the piston seal can make it hard to remove the piston from its bore. Should this be the case, apply low-pressure compressed air through the hydraulic apply hole in the housing to force the piston from its bore.

CAUTION: Always use care when using compressed air, as it can be very dangerous. Use regulated air pressures set to a maximum 35 PSI (240 kPa) and a rubber-tipped nozzle. Always wear safety glasses when checking valves and actuators using compressed air.

Do not use high air pressure and be careful to avoid pinching your hand or dropping the piston as it pops from its bore. Once you remove the piston, check for the following:

- Cracks or scoring in the piston bore
- Nicks, scores, burrs, or signs of wear on the piston
- Seal damage
- Fluid passage obstructions or restrictions

If the piston contains a check valve, make sure it is functional. Remove and discard seals.

HUBS, DRUMS, SHELLS, AND PLANETARIES Clutch hubs, drums, and shells transfer the torque load to the various combinations of planetary gear set members to provide different gear ratios. Hubs, drums, shells, and planetaries are *hard parts* that do not wear out under normal conditions, so they can be reused unless they are damaged. **SEE FIGURE 130–15.**

Carefully check drums and shells for cracks before reusing. Wash with solvent, dry with compressed and filtered air, and then inspect. Planetary gear sets should be checked for proper pinion gear end play and compared to factory specifications. **SEE FIGURE 130–16.**

FIGURE 130–15 The ring gear has damaged gear teeth. This entire planetary gear set must be replaced because the damage also affected the gear teeth of the planetary pinion gears and the sun gear.

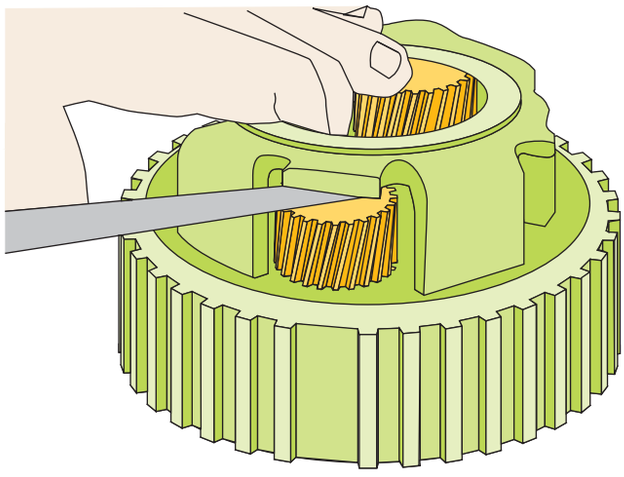

FIGURE 130–16 Pinion gear end play can be checked using a feeler gauge.

REASSEMBLING AN AUTOMATIC TRANSMISSION/TRANSAXLE

CLUTCH ASSEMBLY Before assembling a clutch assembly, soak all friction plates in automatic transmission fluid (ATF). This should be done for as long as possible to allow the friction material to absorb the automatic transmission fluid. Check service information for the exact order of assembly and assemble each clutch pack.

AIR PRESSURE CHECKS Reassembly of an automatic transmission/transaxle involves assembling the various subassemblies, such as a clutch pack clearance, before final assembly is completed. **SEE FIGURES 130–17 AND 130–18.**

If the clutch pack clearance is not correct, often one clutch pack component is a selective member. The selective component could be any of the following:

- Reaction plate
- Pressure plate
- Thrust washer
- Snap ring

After making the needed changes, the clearance should be rechecked to be sure it is within factory specifications.

An **air pressure check** uses air to apply clutches and/or bands to verify that components such as clutch packs perform correctly. The air takes the place of the ATF under pressure when it is being used in the vehicle. Air checking a unit includes the following steps.

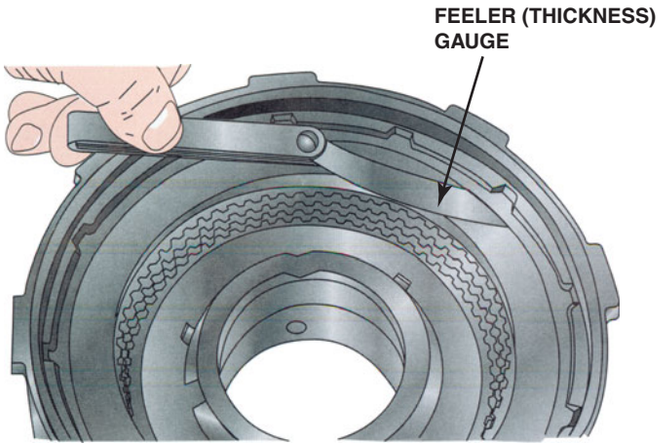

FIGURE 130–17 All clutch packs should be checked for proper clearance. Here, a feeler (thickness) gauge is used to check the clearance to make sure it is within factory specifications.

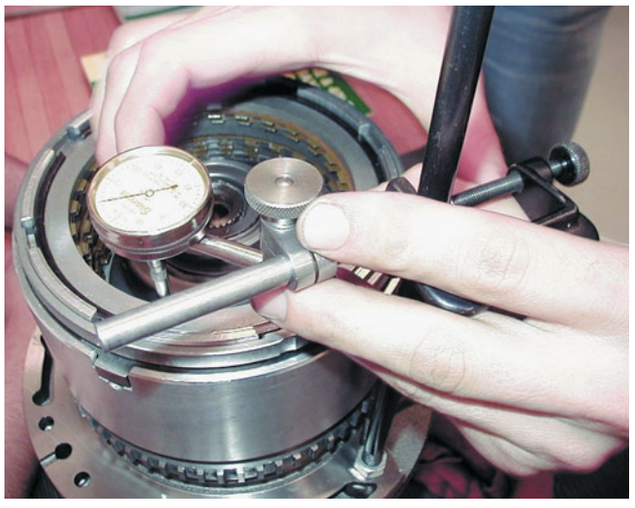

FIGURE 130–18 Checking clutch pack clearance using a dial indicator. This method is used when a feeler gauge cannot be inserted to check for proper clearance.

STEP 1 Use the factory service information regarding where to air check and what the results should be.

STEP 2 Use a rubber-tipped air nozzle and regulate the air supply to about 35 PSI (240 kPa).

STEP 3 A typical result is a dull thud or clunk heard when air pressure is applied to a clutch pack or servo piston. ● **SEE FIGURE 130–19.**

STEP 4 When the air pressure is removed, the unit should release. If there is a seal leak, air can usually be heard hissing from around the seal.

● **SEE FIGURE 130–20.**

BUSHINGS All bushings should be inspected and replaced if necessary. ● **SEE FIGURE 130–21.**

ONE-WAY CLUTCHES Always double check that all one-way roller clutches are installed correctly. The transmission will not work correctly if the one-way clutch is installed upside down. Check service information for the exact method to use to ensure that they are installed correctly. ● **SEE FIGURE 130–22.**

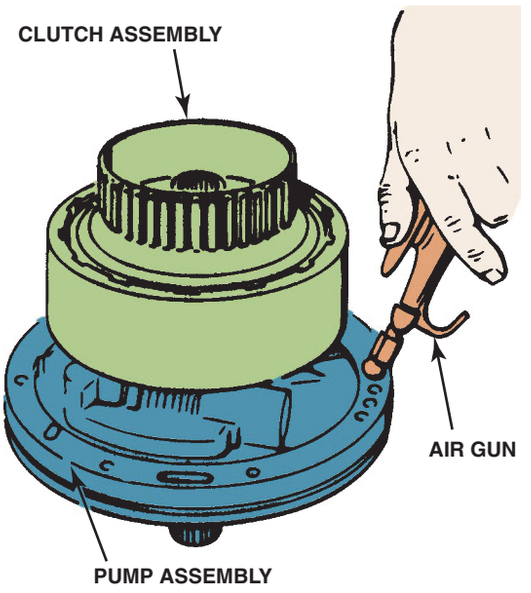

FIGURE 130–19 Air testing a clutch pack before installing it into an automatic transmission or transransaxle.

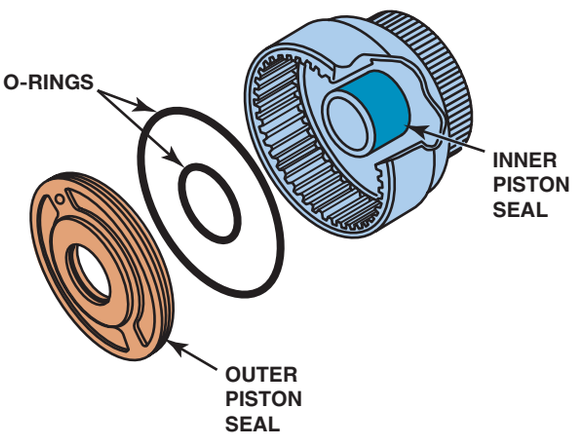

FIGURE 130–20 Both the inner and outer seals are checked when air testing a clutch pack assembly.

FIGURE 130–21 A typical brass bushing used in an automatic transmission.

SPECIAL TOOLS Special tools are often specified by the vehicle manufacturer. These tools allow the service technician to disassemble and reassemble the transmission/transaxle more easily without harming the unit. ● **SEE FIGURE 130–23.**

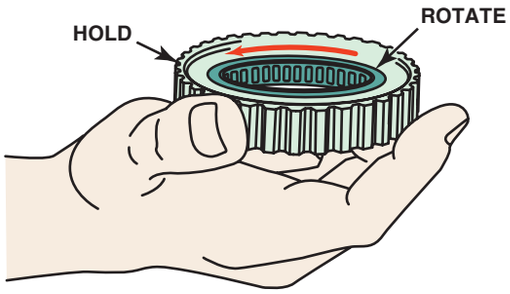

FIGURE 130–22 Service information states that this one-way roller clutch should be installed as shown. Check by holding the outer race so that the inner race is free to rotate counterclockwise as shown.

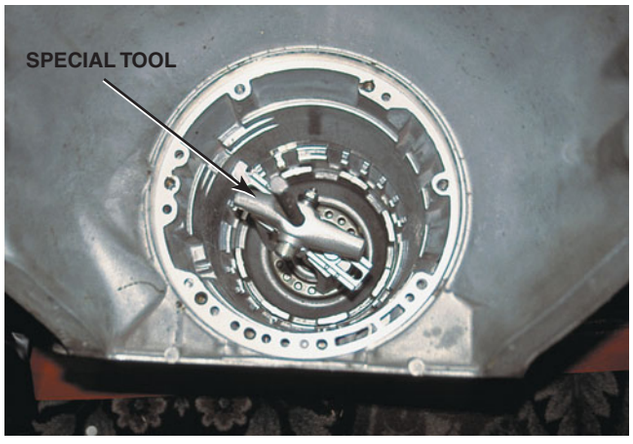

FIGURE 130–23 A special clamp makes removal and reinstallation of this clutch pack easier.

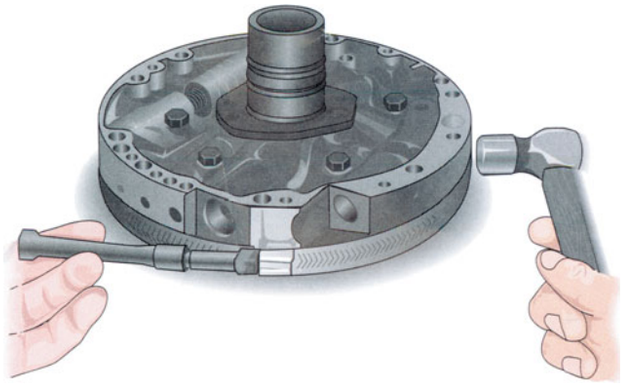

FIGURE 130–24 Using an alignment clamp to assemble both pump halves. To ensure proper alignment, many experts recommend lightly tapping the outer edges of the pump while tightening the clamp.

PUMP ASSEMBLY Follow the vehicle manufacturer's recommended procedures. For example, a special clamp is often necessary to properly assemble a pump. ● **SEE FIGURE 130–24.**

END PLAY CHECKS Perform all end play checks during assembly to ensure that the unit was properly assembled and that the proper internal clearances are achieved. ● **SEE FIGURE 130–25.**

VALVE BODY CHECKS The valve body can be checked using a tester especially designed for this purpose. Adapters are available for all commonly serviced automatic transmissions/transaxles, and the pressure gauges that are part of the tester are used to monitor the movement and flow through the valve body. This unit also heats the automatic transmission fluid so that the valve body is being tested under the same conditions as will be occurring in the

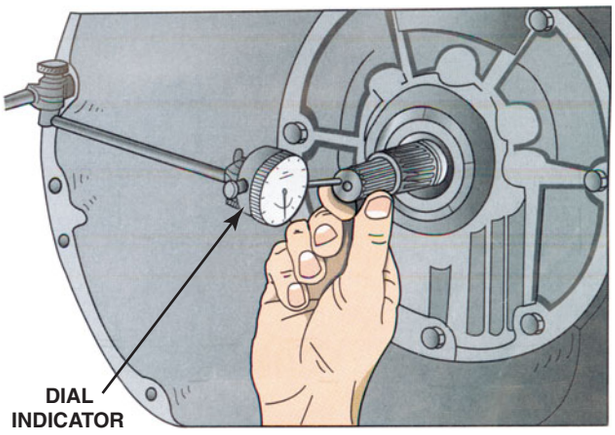

FIGURE 130–25 A dial indicator being used to measure the end play of an input shaft. If the end play is not within factory specifications, the unit may not have been assembled correctly.

FIGURE 130–26 Blue assembly lube.

TECH TIP

Avoid Using Red Assembly Lube

Assembly lube is used during the reassembly of automatic transmissions. If red assembly lube is used on seals, it may look like an automatic transmission fluid leak when the transmission gets hot and the lube melts. If you use blue, green, brown, or clear assembly lube, then the color will immediately identify it as assembly lube. ● **SEE FIGURE 130–26.**

Many transmissions have been disassembled because the service technician thought that the red liquid dripping from parts of the transmission was automatic transmission fluid when, in fact, it was only assembly lube that melted and ran when the transmission reached normal operating temperature.

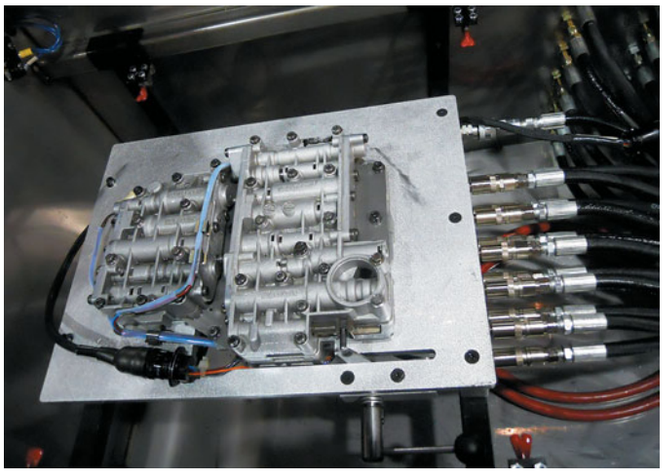

FIGURE 130–27 A valve body being tested on a valve body tester. While it takes some setup time to adapt each valve body to the proper hoses, this type of machine can find valve body problems before the transmission/transaxle is installed in the vehicle.

TECH TIP

Change the Bolts and Washers

When reassembling an automatic transmission, always replace the pump bolts and sealing washers to avoid the possibility of a leak. A leak in the area of the pump can cause quite a headache for the technician because the entire assembly must be removed from the vehicle again to fix it.

vehicle. It is easier to repair a fault with the valve body than wait until the valve body and the transmission are installed in the vehicle. ● **SEE FIGURE 130–27.**

CAUTION: It is critical that the valve body be torqued in the proper sequence to the correct specification to avoid warpage which could cause a sticking valve.

FLUSHING THE COOLER AND TORQUE CONVERTER

PURPOSE All vehicle manufacturers recommend that the automatic transmission fluid cooler be checked for proper flow and, if not, then it should be replaced whenever a replacement or overhauled automatic transmission/transaxle is installed in a vehicle. Most vehicle manufacturers are recommending to NOT flush the cooler. The major reason is because most manufacturers have gone to the "flat" tube design, so the passages are too small for flushing. In addition, some coolers have internal thermostats which would be closed during flushing. Instead, manufacturers recommend replacement with either a new radiator or cooler (if remotely mounted).

CHART 130–1

The location of the cooler-out lines varies by vehicle and transmission/transaxle. Check service information for location of the cooler lines on the vehicle being serviced.

NOTE: At least 2 quarts (liters) of ATF should flow through the cooler every 30 seconds or the cooler and/or the lines are restricted. ● SEE CHART 130–1 for the placement of the cooler-out lines on common transmissions/transaxles.

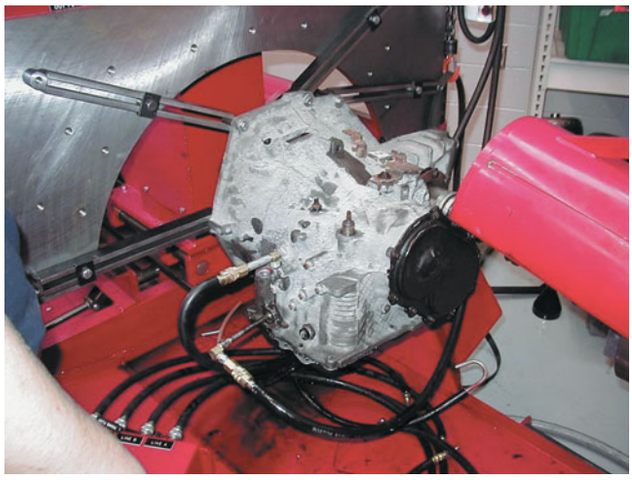

FIGURE 130–28 An electric motor-driven dynamometer being used to check the operation of a 41 TE transaxle.

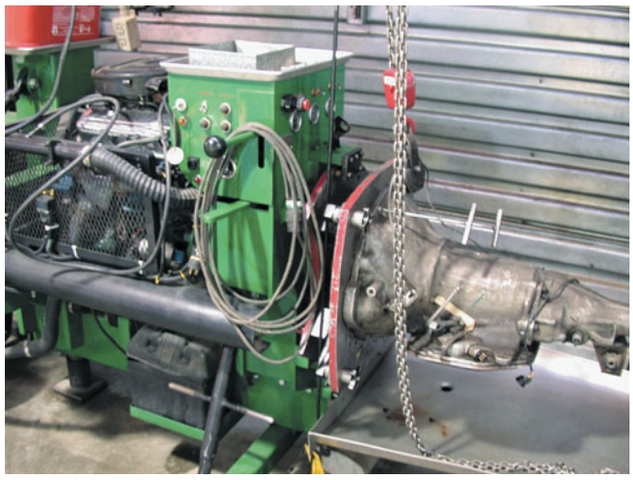

FIGURE 130–29 A gasoline-powered dynamometer being used to test a rear-wheel-drive automatic transmission.

DYNAMOMETER TESTING THE AUTOMATIC TRANSMISSION/TRANSAXLE

A rebuilt automatic transmission/transaxle can be tested on a dynamometer powered by:

- An electric motor (● **SEE FIGURE 130–28.**)
- A gasoline engine (● **SEE FIGURE 130–29.**)

Most dynamometers are equipped with pressure gauges to provide a load so the operation of the unit can be checked before being installing in the vehicle.

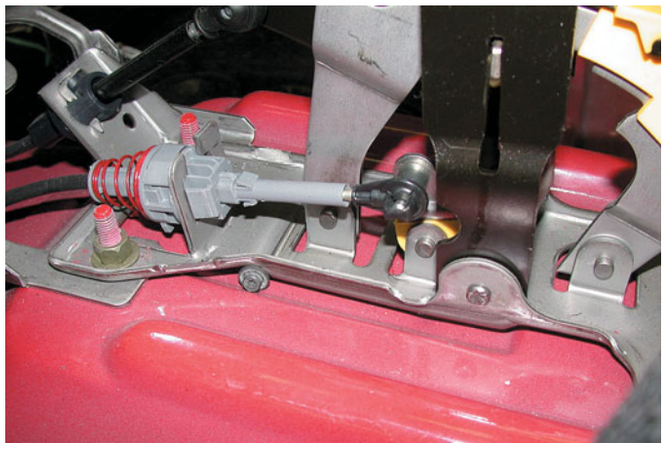

FIGURE 130–30 Check the linkage for proper adjustment so that the shift interlock works correctly and the PRNDL is aligned with the transmission range switch.

REINSTALLING THE AUTOMATIC TRANSMISSION/TRANSAXLE

DOUBLE CHECK END PLAY After the unit has been reassembled and all end play checks indicate that the unit is properly assembled, reinstall the automatic transmission/transaxle in the vehicle. Many experts recommend that new transmission/transaxle mounts be installed to assure proper driveshaft/drive axle shaft angles.

NOTE: New mounts are particularly important if the unit was leaking automatic transmission fluid (ATF). The ATF can soften and deteriorate the rubber used in the mounts.

TORQUE CONVERTER INSTALLATION Before installing the unit into the vehicle, flush the torque converter with clean ATF. Carefully install the torque converter onto the input shaft being sure to fully engage the following:

- Pump gear
- Stator splines
- Turbine splines

TRANSMISSION/TRANSAXLE INSTALLATION Check service information for the exact procedure to follow when installing an automatic transmission/transaxle. Following are the steps often specified.

- Carefully install the unit and use a torque wrench to torque the bolts to the bell housing.
- Attach the torque converter to the flex (drive) plate.
- Reattach all electrical connections, linkages, and cooler lines. ● **SEE FIGURE 130–30.**
- Lower the vehicle and add enough ATF to properly fill the unit. Consult factory information for the recommended amount, to avoid under- or overfilling.

ROAD TEST

FAST LEARN THE PCM/TCM Start the engine and check the level of the ATF. For an electronic transmission/transaxle to operate correctly, a "fast learn" or a "quick learn" should be performed with a scan tool before the vehicle is driven. This action will get the

adaptive settings close to what they should be and will help prevent damage to the unit if this procedure is not done.

In addition, Chrysler has a torque converter burnishing mode that can be activated on the scan tool for some models.

ROAD TEST PROCEDURE Carefully test drive the vehicle, checking for proper operation and shift points. Hoist the vehicle and check for any possible ATF leaks before returning the vehicle to the customer.

FIGURE 130–31 An auxiliary automatic transmission fluid cooler installed on a Chevrolet pickup truck used to haul a car trailer.

TECH TIP

Install a Transmission Cooler

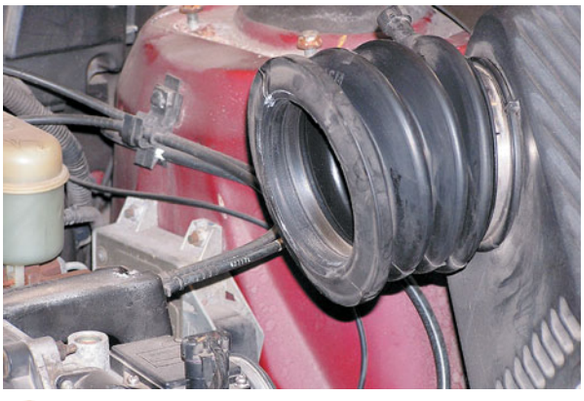
An auxiliary transmission fluid cooler is recommended by most experts to help keep the temperature from becoming excessive, especially when towing or performing other heavy-duty vehicle operation. ● **SEE FIGURE 130–31.**

Most experts recommend that the cooler be connected so that the hot fluids travel through the auxiliary cooler and then through the factory cooler and return to the transmission/transaxle. Using this method of plumbing allows the radiator to warm the transmission fluid in cold weather as well as provide additional cooling of the fluid when the fluid temperature is high.

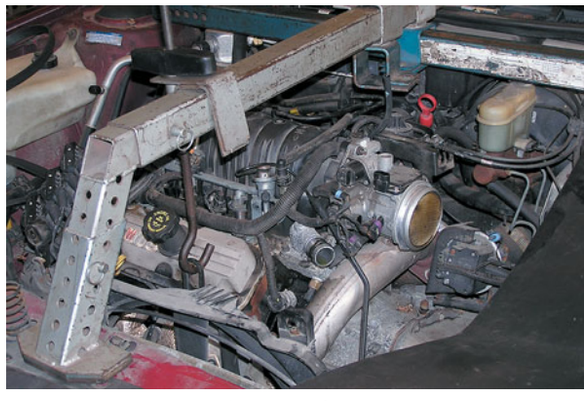
.TECH TIP

If the Torque Converter Is Dropped, Replace It

Torque converters include plastic thrust plates which are very strong under the compressive forces of normal torque converter operation. However, if a torque converter is dropped, even from a distance of less than 6 inches (15 cm), the thrust washer can easily break, ruining the torque converter. Even though torque converts look strong and feel heavy, handle them as if they are glass.



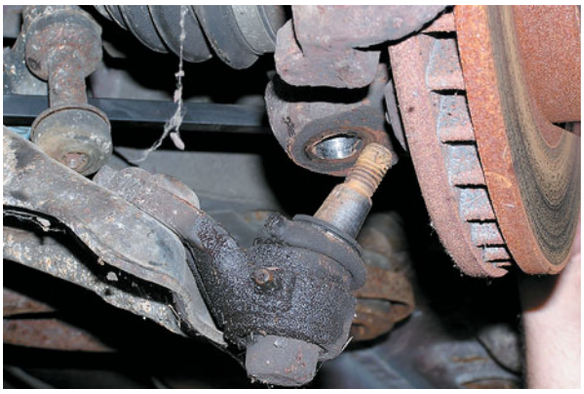
TRANSAXLE REMOVAL



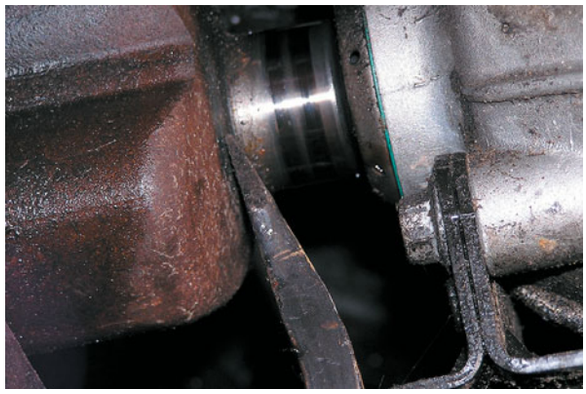
1 For safety purposes, remove the negative battery cable before starting the removal procedure.

2 Remove engine bay cross members that may interfere with access to the transaxle fasteners.

3 Remove the air intake and air filter assembly, which is covering the transaxle in this vehicle.

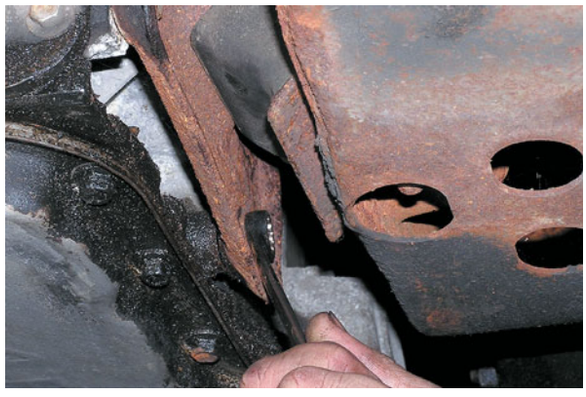


4 Install a support for the engine.



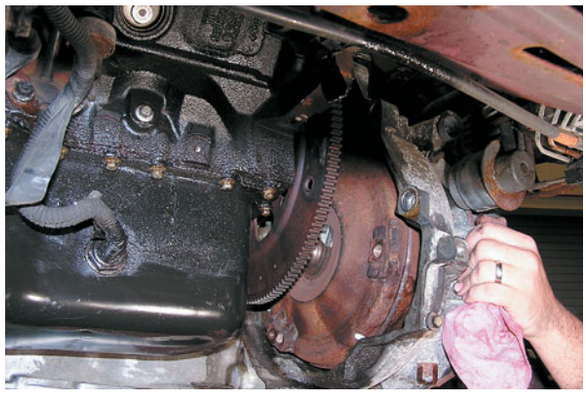
5 Safely hoist the vehicle and remove the wheels.

6 Remove the retaining nut from the drive axle shaft.



7 Disconnect the lower ball joint on the front-wheel-drive vehicle to allow removal of the drive axle shaft.

8 Remove the drive axle shaft from the transaxle using a pry bar.

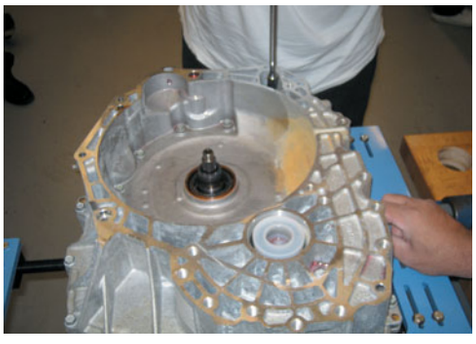


9 Disconnect the cooler lines from the transaxle using a line wrench.

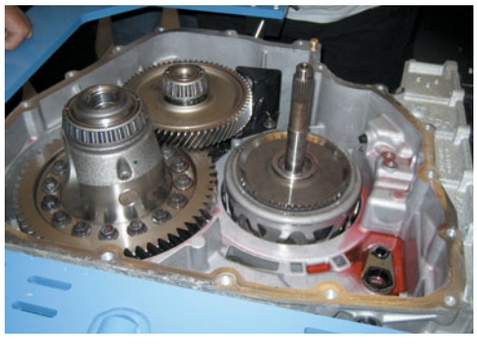
10 Unbolt the torque converter from the flexplate, then remove the transaxle mounts.

11 With the transaxle supported on a transmission jack, remove the retaining bolts from the bell housing.

12 Carefully remove the transaxle from the vehicle.



6T70 TRANSAXLE DISASSEMBLY AND ASSEMBLY

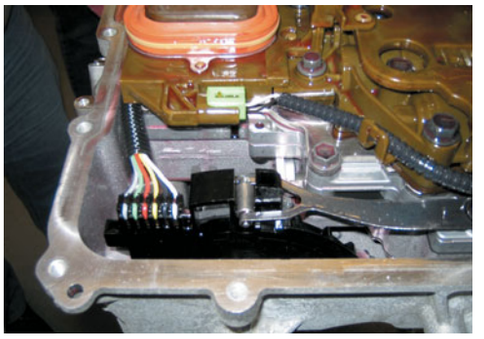


1 The GM 6T70 6 forward speed transaxle was a joint venture with Ford and therefore is similar to the 6F50.

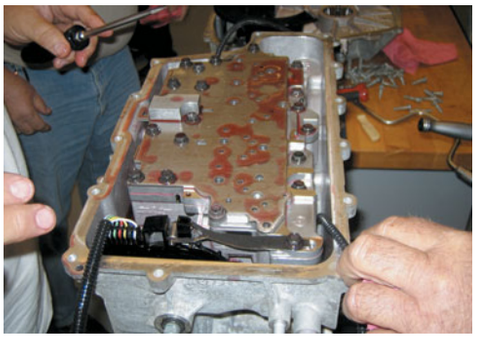
2 A unique thin torque converter is used to help reduce the overall length of the transaxle.

3 After removing the torque converter, the housing is being removed.

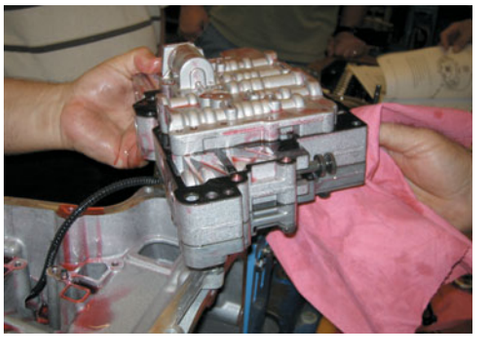
4 The final drive assembly is exposed after the housing has been removed.



5 The final drive is easily lifted out after the housing has been removed.



6 Note the tapered roller bearing used in the final drive assembly component.

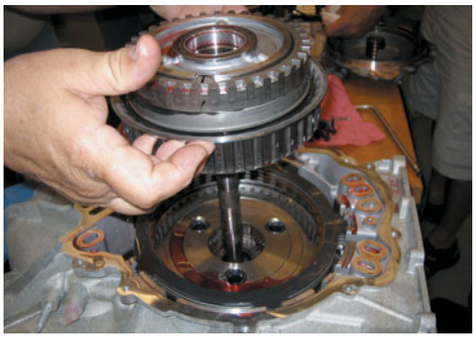


7 The transaxle is rotated and the plastic side cover is removed.

8 Under the side cover is the valve body and integrated solenoid assembly.

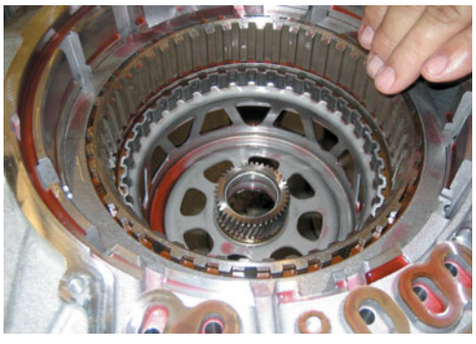
9 Under the plastic electrical solenoid assembly is the valve body assembly.

10 Removing the valve body assembly.



11 Turning the assembly around, showing the end cover.

12 Removing the end cover shows the clutch packs and planetary gear set.



CONTINUED ▶

13 Removing the first of five clutch packs (two driving and three holding).

14 A typical clutch pack in a 6T70 showing the selective thickness steel used to determine clutch pack clearance.

15 A view down into the case where multiple clutch packs are found.

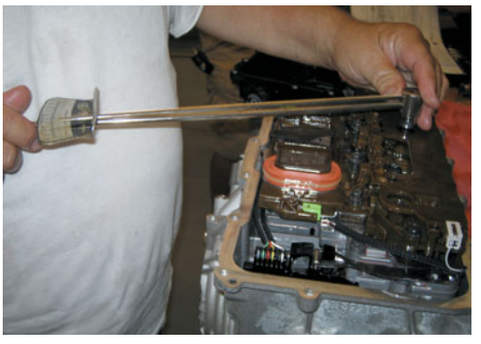
16 The output planetary gear set with four pinions used on 6T70 units. The 6T75 version uses a five pinion carrier and a reinforced case.

17 Reassembly of the clutches. Check service information for specified clutch pack clearance.

18 Notice that the final drive is equipped with tapered roller bearings and this means that the preload must be adjusted.

19 A special set of spacers and blocks used to determine the preload needed. A feeler gauge is then used to measure the clearance.

20 Following the procedure in service information, the designated thickness of shim is selected, which is placed under the bearing race in the bearing packet.



21 The selective shim and race before the race is driven into position.

22 Driving the race into position using the specified driver.

23 Reassembly of the valve body being sure that all fasteners are tightened to factory specifications.

24 The solenoid assembly is replaced as an assembly only if defective and all the fasteners need to be torqued to factory specifications.

REVIEW QUESTIONS

1. What are the typical operations needed when disassembling an automatic transmission/transaxle?
2. What are two methods of checking a clutch pack?
3. Why is it important to perform an end play check of an automatic transmission/transaxle during the reassembly process?
4. Why is it important to flush the automatic transmission fluid cooler when a rebuilt or replacement automatic transmission/transaxle is being installed in a vehicle?

CHAPTER QUIZ

1. Technician A says that the torque converter should be separated from the flex (drive) plate before removing the automatic transmission/transaxle. Technician B says that the clutches should be installed "dry" when replacing the frictions and steels in a clutch pack. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. Air pressure checking is used to test _____.
   a. Clutch packs
   b. TV adjustment
   c. Vacuum modulators
   d. Governors
3. Technician A says that all friction and steel plates in a clutch pack should be replaced during an overhaul. Technician B says that the automatic transmission fluid cooler should always be flushed when a unit is rebuilt or replaced. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. Slide hammers or special pullers are used to remove what component?
   a. Extension housing
   b. Filter
   c. Pump
   d. Rear seal
5. What part must be replaced if dropped?
   a. Pump
   b. Torque converter
   c. Extension housing
   d. Pan
6. Technician A says that the sharp edges of spool valves should be rounded, using 400 grit sandpaper. Technician B says that all valve body parts should be cleaned and then dried using low-pressure, filtered compressed air. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. Clutch pack clearance can be changed if not correct by using selective _____.
   a. Piston
   b. Pressure plate
   c. Snap ring
   d. One of the above depending on the unit
8. Friction discs should be _____ before being installed.
   a. Sanded
   b. Soaked in ATF
   c. Surface roughed up
   d. All of the above
9. How much transmission fluid should flow through the cooler?
   a. 2 quarts every 30 seconds
   b. 1 quart per minute
   c. 2 quarts per minute
   d. 2 pints per minute
10. Why should red assembly lube be avoided?
    a. Can harm friction disks
    b. Too slippery
    c. Clogs filters
    d. Looks like an ATF leak when it melts
